14 including but not limited to NDCs. Country distribution of this literature is very unequal (*robust*
15 *evidence, high agreement*). Current policies lead to median global GHG emissions of 57 GtCO₂-eq with
16 a full range of 52-60 by 2030. NDCs with unconditional and conditional elements¹ lead to 53 (50-57)
17 and 50 (47-55) GtCO₂-eq, respectively (*medium evidence, medium agreement*) (Table 4.3). This leaves
18 estimated *emissions gaps* in 2030 between projected outcomes of unconditional elements of NDCs and
19 emissions in scenarios that limit warming to 1.5°C with no or limited overshoot of 20-26 GtCO₂-eq,
20 and 10-17 GtCO₂-eq for scenarios that *likely* limit warming to 2°C with immediate action. When
21 conditional elements of NDCs are included, these gaps narrow to 16-24 GtCO₂-eq and 7-14 GtCO₂-eq,
22 respectively. {Cross-Chapter Box 4, Figure 1}

23 **Studies evaluating up to 105 updated NDCs submitted by October 2021 indicate that emissions in**
24 **conditional NDCs have been reduced by 4.5 (2.7-6.3) GtCO₂-eq, but only closes the emission gaps**
25 **by about one-third to 2°C and about 20% to 1.5°C compared to the original NDCs submitted in**
26 **2015/16 (*medium evidence, medium agreement*).** The magnitude of these emission gaps calls into
27 question whether current development pathways and efforts to accelerate mitigation are adequate to
28 achieve the Paris mitigation objectives. In addition, an *implementation gap* exists between the projected
29 emissions of ‘current policies’ and the projected emissions resulting from the implementation of the
30 unconditional and conditional elements of NDCs, and is estimated to be around 4 and 7 GtCO₂-eq in
31 2030, respectively (*medium evidence, medium agreement*), with many countries requiring additional
32 policies and associated climate action to meet their autonomously determined mitigation targets as
33 specified under the first NDCs (*limited evidence*). There is, furthermore, a potential difference between
34 mitigation targets set in NDCs *ex ante* and what is achieved *ex post*. A limited number of studies assess
35 the implementation gaps of conditional NDCs in terms of finance, technology and capacity building
36 support. The disruptions triggered by the COVID-19 epidemic increase uncertainty over range of
37 projections relative to pre-COVID-19 literature. As indicated by a growing number of studies at the
38 national and global level, how large near- to mid-term emissions implications of the COVID-19
39 pandemic are, to a large degree depends on how stimulus or recovery packages are designed. {4.2,
40 4.2.2.5, Cross-Chapter Box 4}

41 **Given the gaps, there is a need to explore accelerated mitigation (relative to NDCs and current**
42 **policies).** There is increasing understanding of the technical content of accelerated mitigation pathways,
43 differentiated by national circumstances, with considerable though uneven literature at country-level
44 (*medium evidence, high agreement*). Transformative technological and institutional changes for the

FOOTNOTE¹ See section 4.2.1 for description of ‘unconditional’ and ‘conditional’ elements of NDCs.

1 near-term include demand reductions through efficiency and reduced activity, rapid decarbonisation of
2 the electricity sector and low-carbon electrification of buildings, industry and transport (*robust*
3 *evidence, medium agreement*). A focus on energy use and supply is essential, but not sufficient on its
4 own – the land sector and food systems deserve attention. The literature does not adequately include
5 demand-side options and systems analysis, and captures the impact from non-CO₂ GHGs with medium
6 confidence. Countries and regions will have different starting points for transition pathways. Some
7 factors include climate conditions resulting in different heating and cooling needs, endowments with
8 different energy resources, patterns of spatial development, and political and economic conditions.
9 {4.2.5}

10 **Accelerated mitigation alone may run into obstacles.** If such obstacles are rooted in underlying
11 structural features of society, then transforming such structures helps remove obstacles, which amounts
12 to shifting development pathways. Various actors have developed an increasing number of mitigation
13 strategies up to 2050 (mid-term). A growing number of such strategies aim at net zero GHG or CO₂
14 emissions, but it is not yet possible to draw global implications due to the limited size of sample
15 (*medium evidence; low agreement*). Non-state actors are also engaging in a wide range of mitigation
16 initiatives. When adding up emission reduction potentials, sub-national and non-state international
17 cooperative initiatives could reduce up to about 20 GtCO₂-eq in 2030 (*limited evidence, medium*
18 *agreement*). Yet perceived or real conflicts between mitigation and other Sustainable Development
19 Goals (SDGs) can impede such action. If undertaken without precaution, accelerated mitigation is found
20 to have significant implications for development objectives and macroeconomic costs at country level.
21 For example, most country-level mitigation modelling studies in which GDP is an endogenous variable
22 report negative impacts of mitigation on GDP in 2030 and 2050, relative to the reference. In all reviewed
23 studies, however, GDP continues to grow even with mitigation (*robust evidence, high agreement*). The
24 literature finds that employment effect of mitigation policies tends to be limited on aggregate, but can
25 be significant at sectoral level (*limited evidence, medium agreement*). Detailed design of mitigation
26 policies is critical for distributional impacts and avoiding lock-in (*robust evidence, high agreement*),
27 though further research is needed in that direction. {4.2.3, 4.2.4, 4.2.6}

28 **Shifting development pathways towards sustainability offers ways to (i) broaden the range of**
29 **levers and enablers that a society can use to provide enabling conditions and accelerate**
30 **mitigation; and (ii) increase the chances of advancing at the same time towards mitigation and**
31 **towards other development goals.** The way countries develop determines their capacity to accelerate
32 mitigation and achieve other sustainable development objectives simultaneously (*medium-robust*
33 *evidence, medium agreement*). Yet meeting ambitious mitigation and development goals cannot be
34 achieved through incremental change, hence the focus on shifting development pathways (*robust*
35 *evidence, medium agreement*). Though development pathways result from the actions of a wide range
36 of actors, it is possible to shift development pathways through policies and enhancing enabling
37 conditions (*limited evidence, medium agreement*). For example, policies such as those listed in Table
38 4.12 are typically associated with broader objectives than greenhouse gas mitigation. They are generally
39 conceived and implemented in the pursuit of overall societal development objectives, such as job
40 creation, macro-economic stability, economic growth, and public health and welfare. In some countries,
41 such policies are framed as part of a just transition. However, they can have major influence on
42 mitigative capacity, and hence can be seen as tools to broaden mitigation options, as illustrated by the
43 Illustrative Mitigation Pathway “Shifting Pathways” (*medium evidence, medium agreement*). There are
44 practical options to shift development pathways in ways that advance mitigation and other sustainable
45 development objectives, supporting political feasibility, increase resources to meet multiple goals, and
46 reduce emissions (*limited evidence, high agreement*). Concrete examples assessed in this chapter
47 include high employment and low emissions structural change, fiscal reforms for mitigation and social
48 contract, combining housing policies to deliver both housing and transport mitigation, and change
49 economic, social and spatial patterns of development of the agriculture sector provide the basis for

1 sustained reductions in emissions from deforestation. These examples differ by context. Examples in
2 other chapters include transformations in energy, urban, building, industrial, transport, and land-based
3 systems, changes in behaviour and social practices, as well as transformational changes across whole
4 economies and societies. Coordinated policy mixes would need to coordinate multiple actors—
5 individuals, groups and collectives, corporate actors, institutions and infrastructure actors—to deepen
6 decarbonisation and shift pathways towards sustainability. Shifts in one country may spill over to other
7 countries. Shifting development pathways can jointly support mitigation and adaptation. Some studies
8 explore the risks of high complexity and potential delay attached to shifting development pathways.
9 {4.3, 4.3.1, 4.3.2, 4.4.2, 4.4.3, 4.4.1.7-4.4.1.10, Figure 4.7, Cross-Chapter Box 5, 5.8, Box 6.2, 8.2,
10 8.3.1, 8.4, 9.8.1, 9.8.2, 10.4.1, Cross-Chapter Box 5, Cross-Chapter Box 7, Cross-Chapter Box 12}

11 **The literature identifies a broad set of enabling conditions that can both foster shifting**
12 **development pathways and accelerated mitigation, along five categories.** (*medium evidence, high*
13 *agreement*). Policy integration is a necessary component of shifting development pathways, addressing
14 multiple objectives. To this aim, mobilising a range of policies is preferable to single policy instruments
15 (*robust evidence, high agreement*). Governance for climate mitigation and shifting development
16 pathways is enhanced when tailored to national and local contexts. Improved institutions and
17 governance enable ambitious climate action and help bridge implementation gaps (*medium evidence,*
18 *high agreement*). Given that strengthening institutions may be a long term endeavour, it needs attention
19 in the near-term. Accelerated mitigation and shifting development pathways necessitates both re-
20 directing existing financial flows from high- to low-emissions technologies and systems and to provide
21 additional resources to overcome current financial barriers. (*robust evidence, high agreement*).
22 Opportunities exist in the near-term to close the finance gap. At the national level, public finance for
23 actions promoting the SDG agenda helps broaden the scope of mitigation (*medium evidence, medium*
24 *agreement*). Changes in behaviour and lifestyles are important to move beyond mitigation as
25 incremental change, and when supporting shifts to more sustainable development pathways will
26 broadening the scope of mitigation (*medium evidence, medium agreement*). The direction of innovation
27 matters (*robust evidence, high agreement*). The necessary transformational changes are likely to be
28 more acceptable if rooted in the development aspirations of the economy and society within which they
29 take place. {4.4.1, 4.4.1.2, 4.4.1.3, 4.4.1.4, 4.4.1.5, 4.4.1.6, Figure 4.8, 15.2.2}

30 **Equity can be an important enabler of deeper ambition for accelerated mitigation,** dealing with
31 the distribution of costs and benefits and how these are shared as per social contracts, national policy
32 and international agreements. Transition pathways have distributional consequences such as large
33 changes in employment and economic structure (*robust evidence, high agreement*). In that regard, the
34 just transition concept has become an international focal point tying together social movements, trade
35 unions, and other key stakeholders to ensure equity is better accounted for in low-carbon transitions .
36 Effectiveness of cooperative action and the perception of fairness of such arrangements are closely
37 related, in that pathways that prioritise equity and allow broad stakeholders participation can enable
38 broader consensus for the transformational change implied by deeper mitigation efforts (*robust*
39 *evidence, medium agreement*). Hence, equity is a concept that is instrumentally important. {4.5, Figure
40 4.9}

41 **In sum, this Chapter suggests that the immediate tasks are to broaden and deepen mitigation** in
42 the near-term if the global community is to deliver emission reductions at the scale required to keep
43 temperature well below 2°C and pursue efforts at 1.5°C. Deepening mitigation means more rapid
44 decarbonisation. Shifting development pathways to increased sustainability (SDPS) broadens the scope
45 of mitigation. Putting the enabling conditions above in place supports both. Depending on context, some
46 enabling conditions such as shifting behaviour may take time to establish, underscoring the importance
47 of early action. Other enabling conditions, such as improved access to financing, can be put in place in
48 a relatively short time frame, and can yield results rapidly.

1 **Accelerating mitigation:** The literature points to well-understood policy measures and technologies
2 for accelerating mitigation, though the balance depends on country specificities: 1) decarbonising
3 electricity supply to produce net zero CO₂, including renewable energy, 2) radically more efficient use
4 of energy than today; 3) electrification of end-uses including transport; 4) dramatically lower use of
5 fossil fuels than today; 5) converting other uses to low- or zero-carbon fuels (e.g., hydrogen, bioenergy,
6 ammonia) in hard-to-decarbonise sectors; 6) promote bioenergy, demand reduction, dietary changes,
7 and policies, incentives, and rules for mitigation in the land sector; 7) setting and meeting ambitious
8 targets to reduce methane and other short-lived climate forcers. Charting just transitions to net zero may
9 provide a vision, which policy measures can help achieve. Though there is increasing experience with
10 pricing carbon directly or indirectly, decision-makers might consider a broader toolbox of enablers and
11 levers that is available in domains that have not traditionally been climate policy. {4.5, Annex II Part
12 IV Section 11}

13 **Broadening opportunities** by focusing on development pathways and considering how to shift them:
14 Some of the policy measures may yield rapid results, whereas other, larger transformations may take
15 longer. If we are to overcome obstacles, a near-term priority is to put in place the enabling conditions
16 to shifting development pathways to increased sustainability. Learning from the examples above,
17 focusing on SDPS also provides a broader set of tools to accelerating mitigation and achieve other
18 sustainable development goals. Consider climate whenever you make choices about development, and
19 *vice versa*. {4.4.1}
20

1 **4.1 Introduction**

2 The recent IPCC Report on Global Warming of 1.5°C (SR15) made clear that the next three decades
3 are critical if we are to achieve the long-term mitigation goal of the Paris Agreement (IPCC 2018a).
4 The present Chapter assesses the literature on mitigation and development pathways over that
5 timeframe, in the near- (up to 2030) and mid-term (up to 2050).

6 It considers three questions: (1) Where are we heading now? That is, what is the current state of affairs
7 with respect to climate mitigation and how did we get here? (2) Where do we want to go? I.e., what
8 state of affairs would meet the objectives of the Paris Agreement and achieving the Sustainable
9 Development Goals (SDGs)? and (3) How do we bring about this shift? I.e., what interventions are at
10 societies' disposal to bring about the necessary change in an equitable manner?

11 **Where are we heading now?** Despite the drop in emissions due to the COVID-19 crisis, the gap
12 between projected emissions based on Nationally Determined Contributions (NDCs) in 2030 and
13 emissions pathways compatible with the long term temperature goal set in the Paris Agreement remains
14 large (4.2.2). In addition to this persistent emissions gap, we face an implementation gap, as current
15 policies are insufficient to achieve mitigation targets in NDCs, and sufficient international support is
16 not yet available to developing countries who have requested and quantified support needs. Continuing
17 along a development pathway characterized by the same underlying drivers, structural obstacles and
18 insufficient enabling conditions that led to high emissions will not address the problem (*robust*
19 *evidence, high agreement*).

20 The analysis of the gap is conducted together with Chapter 3 (see Cross-Chapter Box 4). Chapter 3 is
21 working backward, assessing mitigation in the long-term (beyond 2050 up to 2100) to draw the near-
22 and mid-term implications of long-term temperature and mitigations goals. Chapter 4, on the other hand,
23 works forward from current and planned mitigation (including NDCs) (4.2.1, 4.2.2) and from current
24 development paths to assess the implications for near- and mid-term Greenhouse Gases (GHG)
25 emissions and development goals. Some countries, regions, cities, communities and non-state actors are
26 taking leadership in implementing more ambitious action (4.2.3). This chapter also assesses national
27 low emission development strategies (4.2.4).

28 **Where do we want to go?** Technical alternatives and policy options exist to bridge the emissions and
29 implementation gaps, and the literature illustrates these with a wide range of accelerated techno-
30 economic pathways that deepen decarbonisation closer to the pace and scale required (4.2.5), and
31 examines their impacts on other development objectives (4.2.6). In practice, however, scaling up at the
32 broader, deeper, and faster level required to meet climate goals while advancing other development
33 objectives regularly faces prohibitive obstacles (4.2.7). Mitigation policies grafted on to existing
34 development pathways are unlikely to achieve rapid and deep emission reductions.

35 Secondly, even if carefully designed, climate policies to accelerate mitigation may have adverse
36 consequences for other development objectives. As a complement to mitigation action, taking action to
37 shift development pathways towards sustainability broadens the range of mitigation options, while
38 increasing the possibility to meet other development priorities at the same time (*medium evidence, high*
39 *agreement*).

40 Development pathways and shifting them to increased sustainability are introduced in Chapter 1, and
41 constitute a thread throughout the report (see glossary entry on development pathways). The WGII
42 Report highlights the related concept of *climate resilient development pathways* (Chapter 18). Cross-
43 Chapter Box 5 on shifting sustainable pathway towards sustainability elaborates on the concept. The
44 influence of development pathways on emissions and mitigative capacity is discussed in Chapter 2.
45 Chapter 3 assesses modelling of shifts in development pathways, illustrated by the illustrative mitigation
46 pathway called “shifting pathways”. The importance of behavioural change as societies make decisions

1 that intentionally shift their future development pathway is emphasized in Chapter 5. The systems
2 Chapters (6-12) take sectoral perspectives, while pathways that are sustainable are the specific focus of
3 Chapter 17.

4 **How can one shift development pathway and accelerate mitigation?** The literature does not provide
5 a complete handbook for shifting development pathways and accelerating mitigation. The literature
6 does, however, shed light on some of the underlying dynamics. Shifting development pathways can be
7 necessitated by the existence of pervasive obstacles that prove prohibitive to reaching mitigation and
8 other development objectives (4.2.7). Deliberate measures taken to facilitate the shifting of
9 development pathways and accelerated mitigation involve putting in place key enabling conditions that
10 help overcome those obstacles (see Figure 4.6)—improving governance and institutional capacity,
11 fostering behavioural change and technological innovation, designing and implementing adequate
12 policy, and finance. Just transitions, while they will differ by context, are critical to identifying and
13 avoiding or addressing inequitable distributive consequences (*robust evidence, high agreement*).

14 Enabling conditions necessary to accelerate mitigation and shift development pathways are discussed
15 in depth in Chapters 5, 13, 14, 15 and 16. In addition, Chapters 13 and 14 detail the policy instruments
16 that could help shift development pathways and accelerate the scale and pace of mitigation, while
17 Chapter 4 describes those in broad strategies terms. Chapter 13 adds more texture on institutional and
18 governance machinery; policy choice, design and implementation; as well as policy formulation
19 processes, actors and structure across scales.

20 Since development pathways and mitigation options depend to large extent on national objectives and
21 circumstances, this chapter is primarily concerned with literature at national level (or in the case of the
22 European Union, at regional level), while Chapter 3 is primarily concerned with literature at global
23 scale. The national scale selected in this Chapter requires attention as national mitigation pathways
24 cannot be linked directly to global mitigation goals (see Box 4.2). This chapter is also concerned mostly
25 with economy-wide development and mitigation pathways, as distinct from detailed sectoral work that
26 is assessed in the systems chapters 6 to 12. The present chapter also assesses literature on non-state
27 action.

28 Chapter 4 draws on five major strands of literature: (1) an emerging literature on development
29 pathways—conceptual, empirical, and model-based, including at the national and sub-national scales;
30 (2) a rapidly expanding, model-based, literature on mitigation pathways in the near- and mid-term
31 (Lepault and Lecocq 2021); (3) studies of NDCs and mid-century strategies; (4) a broader literature on
32 transformation and shifts in development pathways, including from non-climate literatures; and (5) a
33 significant literature on equity, including just transitions. This is supported by a database of country-
34 level mitigation scenarios at country level assembled for the preparation of this Chapter (Annex III,
35 Table I.10 and I.11).

36 The Chapter builds on past IPCC reports. In AR5, all mitigation pathways were assessed in a single
37 chapter (Clarke et al. 2014), which focused mostly on the long-term. SR1.5 included a chapter on
38 mitigation pathways compatible with the temperature goal in the Paris Agreement (Rogelj et al. 2018a),
39 mostly at the global level. It also considered strengthening mitigation (de Coninck et al. 2018) in the
40 context of poverty, inequality and sustainable development (Roy et al. 2018). Development pathways
41 have also been explored, albeit less frequently, in past IPCC reports starting with the Special Report on
42 Emissions Scenarios (Nakicenovic et al. 2000). Some early framing of development pathways was
43 included in the Third Assessment Report (William R. Moomaw et al. 2001), further developed in the
44 Fourth Assessment Report (Sathaye et al. 2007). An extended discussion of climate change and equity
45 was conducted in AR5 (Fleurbay et al. 2014).

1 Chapter 4 examines mitigation within the broader context of development pathways, and examines how
2 shifting development pathways can have a major impact on mitigative capacity and broadening
3 mitigation options. It is organized as follows.

4 Section 4.2 demonstrates that collective mitigation actions fall short of pathways that keep in reach the
5 Paris temperature goals in the long-term. Section 4.3 introduces development pathways (given its
6 relative novelty in IPCC assessments), considers the implications of mitigation for development and
7 *vice versa*, and articulates an approach on *both* accelerating mitigation *and* shifting development
8 pathways.

9 Section 4.4 discusses how to shift development pathway and accelerate the scale and pace of mitigation,
10 what levers are available to policy makers, and how policies may intersect with adaptation goals. It
11 points out that development pathways also drive adaptation and adaptative capacity, and discusses
12 various risks associated with shifting development pathways and accelerated mitigation strategies.

13 Finally, equity and just transitions are recurring themes in the Chapter, specifically in relation to
14 accelerating mitigation and shifting development pathways toward sustainability. In section 4.2.2.7,
15 equity is discussed in the context of Parties' assertions regarding the fairness of their NDCs, alongside
16 reflections from academic scholarship on the ethical underpinnings of these assertions and of various
17 quantitative analyses of equitable effort-sharing. Section 4.2.6 discusses certain distributional
18 implications of domestic mitigation efforts, such as shifts in employment. Sections 4.2.7 and 4.3 note
19 the relevance of potential distributional impacts as an obstacle to climate action, as well as the
20 inequitable distribution of decision-making authority. Finally, section 4.5 recognizes the structural
21 relationship between equity and climate, explores just transitions as an international focal point tying
22 together social movements, trade unions, and other stakeholders, and thus an instrumental role in
23 establishing consensus.

24

25 **4.2 Accelerating mitigation actions across scales**

26 **4.2.1 Mitigation targets and measures in nationally determined contributions**

27 A central instrument of the Paris Agreement is the NDCs, submitted by each country, and reflecting
28 national efforts to reduce GHG emissions and build resilience to the impacts of climate change. Every
29 five years, collective progress will be compared against long-term goals of the Paris Agreement.
30 Considering the outcome of a global stocktake, countries will prepare subsequent NDCs, showing
31 progression in their ambition and enhancing international cooperation (UNFCCC 2015a).

32 Prior to COP21, in 2015, most countries submitted their INDCs (Intended Nationally Determined
33 Contributions), which included mitigation targets for 2025 or 2030. INDCs become first NDCs on
34 ratification and/or after national governments' revision, and by 11 October 2021, the official NDC
35 registry contained 194 first NDCs with 105 new and updated NDCs from 132 Parties to the Paris
36 Agreement, covering 53% of the total global emissions in 2019 of 52.4 GtCO₂-eq without LULUCF,
37 and 13 second NDCs. Most of the Parties that submitted new or updated NDCs have demonstrated
38 increased ambition in addressing climate change. Moreover, though some countries like China have not
39 submitted their updated NDCs yet, they have already announced their updated NDC goals somewhere.
40 Countries will take the first stock in 2023 based on their progression towards achieving the objectives
41 of Paris Agreement (UNFCCC 2015a, 2018a; SB Chairs 2021) (14.3.2.5).

42 Submitted NDCs vary in content, scope and background assumptions. First NDCs contain mitigation
43 targets, and in many cases also provisions about adaptation. The mitigation targets range from economy-
44 wide absolute emission reduction targets to strategies, plans and actions for low-emission development.
45 Baseline years vary from 1990 to 2015 and in almost all NDCs the targeted time frame is 2030, with a

1 few specified periods of until 2025, 2035, 2040 or 2050. Around 43% of the mitigation targets in first
2 NDCs are expressed in terms of deviation below business-as-usual by a specified target year, either for
3 the whole economy or for specific sectors, while around 35% include fixed-level targets (either
4 reductions or limitations compared to base years), and another 22% refer to intensity targets (in terms
5 of GHG, CO₂ or energy) or policies and measures, with an increasing number of Parties moving to
6 absolute emission reduction targets in their new or updated NDCs (UNFCCC 2016a, 2021). Some
7 developing countries' NDCs include unconditional elements, while others include conditional ones, the
8 latter with higher ambition if finance, technology and capacity building support from developed
9 countries is provided (UNFCCC 2016a).² In some NDCs, the additional mitigation is quantified, in
10 others not (Figure 14.2).

11 Most first NDCs cover all specific sectors, including LULUCF, and communicate specific targets for
12 individual sub-sectors to support their overall mitigation targets. Concrete actions and priority areas are
13 more detailed in the energy sector, with increased share of renewable energies and energy efficiency
14 being highlighted in the majority of NDCs. Given the uncertainty behind LULUCF emission and
15 removal accounting (Grassi et al. 2017; Jian et al. 2019), several countries state that their accounting
16 framework will only be defined in later NDCs. The GHG included and the global warming potentials
17 (GWPs) used to aggregate emissions also vary across NDCs. Most countries only refer to carbon
18 dioxide, methane and nitrous oxide emissions aggregated based on IPCC AR2 or AR4 metrics, while
19 few NDCs also include fluorinated gases and use IPCC AR5 GWPs. The shares of Parties that indicate
20 possible use of at least one type of voluntary cooperation and set qualitative limits on their use have
21 both nearly doubled in new or updated NDCs.

22 There is considerable literature on country-level mitigation pathways, including but not limited to
23 NDCs. Country distribution of this literature is very unequal (*robust evidence, high agreement*). In
24 particular, there is a growing literature on (I)NDCs, with a wide scope which includes estimate of
25 emissions levels of NDCs (see section 4.2.2.2); alignment with sustainable development goals (Caetano
26 et al. 2020; Campagnolo and Davide 2019; Fuso Nerini et al. 2019; Antwi-Agyei et al. 2018); ambition
27 (Höhne et al. 2018; Vogt-Schilb and Hallegatte 2017; Hermwille et al. 2019); energy development
28 (Scott et al. 2018); and the legality of downgrading NDCs (Rajamani and Brunnée 2017). Other studies
29 note that many NDCs contain single-year mitigation targets, and suggest that a multi-year trajectory is
30 important for more rigorous monitoring (Elliott et al. 2017; Dagnet et al. 2017).

31 The literature also points out that beyond the 'headline numbers', information in (I)NDCs is difficult to
32 analyse (Pauw et al. 2018). Information for 'clarity, transparency and understanding' is to be
33 communicated with NDCs, although initial guidance was not specific (UNFCCC 2014). While the
34 adoption of the Paris rule-book provided some greater specificity (UNFCCC 2018b,c), the information
35 included in the NDCs remains uneven. Many NDCs omit important mitigation sectors and do not
36 adequately provide details on costs and financing of implementation (Pauw et al. 2018). Countries are
37 also invited to explain how their NDCs are fair and ambitious, though the way this has been done so far
38 has been criticised as insufficiently rigorous (Winkler et al. 2018).

FOOTNOTE² "Unconditional" NDCs refer to abatement efforts pledged without any conditions (this terminology is used by the literature, not by the Paris Agreement). They are based mainly on domestic abatement actions, although countries can use international cooperation to meet their targets. (2) "Conditional" NDCs require international cooperation, for example bilateral agreements under article 6, financing or monetary and/or technological transfers (14.3.2).

4.2.2 Aggregate effects of NDCs and other mitigation efforts relative to long-term mitigation pathways

4.2.2.1 Introduction

Near-term mitigation targets submitted as part of NDCs to the UNFCCC, as well as currently implemented policies, provide a basis for assessing potential emissions levels up to 2030 at the national, regional and global level. The following sections present an evaluation of the methods used for assessing projected emissions under NDCs and current policies (4.2.2.2), and the results of these assessments at global, regional and national level assessing a broad available literature based on first NDC submissions from 2015/16 and pre-COVID economic projections (4.2.2.3). The impacts of the COVID-19 pandemic and related government responses on emissions projections are then discussed in 4.2.2.4 and the implications of updated NDCs submitted in 2020/21 on emissions follow in 4.2.2.5. Section 0 presents an assessment of the so-called “implementation gap” between what currently implemented policies are expected to deliver and what the ambitions laid out under the full implementation of the NDCs are projected to achieve. Finally, a comparison of ambitions across different countries or regions (4.2.2.7) is presented and the uncertainties of projected emissions associated with NDCs and current policies are estimated, including a discussion of measures to reduce uncertainties in the specification of NDCs (4.2.2.8).

The literature reviewed in this section includes globally comprehensive assessments of NDCs and current policies, both peer-reviewed and non-peer-reviewed (but not unpublished model results) as well as synthesis reports by the UNFCCC Secretariat, government reports and national studies.

The aggregate effects of NDCs provide information on where emissions might be in 2025/2030, working forward from their recent levels. Chapter 3 of this report works backwards from temperature goals, defining a range of long-term global pathways consistent with 1.5°C, 2°C and higher temperature levels. By considering the two together, it is possible to assess whether NDCs are collectively consistent with 1.5°C, 2°C and other temperature pathways (Cross-Chapter Box 4, p.4-22).

4.2.2.2 Methods to project emissions under NDCs and current policies

A variety of different methods are used to assess emissions implications of NDCs and current policies over the time horizon to 2025 or 2030. Some of these projections were explicitly submitted as part of an official communication to UNFCCC (e.g., Biennial Report, Biennial Update Reports or National Communications) while the majority is from independent studies.

Methods that are used in independent studies (but that can also underlie the official communications) can broadly be separated into two groups,

- (i) system modelling studies which analyse policies and targets in a comprehensive modelling framework such an integrated assessment, energy systems or integrated land-use model to project emissions (or other indicators) of mitigation targets in NDCs and current policies, either at the national or global scale (noting some differences in the systems), and
- (ii) hybrid approaches that typically start out with emissions pathways as assessed by other published studies (e.g., the IEA World Energy Outlook, national emissions pathways such as those specified in some NDCs) and use these directly or apply additional modifications to them.

System modelling studies are conducted at global, regional and national scales. Global models provide an overview, are necessary for assessment of global phenomena (e.g., temperature change), can integrate climate models and trade effects. National models typically include more details on sectors, technology, behaviour and intersectoral linkages, but often use simplifying assumptions for international trade (e.g., the Armington elasticity approach). Critically, they can also better reflect local socio-economic and political conditions and their evolution (i.e., national development pathways). A

1 variety of modelling paradigms are found, including optimisation and simulation models, myopic and
2 with foresight, monolithic and modular (see Annex III: Scenarios and modelling methods).

3 Among the hybrid approaches, three broader categories can be distinguished, (i) direct use of official
4 emission projection as part of submitted NDC or other communication to UNFCCC, (ii) historical trend
5 extrapolation of emissions based on inventory data, possibly disaggregated by sector and emission
6 species, and (iii) use of Reference/Business-As-Usual pathways from an independent published study
7 (e.g., IEA WEO). In all cases, the reductions are then estimated on top of the resulting emission
8 trajectory. Note that globally comprehensive studies may vary the approach used depending on the
9 country.

10 Beyond the method applied, studies also differ in a number of dimensions, including (i) their spatial
11 resolution and coverage, (ii) their sectoral resolution and coverage, (iii) the GHGs that are included in
12 the assessment, the GWPs (or other metrics) to aggregate them, the emissions inventory (official vs.
13 independent inventory data) and related accounting approaches used as a starting point for the
14 projections, (iv) the set of scenarios analysed (Reference/Business-As-Usual, Current Policies, NDCs,
15 etc.), and (v) the degree to which individual policies and their impact on emissions are explicitly
16 represented (Table 4.1).

17 First, the studies are relevant to different spatial levels, ranging from macro-scale regions with globally
18 comprehensive coverage to national level (4.2.2.3) and subnational and company level in a few cases
19 (4.2.3). It is important to recognise that globally comprehensive studies typically resolve a limited
20 number of countries individually, in particular those that contribute a high share to global emissions,
21 but have poor resolution of remaining countries or regions, which are assessed in aggregate terms.
22 Conversely, studies with high resolution of a particular country tend to treat interactions with the global
23 scale in a limited way. The recent literature includes attempts to provide a composite global picture
24 from detailed national studies (Bataille et al. 2016a; Deep Decarbonization Pathways Project 2015;
25 Roelfsema et al. 2020).

26 A second dimension in which the studies are different is their comprehensiveness of covering different
27 emitting sectors. Some studies focus on the contribution of a single sector, for example the Agriculture,
28 Forestry and Other Land Use (AFOLU) sector (Fyson and Jeffery 2019; Grassi et al. 2017) or the energy
29 system (including both energy supply and demand sectors), to emission reductions as specified in the
30 NDC. Such studies give an indication of the importance of a given sector to achieving the NDC target
31 of a country and can be used as a benchmark to compare to comprehensive studies, but adding sectoral
32 contributions up represents a methodological challenge.

33 Third, GHG coverage is different across studies. Some focus on CO₂ only, while others take into
34 account the full suite of Kyoto gases (CO₂, CH₄, N₂O, HFCs, PFCs and SF₆, see glossary). For the latter,
35 different metrics for aggregating GHGs to a CO₂-equivalent metric are being used, typically GWP 100
36 from different IPCC assessments (Table 4.1)

37 Fourth, studies typically cover a set of scenarios, though how these scenarios are defined varies widely.
38 The literature reporting IAM results often includes *Nationally Determined Contribution* (NDC), which
39 are officially communicated, and *Current Policies* (CP) as interpreted by modellers. Studies based on
40 national modelling, by contrast, tend to define scenarios reflecting very different national contexts. In
41 both cases, modellers typically include so-called *No Policy Baseline* scenarios (alternatively referred to
42 as *Reference* or *Business-as-Usual scenarios*) which do not necessarily reflect currently implemented
43 policies and thus are not assessed as reference pathways (see section 4.2.6.1). There are also various
44 approaches to considering more ambitious action compared to the CP or NDC projections that are
45 covered in addition.

46 Fifth, studies differ in the way they represent policies (current or envisioned in NDCs), depending on
47 their internal structure. For example, a subsidy to energy efficiency in buildings may be explicitly

1 modelled (e.g., in a sectoral model that represents household decisions relative to building insulation),
2 represented by a proxy (e.g., by an exogenous decrease in the discount rate households use to make
3 choices), or captured by its estimated outcome (e.g., by an exogenous decrease in the household demand
4 for energy, say in an energy system model or in a compact CGE). Detailed representations (such as the
5 former example) do not necessarily yield more accurate results than compact ones (the latter example),
6 but the set of assumptions that are necessary to represent the same policy will be very different.

7 Finally, policy coverage strongly varies across studies with some just implementing high level targets
8 specified in policy documents and NDCs while others represent the policies with the largest impact on
9 emissions and some looking at very detailed measures and policies at subnational level. In addition, in
10 countries with rapidly evolving policy environments, slightly different cut-off dates for the policies
11 considered in an emission projection can make a significant difference for the results (Dubash et al.
12 2018).

13 The challenges described above are dealt with in the assessment of quantitative results in Section 4.2.2.3
14 by (i) comparing national studies with country-level results from global studies to understand systematic
15 biases, (ii) comparing economy-wide emissions (incl. AFOLU) as well as energy-related emissions,
16 (iii) using different emission metrics including CO₂ and Kyoto GHG emissions where the latter have
17 been harmonized to using AR6 GWP100 metrics, and (iv) tracking cut-off dates of implemented
18 policies and NDCs used in different references (Table S4.1). The most notable differences in
19 quantitative emission estimates related to current policies and NDCs relate to the COVID-19 pandemic
20 and its implications and to the updated NDCs mostly submitted since early 2020 which are separately
21 dealt with in Sections 4.2.2.4 and 4.2.2.5, respectively.

22 In addition to assessing the emissions outcomes of NDCs, some studies report development indicators,
23 by which they mean a wide diversity of socio-economic indicators (Altieri et al. 2016; Jiang et al. 2013;
24 Benavides et al. 2015; Chai and Xu 2014; Delgado et al. 2014; La Rovere et al. 2014a; Paladugula et
25 al. 2018; Parikh et al. 2018; Zevallos et al. 2014; Zou et al. 2016; Yang et al. 2021; Bataille et al. 2016a),
26 share of low-carbon energy (Bertram et al. 2015; Riahi et al. 2015), renewable energy deployment
27 (Roelfsema et al. 2018), production of fossil fuels (SEI et al. 2020) or investments into low-carbon
28 mitigation measures (McCollum et al. 2018) to track progress towards long-term temperature goals.

29 **4.2.2.3 Projected emissions under NDCs and current policies by 2025/2030**

30 The emissions projections presented in this section relate to the first NDCs, as communicated in 2015
31 and 2016, and on which an extensive literature exists. New and updated NDCs, mostly submitted since
32 the beginning of 2020, are dealt with in Section 4.2.2.5. Similarly, the implications of COVID-19 and
33 the related government responses on emissions projections is specifically dealt with in Section 4.2.2.4.

34 Table 4.1 presents the evidence base for the assessment of projected emissions of original NDCs and
35 current policies until 2030. It covers 31 countries and regions responsible for about 82% of global GHG
36 emission (excluding FOLU CO₂ emissions) and draws quantitative estimates from more than 40 studies
37 (see Table S4.1 in the Supplementary Material to Chapter 4). The table allows comparing emission
38 projections from national and globally comprehensive studies as well as official communications by
39 countries to the UNFCCC at the national/regional level. The global aggregates presented in Table 4.1
40 derive from globally comprehensive studies only and are not the result of aggregating country
41 projections up to the global level. As different studies report different emission indicators, the table
42 includes four different indicators: CO₂ and GHG emissions, in- or excluding AFOLU emissions. Where
43 possible, multiple indicators are included per study.

44 **Globally comprehensive studies.**

45 The UNFCCC Secretariat has assessed the aggregate effect of NDCs multiple times. The first report
46 considered the intended NDCs in relation to 2°C (UNFCCC 2015b), whereas the second considered
47 NDCs also in relation to 1.5°C (UNFCCC 2016b). New submissions and updates of NDCs in 2020/21

1 are assessed in Section 4.2.2.5. A number of globally comprehensive studies (den Elzen et al. 2016;
2 Luderer et al. 2016; Rogelj et al. 2016, 2017; Vandyck et al. 2016; Rose et al. 2017; Baumstark et al.
3 2021) which estimate aggregate emissions outcomes of NDCs and current policies have previously been
4 assessed in Cross-Chapter-Box 11 of IPCC SR1.5.

5 According to the assessment in this report, studies projecting emissions of current policies based on
6 pre-COVID assumptions lead to median global GHG emissions of 60 GtCO₂-eq with a full range of 54-
7 68 by 2030 and original unconditional and conditional NDCs submitted in 2015/16 to 57 (49-63) and
8 54 (50-60) GtCO₂-eq, respectively (*robust evidence, medium agreement*) (Table 4.1). Globally
9 comprehensive and national-level studies project emissions of current policies and NDCs to 2025 and
10 2030 and, in general, are in good agreement about projected emissions at the country level.

11 These estimates are close to the ones provided by the IPCC SR1.5, Cross-Chapter-Box 11, and the
12 UNEP emissions gap report (UNEP 2020a)³.

13 *National studies*

14 A large body of literature on national and regional emissions projections, including official
15 communications of as part of the NDC submissions and independent studies exist. A subset of this
16 literature provides quantitative estimates for the 2030 timeframe. As highlighted in Section 4.2.1, the
17 number of independent studies varies considerably across countries with an emphasis on the largest
18 emitting countries. This is reflected in Table 4.1 (see also Table S4.1). Despite smaller differences
19 between globally comprehensive and national studies for a few countries, there is generally good
20 agreement between the different types of studies, providing evidence that these quantitative estimates
21 are fairly robust.

22 *Sectoral studies*

23 Sectoral studies are essential to understand the contributions of concrete measures of NDCs and current
24 policies. For example, approximately 98% of NDCs include the energy sector in their mitigation
25 contributions, of which nearly 50% include a specific target for the share of renewables, and about 5%
26 aim at increasing nuclear energy production (Stephan et al. 2016). Transport is covered explicitly in
27 75% of NDCs, although specific targets for the sector exist in only 21% of NDCs (PPMC and SLoCaT
28 2016). Measures or targets for buildings are referred to explicitly in 27% of NDCs (GIZ 2017). 36% of
29 NDCs include targets or actions that are specific to the agriculture sector (FAO 2016). LULUCF
30 (mitigation) is included in 80 % of all submitted NDCs, while 59 % include adaptation and 29 % refer
31 to REDD+.

32 Greater sectoral expertise and involvement will be critical to accomplishing development and climate
33 goals due to enhanced availability of information and expertise on specific sectoral options, greater ease
34 of aligning the NDCs with sectoral strategies, and greater awareness among sector-level decision-
35 makers and stakeholders (NDC Partnership 2017; Fekete et al. 2015). Sector-specific studies are
36 assessed in the sectoral Chapters (6-11) of this report.

FOOTNOTE³ Note that the statistical metrics reported are slightly different across the reports. For example, IPCC SR1.5 reported the 25th to 75th range while the UNEP emissions gap report uses median and 10th to 90th percentile ranges. In addition, this report applies 100-year GWPs from AR6 to aggregate across different GHG emission species, whereas 100-year GWPs from AR4 were applied in IPCC SR1.5 and UNEP 2020. The application of AR6 GWPs on average leads to increase of estimates by about 1.3% and ranges are wider due to the difference in statistical error metrics.

37 **Table 4.1 Assessment of projected 2030 emissions of current policies based on pre-COVID assumptions and original NDCs submitted in 2015/16 for 28 individual**
 38 **countries/regions and the world. The table compares projected emissions from globally comprehensive studies, national studies and, when available, official**
 39 **communications to UNFCCC using different emission sources (fossil fuels, AFOLU sector) and different emission metrics (CO₂, Kyoto GHGs). The comparison**
 40 **allows identifying potential biases across the ranges and median estimates projected by the different sets of studies.**

41 Notes: ^a Countries are abbreviated by their ISO 3166-1 alpha-3 letter codes. EU denotes the European Union. ^b 2018 Share of global Kyoto GHG emissions, excluding FOLU
42 emissions, based on 2019 GHG emissions from Chapter 2 (Minx et al. 2021; Crippa et al. 2021). ^c Type distinguishes between independent globally comprehensive studies
43 (that also provide information at the country/region level), independent national studies and official communications via Biennial Reports, Biennial Update Reports or National
44 Communications. ^d Different estimates from one study (e.g., data from multiple models or minimum and maximum estimates) are counted individually, if available. ^e GHG
45 emissions expressed in CO₂-eq emission using AR6 100-year GWPs (see Section 2.2.2 for a discussion of implications for historical emissions). GHG emissions from scenario
46 data is recalculated from individual emission species using AR6 100-year GWPs. GHG emissions from studies that do provide aggregate GHG emissions using other GWPs
47 are rescaled using 2019 GHG emissions from Chapter 2 (Minx et al. 2021; Crippa et al. 2021). ^f If more than one value is available, a median is provided and the full range of
48 estimates (in parenthesis). To avoid a bias due to multiple estimates provided by the same model, only one estimate per model, typically the most recent update, is included in
49 the median estimate. In the full range, multiple estimates from the same model might be included, in case these reflect specific sensitivity analyses of the “central estimate”
50 (e.g., (Baumstark et al. 2021; Rogelj et al. 2017)). ^g Note that AFOLU emissions from national GHG inventories and global/national land use models are generally different
51 due to different approaches to estimate the anthropogenic CO₂ sink (Grassi et al. 2018, 2021)(7.2.3 and Cross-Chapter Box 6). ^h The estimates for the USA are based on the
52 first NDC submitted prior to the withdrawal from the Paris Agreement, but not including the updated NDC submitted following its re-entry. ⁱ The EU estimates are based on
53 the 28 member states up until 31 January 2020, i.e. including the UK.

4.2.2.4 *Estimated impact of COVID-19 and governmental responses on emissions projections*

The impacts of COVID-19 and national governments' economic recovery measures on current (see 2.2.2) and projected emissions of individual countries and globally under current policies scenarios until 2030 may be significant, although estimates are highly uncertain and vary across the few available studies. The analyses published to date (October 2021) are based on limited information about how COVID-19 has affected the economy and hence GHG emissions across countries so far in 2020, and also based on assumptions about COVID-19's longer term impact. Moreover, the comparison of pre- and post-COVID-19 projections captures the impact of COVID-19 as well as other factors such as the consideration of recently adopted policies not related to COVID-19, as well as methodological changes.

Across different studies (Kikstra et al. 2021; IEA 2020; Dafnomilis et al. 2021; Pollitt et al. 2021; UNEP 2020a; Climate Action Tracker 2020; Keramidis et al. 2021; Dafnomilis et al. 2020), the impact of the general slowdown of the economy due to the COVID-19 pandemic and its associated policy responses would lead to a reduced estimate of global GHG emissions in 2030 of about 1 to 5 GtCO₂eq, equivalent to 1.5 to 8.5 per cent, compared to the pre-COVID-19 estimates (see Table S4.2 for details). Nascimento et al. (2021) analyse the impacts of COVID-19 on current policy emission projections for 26 countries and regions and find a large range of emission reduction—between -1% and -21%—across these.

As indicated by a growing number of studies at the national and global level, how large near- to mid-term emissions implications of the COVID-19 pandemic are to a large degree depends on how stimulus or recovery packages are designed (Wang et al. 2020; Gillingham et al. 2020; Forster et al. 2020; Malliet et al. 2020; Le Quéré et al. 2020; Obergassel et al. 2021; IEA 2020; UNEP 2020a; Pollitt et al. 2021).

Four studies (Climate Action Tracker 2021; den Elzen et al. 2021; JRC 2021; Riahi et al. 2021) provide an update of the current policies assessment presented in Section 4.2.2.3 by taking into account the effects of COVID-19 as well as potential updates of policies. The resulting GHG emissions in 2030 are estimated to be 57 GtCO₂-eq with a full range of 52 to 60 GtCO₂-eq (Table 4.2). This is a reduction of about 3 GtCO₂-eq or 5% compared to the pre-COVID estimates from Section 4.2.2.3.

Table 4.2 Projected global GHG emissions of current policies by 2030.

Total ^d	57 (52-60)	

Notes: ^a GHG emissions expressed in CO₂-eq emission using AR6 100-year GWPs. GHG emissions from studies that provide aggregate GHG emissions using other GWPs are rescaled using 2019 GHG emissions from Chapter 2 (Minx et al. 2021; Crippa et al. 2021). ^b If a range is available from a study, a median is provided in addition to the range. ^c Range includes estimates from four models GEM-E3, MESSAGEix-GLOBIOM, POLES, REMIND-MAgPIE based on sensitivity analysis. ^d To avoid a bias due to multiple estimates provided by the same model, only one estimate per model, typically the most recent update, is included in the median estimate for the total.

4.2.2.5 *Estimated impact of new and updated NDCs on emissions projections*

The number of studies estimating the emissions implications of new and updated NDCs and announced mitigation pledges that can be used for the quantitative assessment is limited to four (Table 4.3) (Climate Action Tracker 2021; den Elzen et al. 2021; Meinshausen et al. 2021; JRC 2021). One other study includes a limited number of NDC updates (Riahi et al. 2021) and another (UNFCCC 2021) excludes LULUCF emissions. They are therefore not directly comparable to the other two. In addition, the UNEP

1 Emissions Gap Report 2021 (UNEP 2021) in itself is assessment of almost the same studies included
2 here. The evidence base for the updated NDC assessment is thus considerably smaller compared to that
3 of the assessment of emissions implications of original NDCs presented in Section 4.2.2.3. However, it
4 is worthwhile to note that the earlier versions of the studies summarized in Table 4.2 and Table 4.3 are
5 broadly representative for the emissions range implied by the pre-COVID-19 current policies and
6 original NDCs of the full set of studies shown in Table 4.1, therefore building confidence in estimates.

7 An additional challenge lies in the fact that these studies do not all apply the same cut-off date for NDC
8 updates, potentially leading to larger systematic deviations in the resulting emission estimates. Another
9 complication is the fact that publicly announced mitigation pledges on global 2030 emissions that have
10 not been officially submitted to the UNFCCC NDC registry yet, have been included in several of the
11 studies to anticipate their impact on emission levels (see notes to Table 4.3). In addition to the updates
12 of NDC targets, most of the new studies also include impacts of COVID-19 on future emission levels
13 (as discussed in 4.2.2.4) which may have led to considerable downward revisions of emission trends
14 unrelated to NDCs. Table 4.3 presents the emission estimates of the four studies that form the basis of
15 the quantitative assessment presented here and three other studies to compare with.

16
17 **Table 4.3 Projected global GHG emissions of new and updated NDCs by 2030.**

Study	Cut-off date	Kyoto GHGs ^a [GtCO ₂ -eq]				References
		historical		median (min - max) ^b 2030		
		2015	2019	Unconditional NDCs	Conditional NDCs

ENGAGE ^j	3/2021				51 (49-53)	(Riahi et al. 2021)

18 Notes: ^a GHG emissions expressed in CO₂-eq emission using AR6 100-year GWPs. GHG emissions from studies
19 that provide aggregate GHG emissions using other GWPs are rescaled using 2019 GHG emissions from Chapter
20 2 (Minx et al. 2021; Crippa et al. 2021). Note that due to slightly different system boundaries across historical
21 emission datasets as well as data uncertainties (see Chapter 2, SM2.2 for details) relative change compared to
22 historical emissions should be calculated vis-à-vis the historical emissions data used by a particular study. ^b If a
23 range is available from a study, a median is provided in addition to the range. ^c announced mitigation pledges on
24 global 2030 emissions of China and Japan included. ^d announced mitigation pledges of China, Japan, Republic of
25 Korea included. ^e announced mitigation pledge of Korea not included. ^f announced mitigation pledges of China
26 and Republic of Korea not included, emissions from international aviation and shipping not included. ^g Ranges
27 across four studies are calculated using the median and the full range including the minimum and maximum of
28 studies if available. ^h UNEP EGR 2021 estimate listed for comparison, but since largely relying on the same
29 studies not included in range estimate. ⁱ NDCs submitted until 30 July included, announcements not included,
30 excluding LULUCF emissions. ^j NDC updates of Brazil, EU and announcement of China included as a sensitivity
31 analysis compared to original NDCs.

32 Comparing the emission levels implied by the new and updated NDCs as shown in Table 4.3 with those
33 estimated by the original NDCs from the same studies (as included in Table 4.1), a downward revision

1 of 3.8 (3.0-5.3) GtCO₂-eq of the central unconditional NDC estimates and of 4.5 (2.7-6.3) GtCO₂-eq of
2 the central conditional NDC estimate emerges (*medium evidence, medium agreement*). The emissions
3 gaps between temperature limits and new and updated NDCs are assessed in Cross-Chapter Box 4
4 below. New and updated unconditional NDC reduce the median gap with 2°C emissions pathways in
5 2030 by slightly more than 20%, from a median gap of 17 GtCO₂-eq (9-23) to 13 (10-17). New and
6 updated conditional NDC reduce the median gap with 2°C emissions pathways in 2030 by about one
7 third, from 14 GtCO₂-eq (10-20) to 10 (7-14). New and updated unconditional NDC reduce the median
8 gap with 1.5°C emissions pathways in 2030 by about 15%, from a median gap of 27 GtCO₂-eq (19-32)
9 to 23 GtCO₂-eq (20-26). New and updated conditional NDC reduce the median gap with 1.5°C
10 emissions pathways in 2030 by about 20%, from a median gap of 24 GtCO₂-eq (20-29) to 19 GtCO₂-
11 eq (16-24). Box 4.1 discusses the adaptation gap.

12 Globally, the implementation gap between projected emissions of current policies and the unconditional
13 and conditional new and updated NDCs is estimated to be around 4 and 7 GtCO₂eq in 2030, respectively
14 (Table 4.2 and 4.3) (*medium evidence, medium agreement*), with many countries requiring additional
15 policies and associated climate action to meet their mitigation targets as specified under the NDCs
16 (*limited evidence*) (see 4.2.2.6 for more details). It should be noted that the implementation gap varies
17 considerably across countries, with some having policies in place estimated to be sufficient to achieve
18 the emission targets their NDCs, some where additional policies may be required to be sufficient, as
19 well as differences between the policies in place and action on the ground.

20 **4.2.2.6 Tracking progress in implementing and achieving NDCs**

21 Under the Enhanced Transparency Framework, countries will transition from reporting biennial reports
22 (BRs) and biennial update reports (BURs) to reporting biennial transparency reports (BTRs) starting,
23 at the latest, by December 2024. Each Party will be required to report information necessary to track
24 progress made in implementing and achieving its NDC under the Paris Agreement (UNFCCC 2018b).
25 Thus, no official data exists yet on tracking progress of individual NDCs.

26 Meanwhile, there is some literature at global and national level that aims at assessing whether countries
27 are on track or progressing towards implementing their NDCs and to which degree the NDCs
28 collectively are sufficient to reach the temperature targets of the Paris agreement (Quére et al. 2018;
29 Höhne et al. 2018; Roelfsema et al. 2020; Rogelj et al. 2016; den Elzen et al. 2019; Höhne et al. 2020).
30 Most of these studies focus on major emitters such as G20 countries and with the aim to inform countries
31 to strengthen their ambition regularly, e.g., through progress of NDCs and as part of the global stocktake
32 (Höhne et al. 2018; Peters et al. 2017). However, a limited number of studies assess the implementation
33 gaps of conditional NDCs in terms of finance, technology and capacity building support. Some authors
34 conclude that finance needed to fulfil conditional NDCs exceeds available resources or the current long-
35 term goal for finance (USD100 billion yr⁻¹) (Pauw et al. 2019); others assess financial resources needed
36 for forest-related activities (Kissinger et al. 2019) (15.4.2). The literature suggests that consistent and
37 harmonised approach to track progress of countries towards their NDCs would be helpful (den Elzen et
38 al. 2019; Höhne et al. 2018; Peters et al. 2017), and negotiations on a common tabular format are
39 expected to conclude during COP26 in November 2021.

40 With an implementation gap in 2030 of 4 to 7 GtCO₂-eq (4.2.2.5), many countries will need to
41 implement additional policies to meet their self-determined mitigation targets as specified under the
42 NDCs. Studies that assess the level of projected emissions under current policies indicate that new
43 policies (that have been implemented since the first assessment of the NDCs in 2015 and are thus
44 covered in more recent projections) have reduced projections, by about 2 GtCO₂-eq since the adoption
45 of the Paris Agreement in 2015 to 2019 (Climate Action Tracker 2019; UNEP 2020a; den Elzen et al.
46 2019).

1 **4.2.2.7 Literature on fairness and ambition of NDCs**

2 Most countries provided information on how they consider their NDCs to be fair and ambitious in the
3 NDCs submitted to UNFCCC and many of these NDCs refer to specific national circumstances such as
4 social, economic and geographical factors when outlining why they are fair and ambitious. Further,
5 several Parties provided information on specific criteria for evaluating fairness and ambition, including
6 criteria relating to: responsibility and capability; share of emissions; development and/or technological
7 capacity; mitigation potential; cost of mitigation actions; the degree of progression or stretching beyond
8 the current level of effort; and the link to objectives and global goals (UNFCCC 2016a).

9 According to its Article 2.2, the Paris Agreement will be implemented to reflect equity and the principle
10 of common but differentiated responsibilities and respective capabilities, in the light of different
11 national circumstances, the latter clause being new, added to the UNFCCC principle (Rajamani 2017;
12 Voigt and Ferreira 2016). Possible different interpretations of equity principles lead to different
13 assessment frameworks (Lahn 2018; Lahn and Sundqvist 2017).

14 Various assessment frameworks have been proposed to analyse fair share ranges for NDCs. The
15 literature on equity frameworks including quantification of national emissions allocation is assessed in
16 section 4.5 (see 13.4.2, 14.3.2 and 14.5.3). Recent literature has assessed equity, analysing how fairness
17 is expressed in NDCs in a bottom-up manner (Cunliffe et al. 2019; Mbeva and Pauw 2016; Winkler et
18 al. 2018). Some studies compare NDC ambition level with different effort sharing regimes and which
19 principles are applied to various countries and regions (Robiou du Pont and Meinshausen 2018; Robiou
20 Du Pont et al. 2017; Holz et al. 2018; Peters et al. 2015; Pan et al. 2017; van den Berg et al. 2019).
21 Others propose multi-dimensional evaluation schemes for NDCs that combine a range of indicators,
22 including the NDC targets, cost-effectiveness compared to global models, recent trends and policy
23 implementation into consideration (Aldy et al. 2017; Höhne et al. 2018). Yet other literature evaluates
24 NDC ambition against factors such as technological progress of energy efficiency and low-carbon
25 technologies (Jiang et al. 2017; Wakiyama and Kuramochi 2017; Kuramochi et al. 2017), synergies
26 with adaptation plans (Fridahl and Johansson 2017), the obligations to deploy carbon dioxide removal
27 technologies like BECCS in the future implied by their near-term emission reductions where they are
28 not reflected on in the first NDCs (Fyson et al. 2020; Pozo et al. 2020; Peters and Geden 2017; Mace et
29 al. 2021). Others identify possible risks of unfairness when applying GWP* as emissions metric at
30 national scale (Rogelj and Schleussner 2019). A recent study on national fair shares draws on principles
31 of international environmental law, excludes approaches based on cost and grandfathering, thus
32 narrowing the range of national fair shares previously assessed, and apply this to the quantification of
33 national fair share emissions targets (Rajamani et al. 2021).

34 **4.2.2.8 Uncertainty in estimates**

35 There are many factors that influence the global aggregated effects of NDCs. There is limited literature
36 on systematically analysing the impact of uncertainties on the NDC projections with some exception
37 (Benveniste et al. 2018; Rogelj et al. 2017). The UNEP Gap Report (UNEP 2017a) discusses
38 uncertainties of NDC estimates in some detail. The main factors include variations in overall socio-
39 economic development; uncertainties in GHG inventories; conditionality; targets with ranges or for
40 single years; accounting of biomass; and different GHG aggregation metrics (e.g., GWP values from
41 different IPCC assessments). In addition, when mitigation effort in NDCs is described as measures that
42 do only indirectly translate into emission reductions, assumptions necessary for the translation come
43 into play (Doelle 2019). For a more elaborate discussion of uncertainties in NDCs see Section 14.3.2.

44 Some studies assume successful implementation of all of the NDCs' proposed measures, sometimes
45 including varying assumptions to account for some of the NDC features which are subject to assumed
46 conditions related to finance and technology transfer. Countries "shall pursue domestic mitigation
47 measures" under Article 4.2 of the Paris Agreement (UNFCCC 2015c), but they are not legally bound

1 to the result of reducing emissions (Winkler 2017a). Some authors consider this to be a lack of a strong
2 guarantee that mitigation targets in NDCs will be implemented (Nemet et al. 2017). Others point to
3 growing extent of national legislation to provide a legal basis for action (Iacobuta et al. 2018) (13.2).
4 These factors together with incomplete information in NDCs mean there is uncertainty about the
5 estimates of anticipated 2030 emission levels.

6 The aggregation of targets results in large uncertainty (Benveniste et al. 2018; Rogelj et al. 2017). In
7 particular, clarity on the contributions from the land use sector to NDCs is needed “to prevent high
8 LULUCF uncertainties from undermining the strength and clarity of mitigation in other sectors” (Fyson
9 and Jeffery 2019). Methodological differences in the accounting of the LULUCF anthropogenic CO₂
10 sink between scientific studies and national GHG inventories (as submitted to UNFCCC) further
11 complicate the comparison and aggregation of emissions of NDC implementation (Grassi et al. 2018,
12 2021) (Section 7.2.3 and Cross-Chapter Box 6). This uncertainty could be reduced with clearer
13 guidelines for compiling future NDCs, in particular when it comes to mitigation efforts not expressed
14 as absolute economy-wide targets (Doelle 2019), and explicit specification of technical details,
15 including energy accounting methods, harmonised emission inventories (Rogelj et al. 2017) and finally,
16 increased transparency and comparability (Pauw et al. 2018).

18 **START CCB 4 HERE**

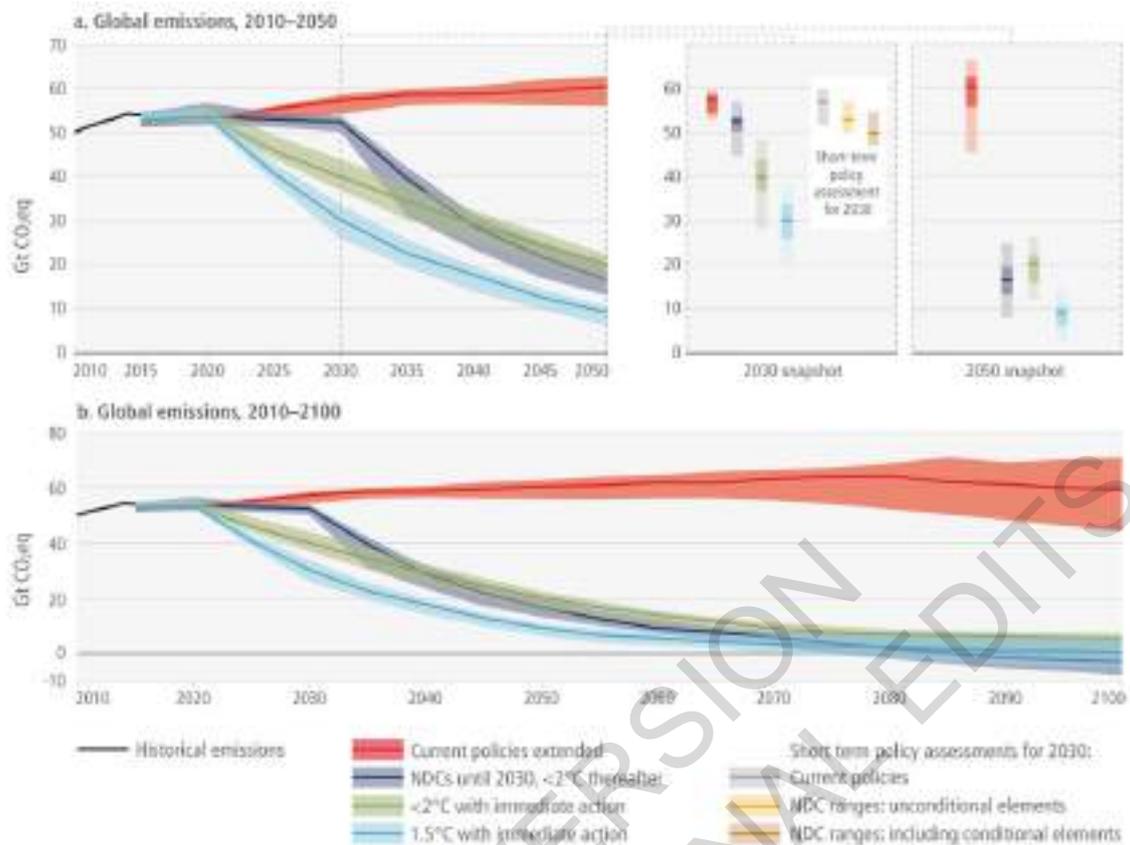

19 **Cross-Chapter Box 4 Comparison of NDCs and current policies with the 2030** 20 **GHG emissions from long-term temperature pathways**

21 Authors: Edward Byers (Ireland/Austria), Michel den Elzen (the Netherlands), Céline Guivarch
22 (France), Volker Krey (Germany/Austria), Elmar Kriegler (Germany), Franck Lecocq (France),
23 Keywan Riahi (Austria), Harald Winkler (Republic of South Africa)

24 **Introduction**

25 The Paris Agreement (PA) sets a long-term goal of holding the increase of global average temperature
26 to ‘well below 2°C above pre-industrial levels’ and pursuing efforts to limit the temperature increase to
27 1.5°C above pre-industrial levels. This is underpinned by the ‘aim to reach global peaking of greenhouse
28 gas emissions as soon as possible’ and ‘achieve a balance between anthropogenic emissions by sources
29 and removals by sinks of GHG in the second half of this century’ (UNFCCC 2015d). The PA adopts a
30 bottom-up approach in which countries determine their contribution to reach the PA’s long-term goal.
31 These national targets, plans and measures are called ‘nationally determined contributions’ or NDCs.

32 The NDCs are a central instrument of the PA to achieve its long-term goal. It thus combines a global
33 goal with a country-driven (bottom-up) instrument to a hybrid climate policy architecture to strengthen
34 the global response to climate change. All signatory countries committed to communicating nationally
35 determined contributions including mitigation targets, every five years. While the NDCs mostly state
36 targets, countries are also obliged to pursue domestic mitigation measures to achieve the objectives.
37 The literature examines the emissions outcome of the range of policies implemented to reach these
38 targets.

1 **Cross-Chapter Box 4, Figure 1 Aggregate GHG emission outcomes of NDCs and long-term mitigation**
 2 **pathways consistent with global temperature limits. Shown are emission ranges that would emerge when**
 3 **assuming the full implementation of current unconditional and conditional NDCs (grey bars, median and**
 4 **full range) and global pathways from the AR6 scenario database that can be grouped into four types:**
 5 **pathways with near-term emissions developments in line with (1) current policies and extended with**
 6 **comparable ambition levels beyond 2030; (2) pathways holding warming below 2°C (66% chance) with**
 7 **near term emissions developments reflecting ambition levels in current NDCs until 2030; and mitigation**
 8 **pathways undertaking immediate action after 2020 towards (3) holding warming below 2°C (66%**
 9 **chance) and (4) limiting warming to 1.5°C by 2100 (>50% chance) with no or limited (<0.1°C) overshoot,**
 10 **respectively. The upper panel shows the emission pathways until 2050 (median and 25th-75th percentiles)**
 11 **with their emissions ranges in 2030 and 2050 broken out in full (median and 5th-95th percentiles). The**
 12 **lower panel shows the ranges (25th -75th percentiles) for the four types of emissions pathways over the 21st**
 13 **century.**

14
 15 Notes: GHG emissions are expressed in CO₂-equivalent based on 100-year GWPs from AR6. Projected emissions
 16 for the current policies and NDCs scenarios from Section 4.2.2 (Tables 4.2/3) show median and full range. The
 17 studies on current policies include post-COVID effects up until 2021 (Table 4.2). Note that NDC estimates include
 18 updates submitted up until October 2021 as well as pledge announcements (Table 4.3). Historical emissions are
 19 from the RCMIP historical compiled dataset comprising various sources and methods, as described in (Nicholls
 20 et al. 2020).

21 Emissions gap

22 A comparison between the projected emission outcomes of current policies, the NDCs (which include
 23 unconditional and conditional elements, see Section 4.2.1) and mitigation pathways acting immediately,
 24 i.e. from 2020 onwards, on reaching different temperature goals in the long-term (see Section 3.3.3)
 25 allows identifying different ‘emission gaps’ in 2030 (Figure 1). First, the implementation gap between
 26 ‘current policies’ and unconditional and conditional NDCs is estimated to be around 4 and 7 GtCO₂eq
 27 in 2030, respectively (Section 4.2.2 and Tables 4.2 and 4.3). Second, the comparison of unconditional

1 (conditional) NDCs and long-term mitigation pathways likely limit warming to 2 °C or lower; giving
2 rise to a 2030 median emissions gap of 20-26 GtCO₂eq (16-24 GtCO₂eq) for limiting end-of-century
3 warming to 1.5°C (50% chance) with no or limited overshoot and 10-17 GtCO₂eq (7-14 GtCO₂eq) for
4 limiting warming to 2°C (66% chance)⁴. GHG emissions of NDCs are broadly consistent with 2030
5 emission levels of cost-effective long-term pathways staying below 2.5°C.

6 **Other ‘gap indicators’**

7 Beyond the quantification of different GHG emissions gaps, there is an emerging literature that
8 identifies gaps between current policies, NDCs and long-term temperature in terms of other indicators,
9 including for example the deployment of low-carbon energy sources, energy efficiency improvements,
10 fossil fuel production levels or investments into mitigation measures (Roelfsema et al. 2020; McCollum
11 et al. 2018; SEI et al. 2020).

12 A 2030 gap in the contribution of low-carbon energy sources to the energy mix in 2030 between current
13 policies and cost-effective long-term temperature pathways is calculated to be around 7%-points (2°C)
14 and 13%-points (1.5°C) by Roelfsema et al. (Roelfsema et al. 2020). The same authors estimate an
15 energy intensity improvement gap 10% and 18% for 2030 between current policies pathways and 2°C
16 and 1.5°C pathways, respectively. SEI et al. (2020) estimates the ‘fossil fuel production gap’, i.e. the
17 level of countries’ planned fossil fuel production expressed in their carbon content to be 120% and 50%
18 higher compared to the fossil fuel production consistent with 1.5°C and 2°C pathways, respectively, as
19 assessed in IPCC SR1.5 (Rogelj et al. 2018a). The methodology used for this estimation is very similar
20 to how emissions gaps are derived (SEI et al. 2019). The gap of global annual average investments in
21 low-carbon energy and energy efficiency in 2030 between following current policy on the one hand and
22 achieving the NDCs, the 2°C and 1.5°C targets on the other hand, is estimated to be approximately USD
23 130, 320, or 480 billion per year (McCollum et al. 2018).

24 It is important to note that such comparisons are less straight forward as the link between long-term
25 temperature goals and these indicators is less pronounced compared to the emission levels themselves;
26 they are therefore associated with greater uncertainty compared to the emissions gap.

27 **END CCB 4 HERE**

28
29 **START BOX 4.1 HERE**

30 **Box 4.1 Adaptation Gap and NDCs**

31 NDCs have been an important driver of national adaptation planning, with cascading effects on sectors
32 and sub-national action, especially in developing countries. Yet, only 40 developing countries have
33 quantifiable adaptation targets in their current NDCs; 49 countries include quantifiable targets in their
34 national legislation (UNEP 2018a).

35 Working Group II contribution to this Assessment finds that the overall extent of adaptation-related
36 responses in human systems is low (*high confidence*) and that there is limited evidence on the extent to
37 which adaptation-related responses in human systems are reducing climate risk (O’Neill et al. 2020).
38 Thus there is an adaptation gap (UNEP 2018a), and bridging that gap requires enablers including
39 institutional capacity, planning and investment (UNEP 2016). Estimates of adaptation costs vary greatly
40 across studies. Recent studies based on climate change under RCP8.5 report adaptation costs for

FOOTNOTE ⁴ The emission gap ranges provided here is calculated as the difference between minimum and maximum emissions estimates of NDCs and the median of the 1.5 and 2°C pathways.

1 developing countries of up to 400 (300 in RCP2.6) billion USD2005 in 2030 (New et al. 2020). Of the
2 NDCs submitted in 2015, fifty countries estimated adaptation costs of USD 39 billion annually. Both
3 public and private finance for adaptation is increasing, but remains insufficient and constitutes a small
4 fraction (4-8%) of total climate finance which is mostly aimed at mitigation. The pledge of developed
5 countries of mobilising finance for developing countries to address adaptation needs globally as part of
6 the Paris Agreement are insufficient. By 2030 the adaptation needs are expected to be 3 to 6 times larger
7 than what is pledged, further increasing towards 2050 (UNEP 2016; New et al. 2020).

8 **END BOX 4.1 HERE**

11 **4.2.3 Mitigation efforts in subnational and non-state action plans and policies**

12 The decision adopting the Paris Agreement stresses the importance of “stronger and more ambitious
13 climate action” by non-government and subnational stakeholders, “including civil society, the private
14 sector, financial institutions, cities and other subnational authorities, local communities and indigenous
15 peoples” (UNFCCC 2015e). The Marrakech Partnership for Global Action, launched in the 2016
16 UNFCCC Conference of Parties by two “high-level champions,” further formalized the contributions
17 of non-government and subnational actors taking action through seven thematic areas (e.g., energy,
18 human settlements, industry, land-use, etc.) and one cross-cutting area (resilience). Since then, non-
19 state actors, e.g., companies and civil society, and subnational actors, e.g. cities and regions, have
20 emerged to undertake a range of largely voluntary carbon mitigation actions (Hsu et al. 2019, 2018)
21 both as individual non-state actors (NSA in the following) and through national and international
22 cooperative initiatives (ICIs) (Hsu et al. 2018). ICIs take a variety of forms, ranging from those that
23 focus solely on non-state actors to those that engage national and even local governments. They can
24 also range in commitment level, from primarily membership-based initiatives that do not require
25 specific actions to those that require members to tackle emissions reductions in specific sectors or aim
26 for transformational change.

27 Quantification of the (potential) impact of these actions is still limited. Almost all studies estimate the
28 potential impact of the implementation of actions by NSA and ICI, but do not factor in that they may
29 not reach their targets. The main reason for this is that there is very limited data currently available from
30 individual actors (e.g., annual GHG inventory reports) and initiatives to assess their progress towards
31 their targets. A few studies have attempted to assess progress of initiatives by looking into the
32 initiatives’ production of relevant outputs (Chan et al. 2018). Quantification does not yet cover all
33 commitments and only a selected number of ICIs are analysed in the existing literature. Most of these
34 studies exclude commitments that are not (self-)identified as related to climate change mitigation, those
35 that are not connected to international networks, or those that are communicating in languages other
36 than English.

37 Non state action could make significant contributions to achieving the Paris climate goals (*limited
38 evidence, high agreement*). However, efforts to measure the extent to which non-state and subnational
39 actors go beyond national policy are still nascent (Kuramochi et al. 2020; Hsu et al. 2019) and we do
40 not fully understand the extent to which ambitious action by non-state actors is additional to what
41 national governments intend to do. Subnational and non-state climate action may also have benefits in
42 reinforcing, implementing, or piloting national policy, in place of or in addition to achieving additional
43 emissions reductions (Broekhoff et al. 2015; Heidrich et al. 2016; Hsu et al. 2017).

44 Quantification of commitments by individual NSAs are limited to date. Attempts to quantify aggregate
45 effects in 2030 of commitments by individual non-state and subnational actors are reported by
46 (Kuramochi et al. 2020; Hsu et al. 2019). (Kuramochi et al. 2020) estimate potential mitigation by more
47 than 1,600 companies, around 6,000 cities and many regions (cities assessed have a collective

1 population of 579 million, and regions 514 million). Individual commitments by these subnational
2 regions, cities and companies could reduce GHG emissions in 2030 by 1.2 to 2.0 GtCO₂-eq yr⁻¹
3 compared to current national policies scenario projections, reducing projected emissions by 3.8%–5.5%
4 in 2030, if commitments are fully implemented and do not lead to weaker mitigation actions by others
5 (Figure 4.1 left). In several countries, NSA commitments could potentially help meet or exceed national
6 mitigation targets.

7 Quantification of potential emission reductions from international cooperative initiatives have been
8 assessed in several studies, and recently synthesised (Hsu et al. 2020; Lui et al. 2021), with some
9 initiatives reporting high potential. In Table 4.4 and Figure 4.1, we report estimates of the emissions
10 reductions from 19 distinct sub-national and non-state initiatives to mitigate climate change. The table
11 shows wide ranges of potential mitigation based on current, target or potential membership, as well as
12 a wide diversity of actors and membership assumptions. Current membership reflects the number of
13 non-state or subnational actors that are presently committed to a particular initiative; while targeted or
14 potential membership represents a membership goal (e.g., increasing from 100 to 200 members) that an
15 initiative may seek to achieve (Kuramochi et al. 2020). When adding up emission reduction potentials,
16 sub-national and non-state international cooperative initiatives could reduce up to about 20 Gt of CO₂-
17 eq in 2030 (*limited evidence, medium agreement*). Chapter 8 also presents data on the savings potential
18 of cities and it suggests that these could reach 2.3 GtCO₂-eq annually by 2030 and 4.2 GtCO₂-eq
19 annually for 2050.

Table 4.4 Emissions reduction potential for sub-national and non-state international cooperative initiatives by 2030

<u>Sector</u>	<u>Leading Actor</u>	<u>Name</u>	<u>Scale</u>	<u>Target(s)</u>	<u>2030 emissions reduction potential compared to no policy, current policies or NDC baseline (GtCO₂-eq yr⁻¹)</u>		<u>Membership assumptions</u>
					<i>Min</i>	<i>Max</i>	
Energy efficiency	Intergovernmental (UNEP)	United for Efficiency (U4E)	Global (focus on developing countries)	Members to adopt policies for energy-efficient appliances and equipment	0.6	1.25	Current membership
Energy efficiency	Intergovernmental	Super-efficient Equipment and Appliance Deployment (SEAD) Initiative	Global	Members to adopt current policy best practices for energy efficiency product standards	0.5	1.7 (excl. China)	Current membership
Buildings	Business	Architecture 2030	Global (focus on North America)	New buildings and major renovations shall be designed to meet an energy consumption performance standard of 70% below the regional (or country) average/median for that building type and to go carbon-neutral in 2030	0.2	0.2	Current membership
Transport	Business (aviation sector)	Collaborative Climate Action Across the Air Transport World (CAATW)	Global	Two key objectives: 1) 2% annual fuel efficiency improvement through 2050, 2) Stabilise net carbon emissions from 2020	0.3	0.6	Current membership
Transport	Business	Lean and Green	Europe	Member companies to reduce CO ₂ emissions from logistics and freight activity by at least 25% over a five-year period	0.02	0.02	Current membership
Transport	Hybrid	Global Fuel Economy Initiative (GFEI)	Global	Halve the fuel consumption of the LDV fleet in 2050 compared to 2005	0.5	1.0	Current membership

Transport	Business	Below50 LCTPi ¹⁾	Global	Replace 10% of global transportation fossil fuel use with low-carbon transport fuels by 2030	0.5	0.5	Scaled-up global potential
Renewable energy	Business	European Technology & Innovation Platform Photovoltaic (ETIP PV)	Europe	Supply 20% of electricity from solar Photovoltaic PV technologies by 2030	0.2	0.5	Current membership
Renewable energy	Intergovernmental (African Union)	Africa Renewable Energy Initiative (AREI)	Africa	Produce 300 GW of electricity for Africa by 2030 from clean, affordable and appropriate forms of energy	0.3	0.8	Current membership
Renewable energy	Hybrid	Global Geothermal Alliance (GGA)	Global	Achieve a five-fold growth in the installed capacity for geothermal power generation and a more than two-fold growth in geothermal heating by 2030	0.2	0.5	Targeted capacity
Renewable energy	Business	REscale LCTPi ¹⁾	Global	Support deployment of 1.5 TW of additional renewable energy capacity by 2025 in line with the IEA's 2°C scenario	5	5	Scaled-up global potential
Renewable energy	Business	RE100 initiative	Global	2,000 companies commit to source 100% of their electricity from renewable sources by 2030	1.9	4	Targeted membership
Forestry	Hybrid	Bonn Challenge / Governors' Climate and Forests Task Force (GCFTF) / New York Declaration on Forests (NYDF)	Global	End forest loss by 2030 in member countries and restore 150 million hectares of deforested and degraded lands by 2020 and an additional 200 million hectares by 2030	3.8	8.8	Scaled-up global potential
Non-CO ₂ emissions	Government	Climate & Clean Air Coalition (CCAC)	Global	Members to implement policies that will deliver substantial short-lived climate forcers (SLCP) reductions in the near- to medium-term (i.e., by 2030) for HFCs and methane	1.4	3.8	Current membership
Non-CO ₂ emissions	Intergovernmental	Zero Routine Flaring	Global	Eliminate routine flaring no later than 2030	0.4	0.4	Current membership

	(World Bank)						
Multisectoral	Cities and regions	Under2 Coalition	Global	Local governments (220 members) aim to limit their GHG emissions by 80 to 95% below 1990 levels by 2050	4.6	5	Current membership
Multisectoral	Cities and regions	Global Covenant of Mayors for Climate & Energy (GCoM)	Global	Member cities have a variety of targets (+9,000 members)	1.4	1.4	Current membership
Multisectoral	Cities and regions	C40 Cities Climate Leadership Group (C40)	Global	94 member cities have a variety of targets, aiming for 1.5°C compatibility by 2050. The network carries two explicit goals: 1) to have every C40 city develop a climate action plan before the end of 2020 (Deadline 2020), which is “deliver action consistent with the objectives of the Paris Agreement” and 2) to have cities achieve emissions neutrality by 2050	1.5	3	Current membership
Agriculture	Business	Climate Smart Agriculture (CSA) LCTPi ¹⁾	Global	Reducing agricultural and land-use change emissions from agriculture by at least 50% by 2030 and 65% by 2050. 24 companies and 15 partners	3.7	3.7	Scaled-up global potential
Multisectoral	Business	Science Based Targets initiative (SBTi)	Global	By 2030, 2,000 companies have adopted a science-based target in line with a 2°C temperature goal	2.7	2.7	Targeted membership

22 Note ¹ As of December 2020 most of the Low Carbon Technology Partnerships (LCTPi) initiatives are defunct, except the Climate Smart Agriculture programme

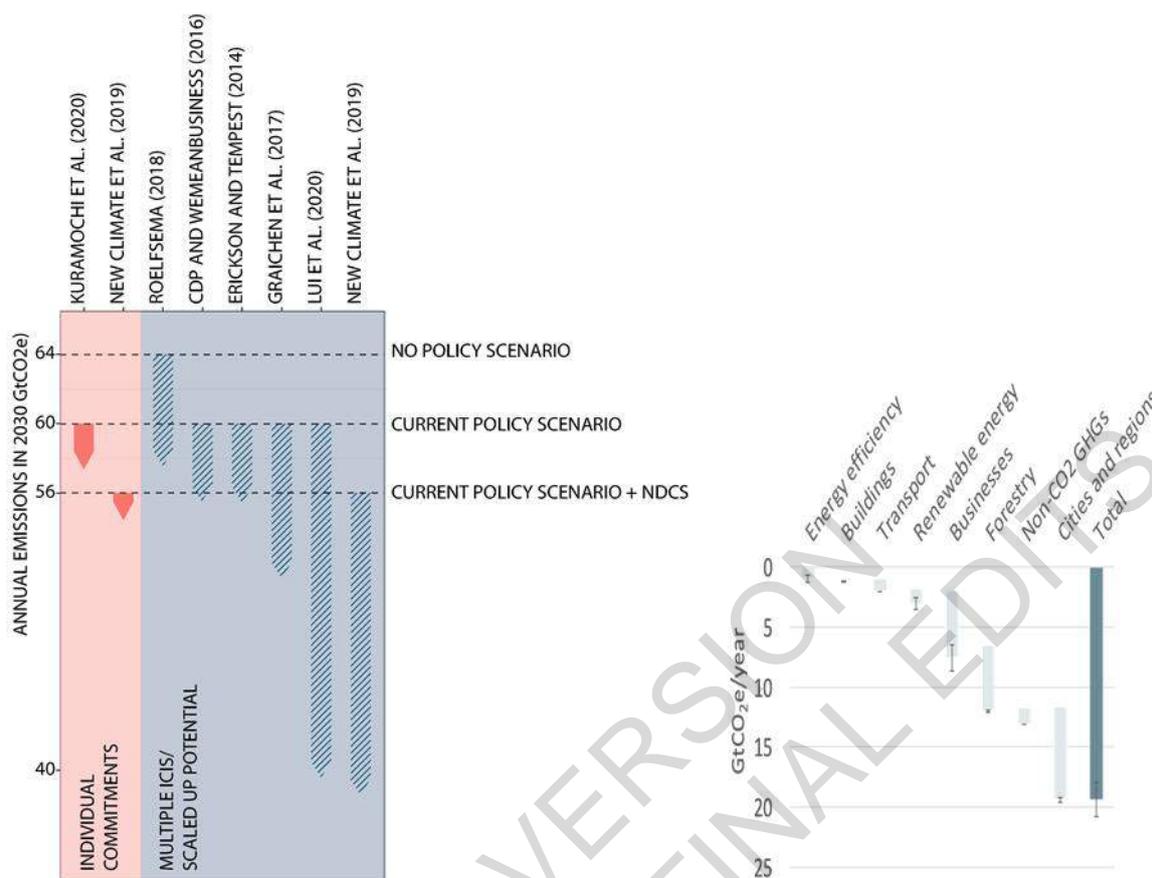

Figure 4.1 Emissions reduction potential for non-state and sub-national actors by 2030

Source: Data in left panel from Hsu et al. (2020), right panel from Lui et al. (2020).

Non-state action may be broader than assessed in the literature so far, though subject to uncertainty. The examples in Table 4.4 and Figure 4.1 do not include initiatives that target the emissions from religious organisations, colleges and universities, civic and cultural groups, and, to some extent, households, and in this sense may underestimate sub-national potential for mitigating emissions, rather than overestimate it. That said, the estimates are contingent on assumptions that subnational and non-state actors achieve commitments—both with respect to mitigation and in some cases membership—and that these actions are not accounted for in nor lead to weakening of national actions.

Care is to be taken not to depict these efforts as additional to action within national NDCs, unless this is clearly established (Broekhoff et al. 2015). There are potential overlaps between individual NSA and ICI, and across ICIs. Kuramochi et al. (2020) propose partial and conservative partial effect methods to avoid double counting when comparing ambition, a matter that merits further attention. As the diversity of actions increased, the potential to count the same reductions multiple times increases.

Equally important to note here is that none of the studies reviewed in Figure 4.1 quantified the potential impact of financial sector actions, e.g., divestment from emission intensive activities (see Section 15.3 for a more detailed discussion of how financial actors and instruments are addressing climate change). Moreover, only a limited number of studies on the impact of actions by diverse actors go beyond 2050 (see Table 4.4), which may reflect analysts' recognition of the increasing uncertainties of longer time horizons. Accurate accounting methods can help to avoiding counting finance multiple times, and methods across mitigation and finance would consider counting carbon market flows and the tons

1 reduced. As Table 4.4 and Figure 4.1 indicate, activities by businesses have potential to significantly
2 contribute to global mitigation efforts. For example, the SBTi (Science-Based Targets Initiative)
3 encourages companies to pledge to reduce their emissions at rates which according to SBTi would be
4 compatible with global pathways to well below 2°C or 1.5°C, with various methodologies being
5 proposed (Andersen et al. 2021; Faria and Labutong 2019). Readers may note, however, that the link
6 between emissions by individual actors and long-term temperature goals cannot be inferred without
7 additional assumptions (see Box 4.2). In the energy sector, some voluntary initiatives are also emerging
8 to stop methane emissions associated with oil and gas supply chains. The Oil and Gas Methane
9 Partnership (OGMP) is a voluntary initiative lead by the Climate and Clean Air Coalition, which has
10 recently published a comprehensive framework for methane detection, measurement and reporting
11 (UNEP 2020b).

12 Initiatives made up of cities and subnational regions have an especially large potential to reduce
13 emissions, due to their inclusion of many actors, across a range of different geographic regions, with
14 ambitious emissions reduction targets, and these actors' coverage of a large share of emissions
15 (Kuramochi et al. 2020). Hsu et al. (2019) find largest potential in that area. Several subnational regions
16 like California and Scotland have set zero emission targets (Höhne et al. 2019), supported by short- and
17 medium-term interim goals (Scottish Government 2020; State of California 2018). Sharing of effort
18 across global and sub-global scales has not been quantified, though one study suggests that non-state
19 actors have increasingly adopted more diverse framings, including vulnerability, human rights and
20 transformational framings of justice (Shawoo and McDermott 2020). Initiatives focused on forestry
21 have high emissions reduction potential due to the current high deforestation rates, and due to the
22 ambitious targets of many of these forestry initiatives, such as the New York Declaration on Forests'
23 goal to end deforestation by 2030 (Höhne et al. 2019; Lui et al. 2021), although the Initiative
24 acknowledges that insufficient progress has to-date been made towards this goal (NYDF Assessment
25 Partners 2020). On the other hand, uncertainties in global forest carbon emissions (and therefore
26 potential reductions) are high and despite a multitude of initiatives in the sector, actually measured
27 deforestation rates have not declined since the initiative was announced in 2014 (7.2, 7.3.1). Moreover,
28 not all initiatives are transparent about how they plan to reach their goals and may also rely on offsets.

29 Initiatives focused on non-CO₂ emissions, and particularly on methane, can achieve sizable reductions,
30 in the order of multiple GtCO₂-eq yr⁻¹ (see Table 4.4). The Global Cement and Concrete Association
31 (formerly the Cement Sustainability Initiative), has contributed to the development of consistent energy
32 and emissions reporting from member companies. The CSI also suggested possible approaches to
33 balance GHG mitigation and the issues of competitiveness and leakage (Cook and Ponsard 2011). The
34 member companies of the GCCA (CSI) have become better prepared for future legislation on managing
35 GHG emissions and developed management competence to respond to climate change compared to
36 non-member companies in the cement sector (Busch et al. 2008; Global Cement and Concrete
37 Association 2020). Accordingly, the cement industry has developed some roadmaps to reach net zero
38 GHG around 2050 (Sanjuán et al. 2020).

39 It is also important to note that individual NSA and ICI that commit to GHG mitigation activities are
40 often scarce in many crucial and 'hard-to-abate' sectors, such as iron and steel, cement and freight
41 transport (see Chapters 10 and 11). Subnational and non-state action efforts could help these sectors
42 meet an urgent need to accelerate the commercialisation and uptake of technical options to achieve low
43 zero emissions (Bataille 2020).

44

1 **4.2.4 Mid-century low-emission strategies at the national level**

2 An increasing amount of literature describes mitigation pathways for the mid-term (up to 2050). We
 3 assess literature reflecting on the UNFCCC process (4.2.4.1), other official plans and strategies (4.2.4.2)
 4 and academic literature on mid-century low-emission pathways at the national level (4.2.4.3). After the
 5 Paris Agreement and the IPCC SR1.5 Report, the number of academic papers analysing domestic
 6 emission pathways compatible with the 1.5°C limit has been increasing. Governments have developed
 7 an increasing number of mitigation strategies up to 2050. Several among these strategies aim at net zero
 8 CO₂ or net zero GHG, but it is not yet possible to draw global implications due to the limited size of
 9 sample (*limited evidence, limited agreement*).

10

11 **START BOX 4.2 HERE**

12

13 **Box 4.2 Direct links between an individual actor’s mitigation efforts in the near-term and global**
 14 **temperature goals in the long-term cannot be inferred; making direct links requires clear**
 15 **distinctions of spatial and temporal scales** (Robertson 2021; Rogelj et al. 2021) **and explicit**
 16 **treatment of ethical judgements made** (Holz et al. 2018; Klinsky et al. 2017a; Rajamani et al. 2021;
 17 Klinsky and Winkler 2018).

18

19 The literature frequently refers to *national* mitigation pathways up to 2030 or 2050 using long-term
 20 temperature limits in the Paris Agreement (i.e., “2°C” or “1.5°C scenario”). Without additional
 21 information, such denomination is incorrect. Working Group I reaffirmed “with high confidence the
 22 AR5 finding that there is a near-linear relationship between cumulative anthropogenic CO₂ emissions
 23 and the global warming they cause” (WGI SPM AR6). It is not the function of any single country’s
 24 mitigation efforts, nor any individual actor’s. Emission pathways of *individual* countries or sectors in
 25 the near- to mid-term can only be linked to a long-term temperature with additional assumptions
 26 specifying (i) the GHG emissions and removals of other countries up the mid-term; and (ii) the GHG
 27 emissions and removals of all countries beyond the near- and mid-term. For example, a national
 28 mitigation pathway can be labelled “2°C compatible” if it derives from a global mitigation pathway
 29 consistent with 2°C via an explicit effort sharing scheme across countries (see 4.2.2.6 and 4.5).

30

31 **END BOX 4.2 HERE**

32

33

34 **4.2.4.1 GHG Mitigation target under UNFCCC and Paris Agreement**

35 The Paris Agreement requests that Parties should strive to formulate and communicate long-term low
 36 GHG development strategies by 2020. (Note that by “long-term”, the UNFCCC means 2050, which is
 37 the end point of the “mid-term” horizon range in the present report.) As of August 25, 2021, 31 countries
 38 and the European Union had submitted low-emissions development strategies (LEDS) (Table 4.5).

39 By 2018, most long-term strategies targeted 80% emissions reduction in 2050 relative to a reference
 40 (1990, 2000 or 2005). After IPCC SR1.5 was published, the number of the countries aiming at net zero
 41 CO₂ or GHG emissions has been increasing.⁵

FOOTNOTE⁵ Specifying gases aids clarity, see Cross-Chapter Boxes 2 and 3. Some countries refer to net zero GHG emissions as ‘climate neutrality’ or ‘carbon neutrality’; the more precise terms are used where supported by the information assessed in this report.

1
2
3**Table 4.5 Countries having submitted long-term low GHG emission development strategy
(as of August 25, 2021)**

Country	Date submitted	GHG reduction target
USA	Nov. 16, 2016	80% reduction of GHG in 2050 compared to 2005 level
Mexico	Nov. 16, 2016	50% reduction of GHG in 2050 compared to 2000 level
Canada	Nov. 17, 2016	80% reduction of GHG in 2050 compared to 2005 level
Germany	Nov. 17, 2016	Greenhouse gas neutrality by 2050
	Rev. Apr. 26, 2017	(Old target: 80-95% reduction of GHG in 2050 compared to 1990 level)
	Rev. May 4, 2017	
France	Dec. 28, 2016	Achieving net zero GHG emissions by 2050
	Rev. Apr. 18, 2017	(Old target: 75% reduction of GHG in 2050 compared to 1990 level)
	Rev. Feb. 8, 2021	
Benin	Dec. 12, 2016	Resilient to climate change and low carbon intensity by 2025
Czech Republic	Jan. 15, 2018	80% reduction of GHG in 2050 compared to 1990 level
UK	April 17, 2018	80% reduction of GHG in 2050 compared to 1990 level
Ukraine	July 30, 2018	66-69% reduction of GHG in 2050 compared to 1990 level
Republic of the Marshall Islands	the Sept. 25, 2018	Net zero greenhouse gas emissions by 2050
Fiji	Feb. 25, 2019	Net zero carbon by 2050 as central goal, and net negative emissions in 2041 under a Very High Ambition scenario
Japan	June 26, 2019	80% reduction of GHG in 2050, and decarbonized society as early as possible in the 2 nd half of 21 st century
Portugal	Sept. 20, 2019	Carbon neutrality by 2050
Costa Rica	Dec. 12, 2019	Decarbonized economy with net zero emissions by 2050
European Union	March 6, 2020	Net zero GHG emissions by 2050
Slovakia	March 30, 2020	Climate neutrality by 2050, with decarbonisation targets implying reduction of at least 90% compared to 1990 (not taking into account removals)
Singapore	March 31, 2020	Halving emissions from its peak to 33 MtCO ₂ -e by 2050, with a view to achieving net zero emissions as soon as viable in the second half of the century.
South Africa	Sep. 23, 2020	Net zero carbon economy by 2050
Finland	Oct.5, 2020	Carbon neutrality by 2035; 87.5-90% reduction of GHG in 2050 to 1990 level (excluding land use sector)
Norway	Nov. 25, 2020	Being a low-emission society by 2050
Latvia	Dec. 9, 2020	Climate neutrality by 2050 (non-reducible GHG emissions are compensated by removals in the LULUCF sector)

Spain	Dec. 10, 2020	Climate neutrality by 2050
Belgium	Dec. 10, 2020	Carbon neutrality by 2050 (Walloon Region); Full climate neutrality (Flemish Region), and the European target of carbon neutrality by 2050 (Brussels-Capital Region)
Austria	Dec. 11, 2020	climate-neutral by no later than 2050
Netherlands	Dec. 11, 2020	Reduction of GHG emissions by 95% by 2050 compared to 1990 level.
Sweden	Dec. 11, 2020	Zero net emissions of GHG into the atmosphere latest by 2045
Denmark	Dec. 30, 2020	Climate neutrality by 2050
Republic of Korea	Dec. 30, 2020	Carbon neutrality by 2050
Switzerland	Jan. 28, 2021	2050 net zero GHG
Guatemala	July 6, 2021	59% reduction of projected emissions by 2050
Indonesia	July 22, 2021	540 MtCO ₂ -e by 2050, and with further exploring opportunity to rapidly progress towards net zero emission in 2060 or sooner
Slovenia	Aug. 23, 2021	Net zero emissions or climate neutrality by 2050

1

2 **4.2.4.2 Other national emission pathways to mid-century**

3 At the 2019 Climate Action Summit, 77 countries indicated their aim to reach net zero CO₂ emissions
4 by 2050, more the number of countries having submitted LEDS to the UNFCCC. Table 4.6 lists the
5 countries that have a national net zero by 2050 target in laws, strategies or other documents (The Energy
6 and Climate Intelligence Unit 2019). Bhutan and Suriname already have achieved net negative
7 emissions. France second “low-carbon national strategy” adopted in 2020 has an objective of GHG
8 neutrality by 2050. Net zero is also the basis of the recent revision of the official notional price of carbon
9 for public investment in France (Quinet et al. 2019). The Committee on Climate Change of the UK
10 analyses sectoral options and concludes that delivering net zero GHG by 2050 is technically feasible
11 but highly challenging (Committee on Climate Change 2019). For Germany, three steps to climate
12 neutrality by 2050 are introduced: First, a 65% reduction of emissions by 2030; second, a complete
13 switch to climate- neutral technologies, leading to a 95% cut in emissions, all relative to 1990 levels by
14 2050; and third balancing of residual emissions through carbon capture and storage (Görz et al. 2020).
15 In addition to the countries in Table 4.6, EU reported the net zero GHG emission pathways by 2050
16 under Green Deal (European Commission 2019). China and South Korea, have made announcements
17 of carbon neutrality by 2060 and net zero GHG emission by 2050, respectively (UN 2020a,b). In the
18 case of Japan, the new target to net zero GHG emission by 2050 was announced in 2020 (UN 2020c).
19 As of August 25, 2021, a total 121 countries participate in the ‘Climate Ambition Alliance: Net Zero
20 2050, together with businesses, cities and regions.

21

22 **Table 4.6 Countries with a national net zero CO₂ or GHG target by 2050 (as of August 25, 2021)**

Country	Target year	Target status	Source
Suriname		Achieved	Suriname INDC
Bhutan		Achieved	Royal Government of Bhutan National Environment Commission

Germany	2045	In Law	KSG
Sweden	2045	In Law	Climate Policy Framework
European Union	2050	In Law	European Climate Law
Japan	2050	In Law	Japan enshrines PM Suga's 2050 carbon neutrality promise into law
United Kingdom	2050	In Law	The Climate Change Act
France	2050	In Law	Energy and Climate Law
Canada	2050	In Law	Canadian Net Zero Emissions Accountability Act
Spain	2050	In Law	New Law
Denmark	2050	In Law	The Climate Act
New Zealand	2050	In Law	Zero Carbon Act
Hungary	2050	In Law	Climate Ambition Alliance: Net Zero 2050
Luxembourg	2050	In Law	Climate Ambition Alliance: Net Zero 2050

Note: In addition to the above list, the numbers of “In Policy Document” and “Target Under discussion” as Target status are 37 countries and 79 countries, respectively.

4.2.4.3 Mid-century low emission strategies at the national level in the academic literature

Since the 2000s, an increasing number of studies have quantified the emission pathways to mid-century by using national scale models. In the early stages, the national emission pathways were mainly assessed in the developed countries such as Germany, UK, France, the Netherlands, Japan, Canada, and USA. For example, the Enquete Commission in Germany identified robust and sustainable 80% emission reduction pathways (Deutscher Bundestag 2002). In Japan, 2050 Japan Low-Carbon Society scenario team (2008) assessed the 70% reduction scenarios in Japan, and summarized the necessary measures to “Dozen Actions towards Low-Carbon Societies.”

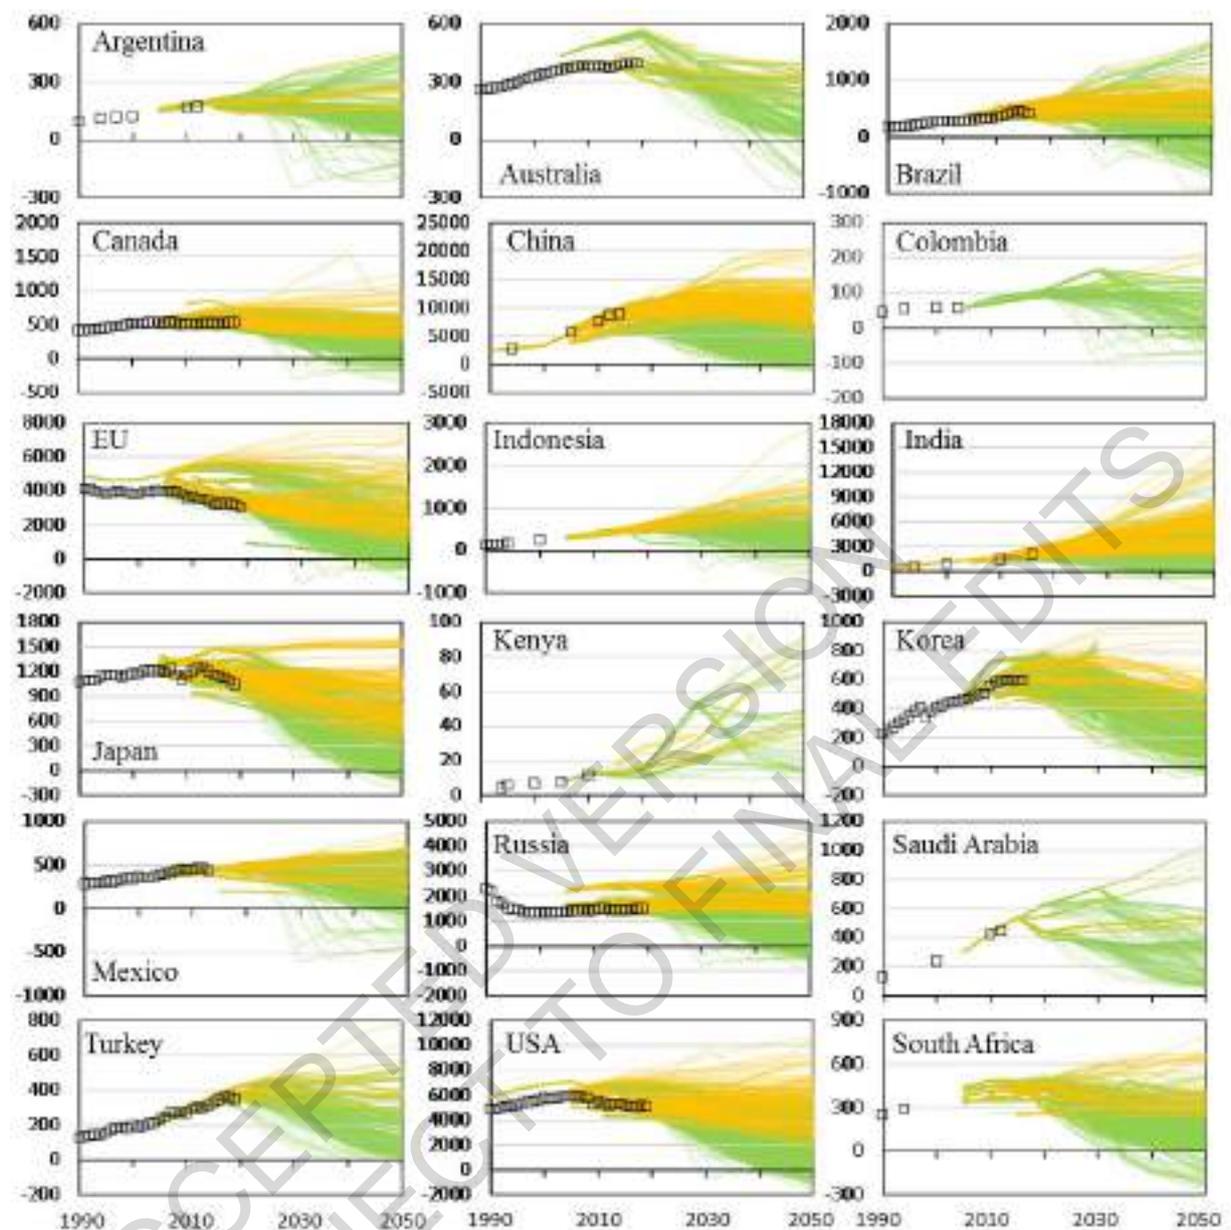

Among developing countries, China, India, South Africa assessed their national emission pathways. For example, detailed analysis was undertaken to analyse pathways to China’s goal for carbon neutrality (EFC 2020). In South Africa, a Scenario Building Team (2007) quantified the Long Term Mitigation Scenarios for South Africa.

Prior to COP21, most of the literature on mid-century mitigation pathways at the national level was dedicated to pathways compatible with a 2°C limit (see Box 4.2 for a discussion on the relationship between national mitigation pathways and global, long-term targets). After COP21 and the IPCC SR15, literature increasingly explored just transition to net zero emissions around 2050. This literature reflects on low-emissions development strategies (cognate with SDPS, see 4.3.1) and policies to get to net zero CO₂ or GHG emissions (Waisman et al. 2021)(Cross-Chapter Box 5).

Figure 4.2 provides a snapshot of this literature. For a selected set of countries, it shows the mid-century emission pathways at national scale that have been registered in the IIASA national mitigation scenario database built for the purpose of this Report (Annex III.3.3). Overall, the database contains scenarios for 50 countries. Total GHG emission are the most comprehensive information to assess the pathways on climate mitigation actions, but energy-related CO₂ emissions are the most widely populated data in

1 the scenarios. As a result, Figure 4.2 shows energy-related CO₂ emission trajectories. Scenarios for EU
2 countries show reduction trends even in the reference scenario, whereas developing countries and non-
3 European developed countries such as Japan and USA show emissions increase in the reference. In
4 most countries plotted on Figure 4.2, studies have found that reaching net zero energy related CO₂
5 emissions by 2050 is feasible, although the number of such pathways is limited.

5

The literature underlines the differences induced by the shift from “2°C scenarios” (typically assumed to imply mitigation in 2050 around 80% relative to 1990) to “1.5°C scenarios” (typically assumed to imply net zero CO₂ or GHG emissions in 2050) (Box 4.2). For Japan, Oshiro et al. (2018) shows the difference between the implications of a 2°C scenario (80% reduction of CO₂ in 2050) and a 1.5 °C scenario (net zero CO₂ emission in 2050), suggesting that for a net zero CO₂ emission scenario, BECCS is a key technology. Their sectoral analysis aims in 2050 at negative CO₂ emissions in the energy sector,

10

1 and near-zero emissions in the buildings and transport sectors, requiring energy efficiency improvement
 2 and electrification. To do so, drastic mitigation is introduced immediately, and, as a result, the
 3 mitigation target of Japan's current NDC is considered not sufficient to achieve a 1.5°C scenario. Jiang
 4 et al. (2018) also show the possibility of net negative emissions in the power sector in China by 2050,
 5 indicating that biomass energy with CCS must be adopted on a large scale by 2040. Samadi et al. (2018)
 6 indicate the widespread use of electricity-derived synthetic fuels in end-use sectors as well as
 7 behavioural change for the 1.5 degree scenario in Germany.

8 In addition to those analyses, Vishwanathan et al. (2018b), Chunark and Limmeechokchai (2018) and
 9 Pradhan et al. (2018b) build national scenarios in India, Thailand and Nepal, respectively, compatible
 10 with a global 1.5°C. Unlike the studies mentioned in the previous paragraph, they translate the 1.5°C
 11 goal by introducing in their model a carbon price trajectory estimated by global models as sufficient to
 12 achieve the 1.5°C target. Because of the high economic growth and increase of GHG emissions in the
 13 reference case, CO₂ emissions in 2050 do not reach zero. Finally, the literature also underlines that to
 14 achieve a 1.5°C target, mitigation measures relative to non-CO₂ emissions become important, especially
 15 in developing countries where the share of non-CO₂ emissions is relatively high. (La Rovere et al. 2018)
 16 treat mitigation actions in AFOLU sector.

17 Chapter 3 reported on multi-model analyses, comparison of results using different models, of global
 18 emissions in the long term. At the national scale, multi-model analyses are still limited, though such
 19 analyses are growing as shown in Table 4.7. By comparing the results among different models and
 20 different scenarios in a country, the uncertainties on the emission pathways including the mitigation
 21 measures to achieve a given emission target can be assessed.

22
 23 **Table 4.7 Examples of research projects on country-level mitigation pathways in the near- to medium-**
 24 **term under the multi-national analyses**

Project name	Features
DDPP (Deep Decarbonisation Pathways Project)	16 countries participated and estimated the deep decarbonisation pathways from the viewpoint of each country's perspective using their own models (Waisman et al. 2019).
COMMIT (Climate Policy assessment and Mitigation Modelling to Integrate national and global Transition pathways)	This research project assessed the country contributions to the target of the Paris Agreement (COMMIT 2019). The mitigation potential and socio-economic implications in Brazil, Chile, Colombia and Peru were assessed (La Rovere et al. 2018; Benavides et al. 2015; Zevallos et al. 2014; Delgado et al. 2014). The experiences of the
MAPS (Mitigation Action Plans and Scenarios)	MAPS programme suggests that co-production of knowledge by researchers and stakeholders strengthens the impact of research findings, and in depth studies of stakeholder engagement provide lessons (Boulle et al. 2015; Kane and Boulle 2018; Raubenheimer et al. 2015), which can assist building capacity for long-term planning in other contexts (Calfucoy et al. 2019).
CD-LINKS (Linking Climate and Development Policies – Leveraging International Networks and Knowledge Sharing)	The complex interplay between climate action and development at both the global scale and some national perspectives were explored. The climate policies for G20 countries up to 2015 and some levels of the carbon budget are assessed for short-term and long-term, respectively (Rogelj et al. 2017).

APEC Energy Demand and Supply Outlook	Total 21 APEC countries assessed 2 degree scenario which follows the carbon emissions reduction pathway included in the IEA Energy Technology Perspectives (IEA 2017) by using the common framework (APEREC 2019).
Low-Carbon Asia Research Project	The low carbon emission scenarios for several countries and cities in Asia were assessed by using the same framework (Matsuoka et al. 2013). The mitigation activities were summarised into 10 actions toward Low Carbon Asia to show a guideline to plan and implement the strategies for an LCS in Asia (Low-Carbon Asia Research Project 2012).
CLIMACAP–LAMP	This is an inter-model comparison exercise that focused on energy and climate change mitigation in Latin America (Clarke et al. 2016).
DDPP-LAC (Latin American Deep Decarbonisation Pathways project)	6 countries in Latin America analysed the activities in AFOLU (agriculture, forestry and land use) commonly (Bataille et al. 2020).
MILES (Modelling and Informing Low-Emission Strategies)	This is an international research project which covers 5 countries and 1 region in order to build capacity and knowledge on low-emissions development strategies both at a national and global level, by investigating the concrete implications of INDCs for the low-carbon transformation by and beyond 2030 (Spencer et al. 2015).

1

2 Another type of multi-model analysis is international, i.e., different countries join the same project and
 3 use their own national models to assess a pre-agreed joint mitigation scenario. By comparing the results
 4 of various national models, such projects help highlight specific features of each country. More robust
 5 mitigation measures can be proposed if different types of models participate. These activities can also
 6 contribute to capacity building in developing countries.

7

8 **4.2.5 What is to be done to accelerate mitigation?**

9 **4.2.5.1 Overview of accelerated mitigation pathways**

10 The literature reports an increasing number of accelerated mitigation pathways that are beyond NDCs
 11 in different regions and countries. There is increasing understanding of the technical content of such
 12 pathways, though the literature remains limited on some dimensions, such as demand-side options,
 13 systems analysis, or mitigation of AFOLU non-CO₂ GHGs. The present section describes insights from
 14 this literature.

15 Overall, the literature shows that pathways considered consistent with likely below 2°C or 1.5°C (see
 16 Box 4.2)—including inter alia 80% reduction of GHG emissions in 2050 relative to 1990 or 100%
 17 renewable electricity scenarios—are technically feasible (Esteban et al. 2018; Esteban and Portugal-
 18 Pereira 2014; Lund and Mathiesen 2009; Young and Brans 2017; Mathiesen et al. 2011; Hansen et al.
 19 2019; Child et al. 2019). They entail increased end-use energy efficiency, significant increases in low-
 20 carbon energy, electrification, other new and transformative technologies in demand sectors, adoption
 21 of carbon capture and sequestration (CCS) to reduce gross emissions, and contribution to net negative
 22 emissions through carbon dioxide removal (CDR) and carbon sinks. For these pathways to be realized,
 23 the literature assumes higher carbon prices, combined in policy packages with a range of other policy
 24 measures.

25 The most recent literature also reflects on accelerated mitigation pathways aiming at reaching net zero
 26 CO₂ emissions or net zero GHG emissions by 2050 (4.2.4, Table 4.6) (see glossary entries on net zero
 27 CO₂ emissions and net zero GHG emissions). Specific policies, measures and technologies are needed

1 to reach such targets. These include, broadly, decarbonising electricity supply, including through low
2 carbon energy, radically more efficient use of energy than today; electrification of end-uses (including
3 transport / electric vehicles); dramatically lower use of fossil fuels than today; converting other uses to
4 low- or zero-carbon fuels (e.g., hydrogen, bioenergy, ammonia) in hard-to-decarbonise sectors; and
5 setting ambitious targets to reduce methane and other short-lived climate forcers (SLCFs).

6 Accelerated mitigation pathways differ by countries, depending *inter alia* on sources of emissions,
7 mitigation opportunities and economic context. In China, India, Japan and other Southeast Asian
8 countries, more aggressive action related to climate change is also motivated by regional concerns over
9 health and air quality related to air pollutants and SLCFs (Ashina et al. 2012; Aggarwal 2017; Dhar et
10 al. 2018; Xunzhang et al. 2017; Khanna et al. 2019; China National Renewable Energy Centre 2019;
11 Energy Transitions Commission and Rocky Mountain Institute 2019; Oshiro et al. 2018; Jiang et al.
12 2018; Kuramochi et al. 2017). Studies of accelerated mitigation pathways in North America tend to
13 focus on power sector and imported fuel decarbonisation in the US , and on electrification and demand-
14 side reductions in Canada (Hammond et al. 2020; Vaillancourt et al. 2017; Jayadev et al. 2020; Hodson
15 et al. 2018; Victor et al. 2018; Bahn and Vaillancourt 2020). In Latin America, many pathways
16 emphasise supply-side mitigation measures, finding that replacing thermal power generation and
17 developing bioenergy (where resources are available) utilisation offers the greatest mitigation
18 opportunities (Nogueira de Oliveira et al. 2016; Lap et al. 2020; Herreras Martínez et al. 2015; Arango-
19 Aramburo et al. 2019; Delgado et al. 2020). The European Union-28's recently announced 2050 climate
20 neutrality goal is explored by pathways that emphasise complete substitution of fossil fuels with
21 electricity generated by low-carbon sources, particularly renewables; demand reductions through
22 efficiency and conservation, and novel fuels and end-use technologies (Capros et al. 2019; Zappa et al.
23 2019; Louis et al. 2020; Duscha et al. 2019; Prognos Öko-Institut Wuppertal-Institut 2020). The limited
24 literature so far on Africa's future pathways suggest those could be shaped by increasing energy access
25 and mitigating the air pollution and health effects of relying on traditional biomass use, as well as
26 cleaner expansion of power supply alongside end-use efficiency improvements (Hamilton and Kelly
27 2017; Oyewo et al. 2020, 2019; Wright et al. 2019; Ven et al. 2019; Forouli et al. 2020).

28 Though they differ across countries, accelerated mitigation pathways share common characteristics as
29 follows. First, energy efficiency, conservation, and reducing energy use in all energy demand sectors
30 (buildings, transport, and industry) are included in nearly all literature that addresses future demand
31 growth (Jiang et al. 2016; Saveyn et al. 2012; Hanaoka and Masui 2018; Thepkhun et al. 2013; Chilvers
32 et al. 2017; Chiodi et al. 2013; Schmid and Knopf 2012; Oshiro et al. 2017a; Shahiduzzaman and Layton
33 2017; Fragkos et al. 2017; Elizondo et al. 2017; Ouedraogo 2017; Lee et al. 2018; Schiffer 2015;
34 Deetman et al. 2013; Zhou et al. 2019; McNeil et al. 2016; Lefèvre et al. 2018; Sugiyama et al. 2019;
35 Kato and Kurosawa 2019; Jacobson et al. 2019, 2017; Dioha and Kumar 2020; Dioha et al. 2019; Nieves
36 et al. 2019; Jiang et al. 2013; Altieri et al. 2016; Oshiro et al. 2018; Ashina et al. 2012; Vaillancourt et
37 al. 2017; Khanna et al. 2019; Victor et al. 2018; Duscha et al. 2019; Hodson et al. 2018; Capros et al.
38 2019; Nogueira de Oliveira et al. 2016; Kuramochi et al. 2017)

39 Similarly, electrification of industrial processes (up to 50% for EU and China) and transport (e.g., 30-
40 60% for trucks in Canada), buildings, and district heating and cooling are commonplace (Ashina et al.
41 2012; Chiodi et al. 2013; Deetman et al. 2013; Fragkos et al. 2017; Massetti 2012; Mittal et al. 2018;
42 Oshiro et al. 2017b; Oshiro et al. 2018; Saveyn et al. 2012; Vaillancourt et al. 2017; Zhou et al. 2019;
43 Xunzhang et al. 2017; Hammond et al. 2020; Jiang et al. 2018; Capros et al. 2019).

44 Third, lower emissions sources of energy, such as nuclear, renewables, and some biofuels, are seen as
45 necessary in all pathways. However, the extent of deployment depends on resource availability. Some

1 countries have set targets of up to 100% renewable electricity, while others such as Brazil rely on
2 increasing biomass up to 40-45% of total or industry energy consumption by 2050.

3 Fourth, CCS and CDR are part of many of the national studies reviewed (Ashina et al. 2012; Chilvers
4 et al. 2017; Jiang et al. 2013; Kuramochi et al. 2018; Herreras Martínez et al. 2015; Massetti 2012;
5 Mittal et al. 2018; Oshiro et al. 2018; Xunzhang et al. 2017; Roberts et al. 2018b; Solano Rodriguez et
6 al. 2017; Thepkhun et al. 2013; Vishwanathan et al. 2018b; Kato and Kurosawa 2019; van der Zwaan
7 et al. 2016). CCS helps reduce gross emissions but does not remove CO₂ from the atmosphere, unless
8 combined with bioenergy (BECCS). CO₂ removal from sources with no identified mitigation measures
9 is considered necessary to help achieve economy-wide net negative emissions (Deetman et al. 2013;
10 Massetti 2012; Solano Rodriguez et al. 2017).

11 Each option is assessed in more detail in the following sections.

12 **4.2.5.2 Accelerated decarbonisation of electricity through renewable energy**

13 Power generation could decarbonise much faster with scaled up deployment of renewable energy and
14 storage. Both technologies are mature, available, and fast decreasing in costs, more than for many other
15 mitigation options. Models continuously underestimate the speed at which renewables and storage
16 expand. Higher penetration of renewable energy in the power sector is a common theme in scenarios.
17 Some studies provide cost optimal electricity mix under emission constraints, while others explicitly
18 explore a 100% renewables or 100% emission free electricity sector (Box 4.3).

19 Figure 4.3 shows an increasing share of renewable electricity in most countries historically, with further
20 increases projected in many decarbonisation pathways. Targets for very high shares of renewable
21 electricity generation—up to 100%—are shown for a number of countries, with the global share
22 projected to range from 60% to 70% for 1.5°C with no overshoot (C0) to below 2°C (C4) scenarios.
23 Countries and States that have set 100% renewables targets include Scotland for 2020 (Scottish
24 Government 2021), Austria (2030), Denmark (2035) and California (2045) (Figure 4.3).

25 While 100% renewable electricity generation by 2050 is found to be feasible, it is not without issues.
26 For example, (Jacobson et al. 2017, 2019) find it feasible for 143 countries with only a 9% average
27 increase in economic costs (considering all social costs) if annual electricity demand can be reduced by
28 57%. Others state that challenges exist with speed of expansion, ensuring sufficient supply at all times
29 or higher costs compared to other alternatives (Clack et al. 2017). In-depth discussion of net zero
30 electricity systems can be found in section 6.6.

32 **START BOX 4.3 HERE**

34 **Box 4.3. Examples of high-renewable accelerated mitigation pathways**

35 Many accelerated mitigation pathways include high shares of renewable energy, with national
36 variations. In Europe, some argue that the EU 2050 net zero GHG emissions goal can be met with 100%
37 renewable power generation, including use of renewable electricity to produce hydrogen, biofuels
38 (including imports), and synthetic hydrocarbons, but will require significant increases in transmission
39 capacity (Duscha et al. 2019; Zappa et al. 2019). Capros et al. (2019) explore a 1.5°C compatible
40 pathway that includes 85% renewable generation, with battery, pumped hydro, and chemical storage
41 for variable renewables. High-renewable scenarios also exist for individual Member States. In France,
42 for example, Krakowski et al. (2016) propose a 100% renewable power generation scenario that relies
43 primarily on wind (62%), solar PV (26%) and oceans (12%). To reach this aim, integration into the
44 European grid is of vital importance (Brown et al. 2018). While debated, incremental costs could be

1 limited regardless of specific assumptions of future costs of individual technologies (Shirizadeh et al.
2 2020). In Germany, similarly, 100% renewable electricity systems are found feasible by numerous
3 studies (Oei et al. 2020; Thomas Klaus et al. 2020; Wuppertal-Institut 2021; Hansen et al. 2019).

4 In South Africa, it is found that long-term mitigation goals could be achieved with accelerated adoption
5 of solar PV and wind generation, if the electricity sector decarbonises by phasing-out coal entirely by
6 2050, even if CCS is not feasible before 2025 (Altieri et al. 2015; Beck et al. 2013). Abundant solar PV
7 and wind potential, coupled with land availability suggest that more than 75% of power generation
8 could ultimately originate from solar PV and wind (Oyewo et al. 2019; Wright et al. 2019).

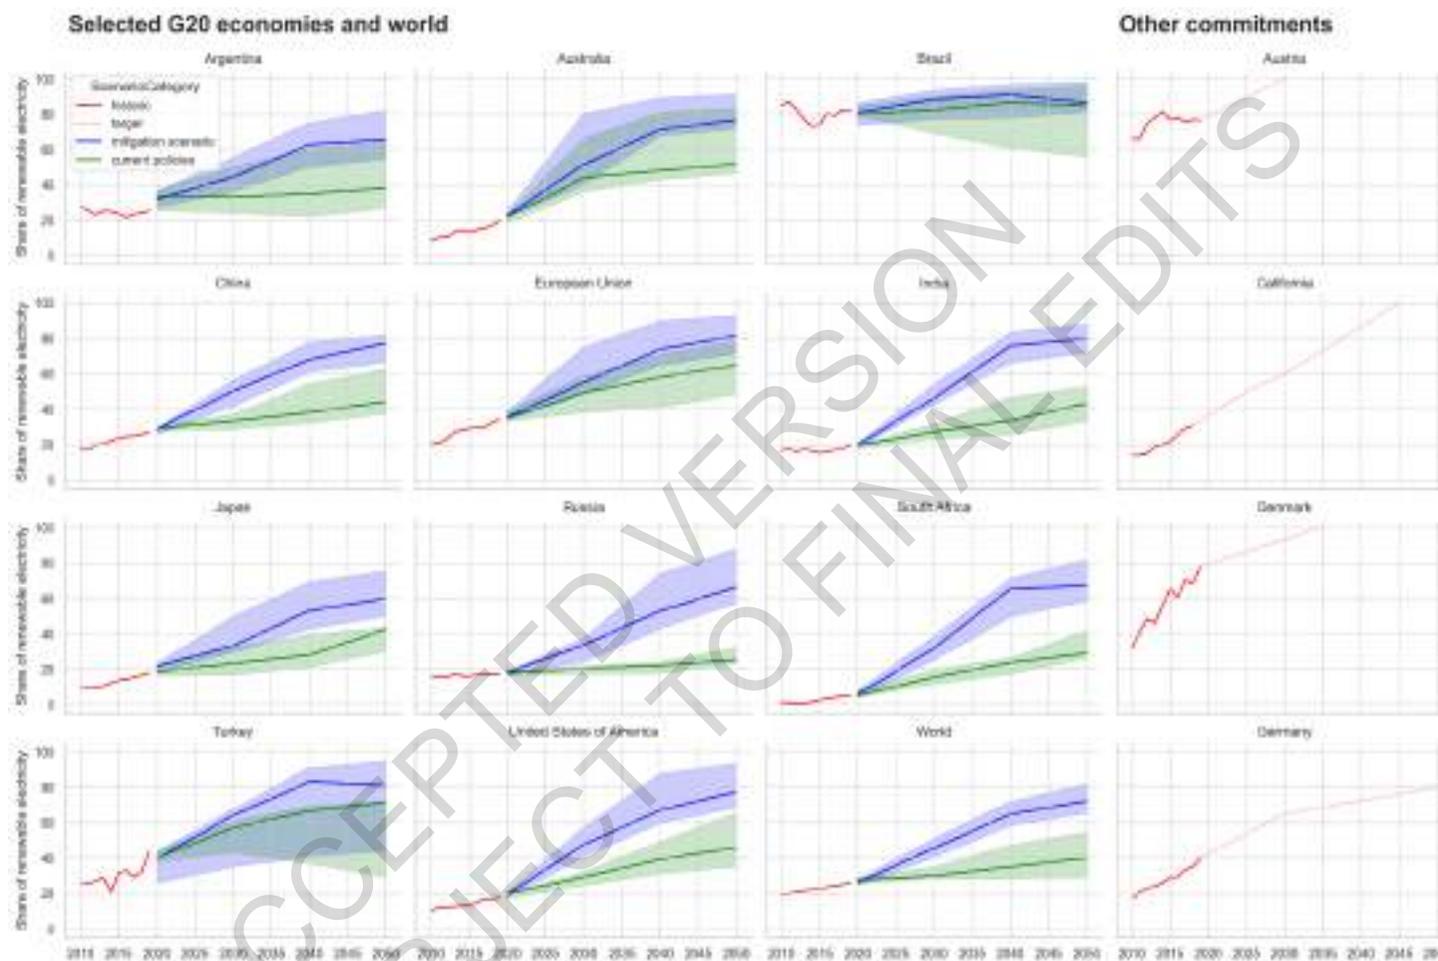

9 For the US, share of renewables in power generation in 2050 in accelerated mitigation scenarios vary
10 widely, 40% in (Hodson et al. 2018; Jayadev et al. 2020), more than half renewable and nuclear in
11 (Victor et al. 2018) to 100% in (Jacobson et al. 2017, 2019).

12 Under cost optimisation scenarios for Brazil, electricity generation, which is currently dominated by
13 hydropower, could reach 100% by adding biomass (Köberle et al. 2020). Other studies find that
14 renewable energy, including biomass, could account for more than 30% of total electricity generation
15 (Portugal-Pereira et al. 2016; Nogueira de Oliveira et al. 2016).

16 In Colombia, where hydropower resources are abundant and potential also exist for solar and wind, a
17 deep decarbonisation pathway would require 57% renewable power generation by 2050 (Arango-
18 Aramburo et al. 2019) while others find 80% would be possible (Delgado et al. 2020).

19 In Asia, Japan sees could have up to 50% variable renewable electricity supply to reduce CO₂ emissions
20 by 80% by 2050 in some of its deep mitigation scenarios (Shiraki et al. 2021; Ju et al. 2021; Silva
21 Herran and Fujimori 2021; Kato and Kurosawa 2019; Sugiyama et al. 2019). One view of China's 1.5°C
22 pathway includes 59% renewable power generation by 2050 (Jiang et al. 2018). One view of India's
23 1.5°C pathway also includes 52% renewable power generation, and would require storage needs for
24 35% of generation (Parikh et al. 2018).

25 **END BOX 4.3 HERE**

Figure 4.3 Historical and projected levels and targets for the share of renewables in electricity generation

Sources: IEA energy balances for past trends, IPCC AR6 scenario dataset including national model and regional versions in global models (10th to 90th percentile of 1.5 with no overshoot (C0) to below 2°C (C4) scenarios), national / regional sources

4.2.5.3 *Bioenergy plays significant role in resource abundant countries in Latin America and parts of Europe*

Bioenergy could account for up to 40% of Brazil's total final energy consumption, and a 60% share of fuel for light-duty vehicles by 2030 (Lefèvre et al. 2018), and is considered most cost-effective in transport and industrial applications (Lap et al. 2020). BECCS in the power sector is also considered cost-effective option for supply-side mitigation (Herrerias Martínez et al. 2015; Lucena et al. 2016; Borba et al. 2012).

Bioenergy also plays a prominent role in some EU countries' deep decarbonisation strategies. Domestic biomass alone can help Germany meet its 95% CO₂ reduction by 2050 goal, and biomass and CCS together are needed to reduce CO₂ by 80% by 2050 in the Netherlands (Mikova et al. 2019). Studies suggest that mitigation efforts in France include biofuels and significant increases in biomass use, including up to 45% of industry energy by 2050 for its net GHG neutrality goal (Doumax-Tagliavini and Sarasa 2018; Capros et al. 2019). Increased imports may be needed to meet significant increases in EU's bioenergy use, which could affect energy security and the sustainability of bioenergy production outside of the EU (Mandley et al. 2020; Daioglou et al. 2020).

While BECCS is needed in multiple accelerated mitigation pathways, large-scale land-based biological CDR may not prove as effective as expected, and its large-scale deployment may result in ecological and social impacts, suggesting it may not be a viable carbon removal strategy in the next 10-20 years (Vaughan and Gough 2016; Boysen et al. 2017; Dooley and Kartha 2018). The effectiveness of BECCS could depend on local contexts, choice of biomass, fate of initial aboveground biomass and fossil-fuel emissions offsets—carbon removed through BECCS could be offset by losses due to land-use change (Harper et al. 2018; Butnar et al. 2020; Calvin et al. 2021). Large-scale BECCS may push planetary boundaries for freshwater use, exacerbate land-system change, significantly alter biosphere integrity and biogeochemical flows (Heck et al. 2018; Stenzel et al. 2021; Fuhrman et al. 2020; Ai et al. 2021). See 7.4 and 12.5 for further discussions.

4.2.5.4 *CCS may be needed to mitigate emissions from the remaining fossil fuels that cannot be decarbonised, but the economic feasibility of deployment is not yet clear*

CCS is present in many accelerated mitigation scenarios in the literature. In Brazil, (Nogueira de Oliveira et al. 2016) consider BECCS and CCS in hydrogen generation more feasible than CCS in thermal power plants, with costs ranging from USD70-100/tCO₂. Overall, (van der Zwaan et al. 2016) estimate that 33-50% of total electricity generation in Latin America could be ultimately covered by CCS. In Japan, CCS and increased bioenergy adoption plus waste-to-energy and hydrogen-reforming from fossil fuel are all considered necessary in the power sector in existing studies, with potential up to 200 MtCO₂ per year (Ashina et al. 2012; Oshiro et al. 2017a; Kato and Kurosawa 2019; Sugiyama et al. 2021). In parts of the EU, after 2030, CCS could become profitable with rising CO₂ prices (Schiffer 2015). CDR is seen as necessary in some net GHG neutrality pathways (Capros et al. 2019) but evidence on cost-effectiveness is scarce and uncertain (European Commission 2013). For France and Sweden, (Millot et al. 2020) include CCS and BECCS to meet net zero GHG emissions by 2050. For Italy, (Masseti 2012) propose a zero-emission electricity scenario with a combination of renewable and coal, natural gas, and BECCS.

In China, an analysis concluded that CCS is necessary for remaining coal and natural gas generation out to 2050 (Jiang et al. 2018; Energy Transitions Commission and Rocky Mountain Institute 2019). Seven to 10 CCS projects with installed capacity of 15 GW by 2020 and total CCS investment of 105 billion RMB (2010 RMB) are projected to be needed by 2050 under a 2°C compatible pathway according to (Jiang et al. 2016, 2013; Lee et al. 2018). Under 1.5°C pathway, an analysis found China would need full CCS coverage of the remaining 12% of power generation from coal and gas power and

1 250 GW of BECCS (Jiang et al. 2018). Combined with expanded renewable and nuclear development,
2 total estimated investment in this study is 5% of China's total GDP in 2020, 1.3% in 2030, and 0.6% in
3 2050 (Jiang et al. 2016).

4 Views regarding feasibility of CCS can vary greatly for the same country. In the case of India's
5 electricity sector for instance, some studies indicate that CCS would be necessary (Vishwanathan et al.
6 2018a), while others do not—citing concerns around its feasibility due to limited potential sites and
7 issues related to socio-political acceptance—, and rather point to very ambitious increase in renewable
8 energy, which in turn could pose significant challenges in systematically integrating renewable energy
9 into the current energy systems (Viebahn et al. 2014; Mathur and Shekhar 2020). Some limitations of
10 CCS, including uncertain costs, lifecycle and net emissions, other biophysical resource needs, and social
11 acceptance are acknowledged in existing studies (Sekera and Lichtenberger 2020; Jacobson
12 2019; Viebahn et al. 2014; Mathur and Shekhar 2020)

13 While national mitigation portfolios aiming at net zero emissions or lower will need to include some
14 level of CDR, the choice of methods and the scale and timing of their deployment will depend on the
15 ambition for gross emission reductions, how sustainability and feasibility constraints are managed, and
16 how political preferences and social acceptability evolve (Cross-Chapter Box 8). Furthermore,
17 mitigation deterrence may create further uncertainty, as anticipated future CDR could dilute incentives
18 to reduce emissions now (Grant et al. 2021), and the political economy of net negative emissions has
19 implications for equity (Mohan et al. 2021).

20 **4.2.5.5 Nuclear power is considered strategic for some countries, while others plan to reach their** 21 **mitigation targets without additional nuclear power**

22 Nuclear power generation is developed in many countries, though larger-scale national nuclear
23 generation does not tend to associate with significantly lower carbon emissions (Sovacool et al. 2020).
24 Unlike other energy sources such as wind and PV solar, levelized costs of nuclear power has been rising
25 in the last decades (Portugal-Pereira et al. 2018; Gilbert et al. 2017; Grubler 2010). This is mainly due
26 to overrun of overnight construction costs related to delays in project approvals and construction, and
27 more stringent passive safety measures, which increases the complexity of systems. After the
28 Fukushima Dai-Ichi accident in Japan, nuclear programs in several countries have been phased out or
29 cancelled (Carrara 2020; Huenteler et al. 2012; Kharecha and Sato 2019; Hoffman and Durlak 2018).
30 Also the compatibility of conventional PWR and BWR reactors with large proportion of renewable
31 energy in the grid it is yet to be fully understood.

32 Accelerated mitigation scenarios offer contrasting views on the share of nuclear in power generation.
33 In the US, (Victor et al. 2018) build a scenario in which nuclear contributes 23% of CO₂ emission
34 reductions needed to reduce GHG emissions by 80% from 2005 levels by 2050. Deep power sector
35 decarbonisation pathways could require a two-folded increase in nuclear capacity according to (Jayadev
36 et al. 2020) for the U.S., and nearly a ten-fold increase for Canada, but may be difficult to implement
37 (Vaillancourt et al. 2017). For China to meet a 1.5°C pathway or achieve carbon neutrality by 2050,
38 nuclear may represent 14%-28% of power generation in 2050 according to (Jiang et al. 2018; China
39 National Renewable Energy Centre 2019; Energy Transitions Commission and Rocky Mountain
40 Institute 2019). For South Korea, (Hong et al. 2014; Hong and Brook 2018) find that increasing nuclear
41 power can help complement renewables in decarbonizing the grid. Similarly, India has put in place a 3-
42 stage nuclear programme which aims to enhance nuclear power capacity from the current level of 6
43 GW to 63 GW by 2032, if fuel supply is ensured (GoI 2015). Nuclear energy is also considered
44 necessary as part of accelerated mitigation pathways in Brazil, although it is not expected to increase
45 significantly by 2050 even under stringent low carbon scenarios (Lucena et al. 2016). France developed
46 its nuclear strategy in response to energy security concerns after the 1970s Oil Crisis, but has committed

1 to reducing nuclear's share of power generation to 50% by 2035 (Millot et al. 2020). Conversely, some
2 analysis find deep mitigation pathways, including net zero GHG emissions and 80-90% reduction from
3 2013 levels, feasible without additional nuclear power in EU-28 and Japan respectively, but assuming
4 a combination of bio- and novel fuels and CCS or land-use based carbon sinks (Kato and Kurosawa
5 2019; Duscha et al. 2019).

6 Radically more efficient use of energy than today, including electricity, is a complementary set of
7 measures, explored in the following.

8 **4.2.5.6 Efficient cooling, SLCFs and co-benefits**

9 In warmer climate regions undergoing economic transitions, improving the energy efficiency of cooling
10 and refrigeration equipment is often important for managing peak electricity demand and can have co-
11 benefits for climate mitigation as well as SLCF reduction, as expected in India, Africa, and Southeast
12 Asia in the future.

13 Air conditioner adoption is rising significantly in low- and middle-income countries as incomes rise
14 and average temperatures increase, including in Southeast Asian countries such as Thailand, Indonesia,
15 Vietnam, and the Philippines, as well as Brazil, Pakistan, Bangladesh, and Nigeria (Biardeau et al.
16 2020). Cooling appliances are expected to increase from 3.6 billion to 9.5 billion by 2050, though up to
17 14 billion could be required to provide adequate cooling for all (Birmingham Energy Institute 2018).
18 Current technology pathways are not sufficient to deliver universal access to cooling or meet the 2030
19 targets under the SDGs, but energy efficiency, including in equipment efficiency like air conditioners,
20 can reduce this demand and help limit additional emissions that would further exacerbate climate
21 change (UNEP and IEA 2020; Dreyfus et al. 2020; Biardeau et al. 2020). Some countries (India, South
22 Africa) have started to recognise the need for more efficient equipment in their mitigation strategies
23 (Paladugula et al. 2018; Altieri et al. 2016; Ouedraogo 2017).

24 One possible synergy between SLCF and climate change mitigation is the simultaneous improvement
25 in energy efficiency in refrigeration and air-conditioning equipment during the hydrofluorocarbon
26 (HFC) phase-down, as recognised in the Kigali Amendment to the Montreal Protocol. The Kigali
27 Amendment and related national and regional regulations are projected to reduce future radiative
28 forcing from HFCs by about half in 2050 compared to a scenario without any HFC controls, and to
29 reduce future global average warming in 2100 from a baseline of 0.3-0.5°C to less than 0.1°C, according
30 to a recent scientific assessment of a wide literature (World Meteorological Organization 2018). If
31 ratified by signatories, the rapid phase-down of HFCs under the Kigali Amendment is possible because
32 of extensive replacement of high-global warming potential (GWP) HFCs with commercially available
33 low-GWP alternatives in refrigeration and air-conditioning equipment. Each country's choices of
34 alternative refrigerants will likely be determined by energy efficiency, costs, and refrigerant toxicity
35 and flammability. National and regional regulations will be needed to drive technological innovation
36 and development (Polonara et al. 2017).

37 **4.2.5.7 Efficient buildings, cooler in summer, warmer in winter, towards net zero energy**

38 Most accelerated mitigation pathway scenarios include significant increase in building energy
39 efficiency. Countries in cold regions, in particular, often focus more on building sector GHG emissions
40 mitigation measures such as improving building envelopes and home appliances, and electrifying space
41 heating and water heating.

42 For example, scenarios for Japan project continued electrification of residential and commercial
43 buildings to 65% and 79% respectively by 2050 to reach 70-90% CO₂ reduction from 2013 levels (Kato
44 and Kurosawa 2019). Similarly, a mitigation pathway for China compatible with 1.5°C would require
45 58% to 70% electrification of buildings according to (Jiang et al. 2018; Energy Transitions Commission

1 and Rocky Mountain Institute 2019; China National Renewable Energy Centre 2019). For the EU-28
 2 to reach net carbon neutrality, complete substitution of fossil fuels with electricity (up to 65% share),
 3 district heating, and direct use of solar and ambient heat are projected to be needed for buildings, along
 4 with increased use of solar thermal and heat pumps for heating (Duscha et al. 2019). In the UK and
 5 Canada, improved insulation to reduce energy demand and efficient building appliances and heating
 6 systems are important building strategies needed to reduce emissions to zero by 2050 (Roberts et al.
 7 2018a; Vaillancourt et al. 2017; Chilvers et al. 2017). In Ireland, achieving 80%-95% emissions
 8 reduction below 1990 levels by 2050 also requires changes in building energy technology and
 9 efficiency, including improving building envelopes, fuel switching for residential buildings, and
 10 replacing service-sector coal use with gas and renewables according to (Chiodi et al. 2013). In South
 11 Africa, improving industry and building energy efficiency is also considered a key part of mitigation
 12 strategies (Ouedraogo 2017; Altieri et al. 2016).

13 In addition, an increasing number of countries have set up Net Zero Energy Building targets (Table 4.8)
 14 (Höhne et al. 2020). Twenty seven countries have developed roadmap documents for NZEBs, mostly
 15 in developed countries in Europe, North America, and Asia-Pacific, focusing on energy efficiency and
 16 improved insulation and design, renewable and smart technologies (Mata et al. 2020). The EU, Japan
 17 and the U.S. (the latter for public buildings only) have set targets for shifting new buildings to 100%
 18 near-zero energy buildings by 2030, with earlier targets for public buildings. Scotland has a similar
 19 target for 2050 (Höhne et al. 2020). Technologies identified as needed for achieving near-zero energy
 20 buildings vary by region, but include energy-efficient envelope components, natural ventilation, passive
 21 cooling and heating, high performance building systems, air heat recovery, smart and information and
 22 communication technologies, and changing future heating and cooling supply fuel mixes towards solar,
 23 geothermal, and biomass (Mata et al. 2020). Subnational regions in Spain, U.S., Germany, and Mexico
 24 have set local commitments to achieving net zero carbon new buildings by 2050, with California having
 25 the most ambitious aspirational target of zero net energy buildings for all new buildings by 2030 (Höhne
 26 et al. 2020). The EU is also targeting the retrofitting of 3% of existing public buildings to zero-energy,
 27 with emphasis on greater thermal insulation of building envelopes (Mata et al. 2020; Höhne et al. 2020).
 28 China's roadmaps have emphasised insulation of building envelope, heat recovery systems in
 29 combination with renewable energy, including solar, shallow geothermal, and air source heat pumps
 30 (Mata et al. 2020).

31

32 **Table 4.8 Targets by countries, regions, cities and businesses on decarbonising the building sector**

	Countries	Subnational Regions	Cities	Businesses
Shift to 100 per cent (near-) zero energy buildings for new buildings	3	6	>28	>44
Fully decarbonise the building sector	1	6	>28	>44
Phase out fossil fuels (for example, gas) for residential heating	1	-	>3	
Increase the rate of zero-energy renovations	1 (public buildings)			

33 Source: (Höhne et al. 2020) (supplementary information). See also <https://newclimate.org/ambitiousactions>

1 **4.2.5.8 Electrifying transport**

2 Electrification of transport in tandem with power sector decarbonisation is expected to be a key strategy
3 for deep CO₂ mitigation in many countries. Passenger transport and light duty freight can already be
4 electrified, but electrifying heavy-duty road transport and fuel switching in aviation and shipping are
5 much more difficult and have not been addressed in most of the recent research.

6 In Germany, widespread electrification of private vehicles is expected by 2030 (Schmid and Knopf
7 2012) while for the EU-28, 50% overall transport electrification (excluding feedstock) and 75%
8 electrification of road transport is needed to reach net carbon neutrality according to (Duscha et al.
9 2019). In addition, novel fuels such as hydrogen, synthetic hydrocarbons and sustainable biogenic fuels
10 are needed to decarbonise aviation and water transport to achieve net carbon neutrality (Duscha et al.
11 2019).

12 In India, electrification, hydrogen, and biofuels are key to decarbonising the transport sector (Dhar et
13 al. 2018; Mittal et al. 2018; Vishwanathan et al. 2018b; Mathur and Shekhar 2020). Under a 1.5°C
14 scenario, nearly half of the light-duty passenger vehicle stock needs to be electrified according to
15 (Parikh et al. 2018). In China, a 1.5°C-compatible pathway would require electrification of 2/5th of
16 transport (Jiang et al. 2018; China National Renewable Energy Centre 2019).

17 Similarly, in Canada, electrification of 59% of light-duty trucks and 23% of heavy-duty trucks are
18 needed as part of overall strategy to reduce CO₂ emissions by 80% by 2050. In addition, hydrogen is
19 expected to play a major role by accounting for nearly one-third of light-duty trucks, 68% of heavy-
20 duty trucks, and 33% of rail by 2050 according to Hammond et al. (2020).

21 **4.2.5.9 Urban form meets information technology**

22 Beyond technological measures, some densely populated countries including Germany, Japan, and
23 India are exploring using information technology/internet-of-things (IOT) to support mode-shifting and
24 reduce mobility demand through broader behaviour and lifestyle changes (Aggarwal 2017; Ashina et
25 al. 2012; Canzler and Wittowsky 2016; Dhar et al. 2018; Vishwanathan et al. 2018b). In Japan,
26 accelerated mitigation pathways consider the use of information technology and IOT to transform
27 human behaviour and transition to a sharing economy (Ashina et al. 2012; Oshiro et al. 2017a, 2018).
28 In Germany, one study points to including electromobility information and communication technologies
29 in the transport sector as key (Canzler and Wittowsky 2016) while another emphasise shifting from
30 road to rail transport, and reduced distances travelled as other possible transport strategies (Schmid and
31 Knopf 2012). India's transport sector strategies also include use of information technology and the
32 internet, a transition to a sharing economy, and increasing infrastructure investment (Dhar et al. 2018;
33 Vishwanathan et al. 2018b). Behaviour and lifestyle change along with stakeholder integration in
34 decision-making are considered key to implementing new transport policies (Aggarwal 2017; Dhar et
35 al. 2018).

36 **4.2.5.10 Industrial energy efficiency**

37 Industrial energy efficiency improvements are considered in nearly all countries but for countries where
38 industry is expected to continue to be a key sector, new and emerging technologies that require
39 significant R&D investment, such as hydrogen and CCS, make ambitious targets achievable.

40 In China, for example, non-conventional electrical and renewable technologies, including low-grade
41 renewable heat, biomass use for high-temperature heat in steel and cement sectors, and additional
42 electrification in glass, food and beverage, and paper and pulp industries, are part of scenarios that
43 achieve 60% reduction in national CO₂ emission by 2050 (Khanna et al. 2019; Zhou et al. 2019), in
44 addition to increased recycled steel for electric arc furnaces and direct electrolysis or hydrogen-based
45 direct reduction of iron and CCS utilisation in clinker and steel-making (China National Renewable

1 Energy Centre 2019; Jiang et al. 2018). Similarly, in India, (Vishwanathan and Garg 2020) point to the
2 need for renewable energy and CCS to decarbonize the industrial sector. In EU-28, net CO₂ neutrality
3 can only be reached with 92% reduction in industrial emissions relative to 1990, through electrification,
4 efficiency improvement and new technologies such as hydrogen-based direct reduction of steel, low
5 carbon cement, recycling (Duscha et al. 2019). Both China and EU see 50% of industry electrification
6 by 2050 as needed to meet 1.5°C and net carbon neutrality pathways (Jiang et al. 2018; Capros et al.
7 2019).

8 Aggressive adoption of technology solutions for power sector decarbonisation coupled with end-use
9 efficiency improvements and low-carbon electrification of buildings, industry and transport provides a
10 pathway for accelerated mitigation in many key countries, but will still be insufficient to meet zero
11 emission/1.5°C goals for all countries. Although not included in a majority of the studies related to
12 pathways and national modelling analysis, energy demand reduction through deeper efficiency and
13 other measures such as lifestyle changes and system solutions that go beyond components, as well as
14 the co-benefits of the reduction of short-lived pollutants, needs to be evaluated for inclusion in future
15 zero emission/1.5°C pathways.

16 **4.2.5.11 Lowering demand, downscaling economies**

17 Studies have identified socio-technological pathways to help achieve net zero CO₂ and GHG targets at
18 national scale, that in aggregate are crucial to keeping global temperature below agreed limits. However,
19 most of the literature focuses on supply-side options, including carbon dioxide removal mechanisms
20 (BECCS, afforestation, and others) that are not fully commercialised (Cross-Chapter Box 8). Costs to
21 research, deploy, and scale up these technologies are often high. Recent studies have addressed lowering
22 demand through energy conversion efficiency improvements, but few studies have considered demand
23 reduction through efficiency (Grubler et al. 2018) and the related supply implications and mitigation
24 measures.

25 Five main drivers of long-term energy demand reduction that can meet the 1.5°C target include quality
26 of life, urbanisation, novel energy services, diversification of end-user roles, and information innovation
27 (Grubler et al. 2018). A low-energy-demand scenario requires fundamental societal and institutional
28 transformation from current patterns of consumption, including: decentralised services and increased
29 granularity (small-scale, low-cost technologies to provide decentralised services), increased use value
30 from services (multi-use vs. single use), sharing economies, digitalisation, and rapid transformation
31 driven by end-user demand. This approach to transformation differs from the status quo and current
32 climate change policies in emphasising energy end-use and services first, with downstream effects
33 driving intermediate and upstream structural change.

34 Radical low carbon innovation involves systemic, cultural, and policy changes and acceptance of
35 uncertainty in the beginning stages. However, the current dominant analytical perspectives are grounded
36 in neoclassical economics and social psychology, and focus primarily on marginal changes rather than
37 radical transformations (Geels et al. 2018). Some literature is beginning to focus on mitigation through
38 behaviour and lifestyle changes, but specific policy measures for supporting such changes and their
39 contribution to emission reductions remain unclear (see also Section 4.4.2 and Chapter 5).

40 **4.2.5.12 Ambitious targets to reduce short-lived climate forcers, including methane**

41 Recent research shows that temperature increases are likely to exceed 1.5°C during the 2030s and 2°C
42 by mid-century unless both CO₂ and short-lived climate forcers (SLCFs) are reduced (Shindell et al.
43 2017; Rogelj et al. 2018a). Because of their short lifetimes (days to a decade and a half), SLCFs can
44 provide fast mitigation, potentially avoiding warming of up to 0.6 °C at 2050 and up to 1.2 °C at 2100
45 (Ramanathan and Xu 2010; Xu and Ramanathan 2017). In Asia especially, co-benefits of drastic CO₂
46 and air pollution mitigation measures reduce emissions of methane, black carbon, sulphur dioxide,

1 nitrogen oxide, and fine particulate matter by approximately 23%, 63%, 73%, 27%, and 65%
2 respectively in 2050 as compared to 2010 levels. Including the co-benefits of reduction of climate
3 forcing adds significantly to the benefits reducing air pollutants (Hanaoka and Masui 2018).

4 To achieve net zero GHG emissions implies consideration of targets for non-CO₂ gases. While methane
5 emissions have grown less rapidly than CO₂ and F-gases since 1990 (Chapter 2), the literature urges
6 action to bring methane back to a pathway more in line with the Paris goals (Nisbet et al. 2020).
7 Measures to reduce methane emissions from anthropogenic sources are considered intractable – where
8 they sustain livelihoods – but also becoming more feasible, as studies report the options for mitigation
9 in agriculture without undermining food security (Wollenberg et al. 2016; Frank et al. 2017; Nisbet et
10 al. 2020). The choice of emission metrics has implications for SLCF (Cain et al. 2019)(Cross-Chapter
11 Box 2). Ambitious reductions of methane are complementary to, rather than substitutes for, reductions
12 in CO₂ (Nisbet et al. 2020).

13 Rapid SLCF reductions, specifically of methane, black carbon, and tropospheric ozone have immediate
14 co-benefits including meeting sustainable development goals for reducing health burdens of household
15 air pollution and reversing health- and crop-damaging tropospheric ozone (Jacobson 2002, 2010). SLCF
16 mitigation measures can have regional impacts, including avoiding premature deaths in Asia and Africa
17 and warming in central and Northern Asia, southern Africa, and the Mediterranean (Shindell et al.
18 2012). Reducing outdoor air pollution could avoid 2.4 million premature deaths and 52 million tonnes
19 of crop losses for four major staples (Haines et al. 2017). Existing research emphasises climate and
20 agriculture benefits of methane mitigation measures with relatively small human health benefits
21 (Shindell et al. 2012). Research also predicts that black carbon mitigation could substantially benefit
22 global climate and human health, but there is more uncertainty about these outcomes than about some
23 other predictions (Shindell et al. 2012). Other benefits to SLCF reduction include reducing warming in
24 the critical near-term, which will slow amplifying feedbacks, reduce the risk of non-linear changes, and
25 reduce long-term cumulative climate impacts—like sea-level rise—and mitigation costs (Hu et al. 2017;
26 UNEP and WMO 2011; Rogelj et al. 2018a; Xu and Ramanathan 2017; Shindell et al. 2012).

27 ***4.2.5.13 System analysis solutions are only beginning to be recognised in current literature on*** 28 ***accelerated mitigation pathways, and rarely included in existing national policies or*** 29 ***strategies***

30 Most models and studies fail to address system impacts of widespread new technology deployment, for
31 example: 1) material and resources needed for hydrogen production or additional emissions and energy
32 required to transport hydrogen; or 2) materials, resources, grid integration, and generation capacity
33 expansion limits of a largely decarbonised power sector and electrified transport sector. These impacts
34 could limit regional and national scale-ups.

35 Systemic solutions are also not being sufficiently discussed, such as low-carbon materials; light-
36 weighting of buildings, transport, and industrial equipment; promoting circular economy, recyclability
37 and reusability, and addressing the food-energy-water nexus. These solutions reduce demand in
38 multiple sectors, improve overall supply chain efficiency, and require cross-sector policies. Using fewer
39 building materials could reduce the need for cement, steel, and other materials and thus the need for
40 production and freight transport. Concrete can also be produced from low carbon cement, or designed
41 to absorb CO₂ from the atmosphere. Few regions have developed comprehensive policies or strategies
42 for a circular economy, with the exception of the EU and China, and policies in the EU have only
43 emerged within the last decade. While China's circular economy policies emphasises industrial
44 production, water, pollution and scaling-up in response to rapid economic growth and industrialisation,
45 EU's strategy is focused more narrowly on waste and resources and overall resource efficiency to
46 increase economic competitiveness (McDowall et al. 2017).

1 Increased bioenergy consumption is considered in many 1.5°C and 2°C scenarios. System thinking is
2 needed to evaluate bioenergy's viability because increased demand could affect land and water
3 availability, food prices, and trade (Sharmina et al. 2016). To adequately address the energy-water-food
4 nexus, policies and models must consider interconnections, synergies, and trade-offs among and within
5 sectors, which is currently not the norm (see 12.4).

6 A systems approach is also needed to support technological innovation. This includes recognising
7 unintended consequences of political support mechanisms for technology adoption and restructuring
8 current incentives to realise multi-sector benefits. It also entails assimilating knowledge from multiple
9 sources as a basis for policy and decision-making (Hoolohan et al. 2019).

10 Current literature does not explicitly consider systematic, physical drivers of inertia, such as capital and
11 infrastructure needed to support accelerated mitigation (Pfeiffer et al. 2018). This makes it difficult to
12 understand what is needed to successfully shift from current limited mitigation actions to significant
13 transformations needed to rapidly achieve deep mitigation.

14 15 **4.2.6 Implications of accelerated mitigation for national development objectives**

16 **4.2.6.1 Introduction**

17 This section examines how accelerated mitigation may impact the realisation of development objectives
18 in the near- and mid-term. It focuses on three objectives discussed in the literature, sustaining economic
19 growth (4.2.6.2), providing employment (4.2.6.3), and alleviating poverty and ensuring equity (4.2.6.4).
20 It complements similar review performed at global level in section 3.6. For a comprehensive survey of
21 research on the impact of mitigation in other areas (including air quality, health, and biodiversity), see
22 Karlsson et al. (2020).

23 **4.2.6.2 Mitigation and economic growth in the near- and mid-term**

24 A significant part of the literature assesses the impacts of mitigation on GDP, consistent with
25 policymakers' interest in this variable. It must be noted upfront that computable equilibrium models,
26 on which our assessments are mostly based, capture the impact of mitigation on GDP and other core
27 economic variables while typically overlooking other effects that may matter (like improvements in air
28 quality). Second, even though GDP (or better, GDP per capita) is not an indicator of welfare (Fleurbaey
29 and Blanchet 2013), changes in GDP per capita across countries and over time are highly correlated
30 with changes in welfare indicators in the areas of poverty, health, and education (Gable et al. 2015).
31 The mechanisms linking mitigation to GDP outlined below would remain valid even with alternative
32 indicators of well-being (5.2.1). Third, another stream of literature criticises the pursuit of economic
33 growth as a goal, instead advocating a range of alternatives and suggesting modelling of post-growth
34 approaches to achieve rapid mitigation while improving social outcomes (Hickel et al. 2021). In the
35 language of the present chapter, these alternatives constitute alternative development pathways.

36 Most country-level mitigation modelling studies in which GDP is an endogenous variable report
37 negative impacts of mitigation on GDP in 2030 and 2050, relative to the reference (*robust evidence*,
38 *high agreement*), for example (Nong et al. 2017) for Australia, (Chen et al. 2013) for Brazil, (Mu et al.
39 2018a; Cui et al. 2019; Zhao et al. 2018; Li et al. 2017; Dong et al. 2018; Dai et al. 2016) for China,
40 (Álvarez-Espinosa et al. 2018) for Colombia, (Fragkos et al. 2017) for the EU, (Mittal et al. 2018) for
41 India, (Fujimori et al. 2019) for Japan, (Veysey et al. 2014) for Mexico, (Pereira et al. 2016) for
42 Portugal, (Alton et al. 2014; van Heerden et al. 2016) for South Africa, (Chunark et al. 2017) for
43 Thailand, (Acar and Yeldan 2016) for Turkey, (Roberts et al. 2018b) for the UK, (Chen and Hafstead
44 2019; Zhang et al. 2017) for the USA, (Nong 2018) for Vietnam) (Figure 4.4). The downward
45 relationship between mitigation effort and emissions is strong in studies up to 2030, much weaker for

1 studies looking farther ahead. In all reviewed studies, however, GDP continues to grow even with
2 mitigation. It may be noted that none of the studies assessed above integrates the benefits of mitigation
3 in terms of reduced impacts of climate change or lower adaptation costs. This is not surprising since
4 these studies are at national or regional scale and do not extend beyond 2050, whereas the benefits
5 depend on global emissions and primarily occur after 2050. Discussion on reduced impacts is provided
6 in section 3.6.2 and Cross-Working Group Box 1.

SUBJECT TO FINAL EDITS

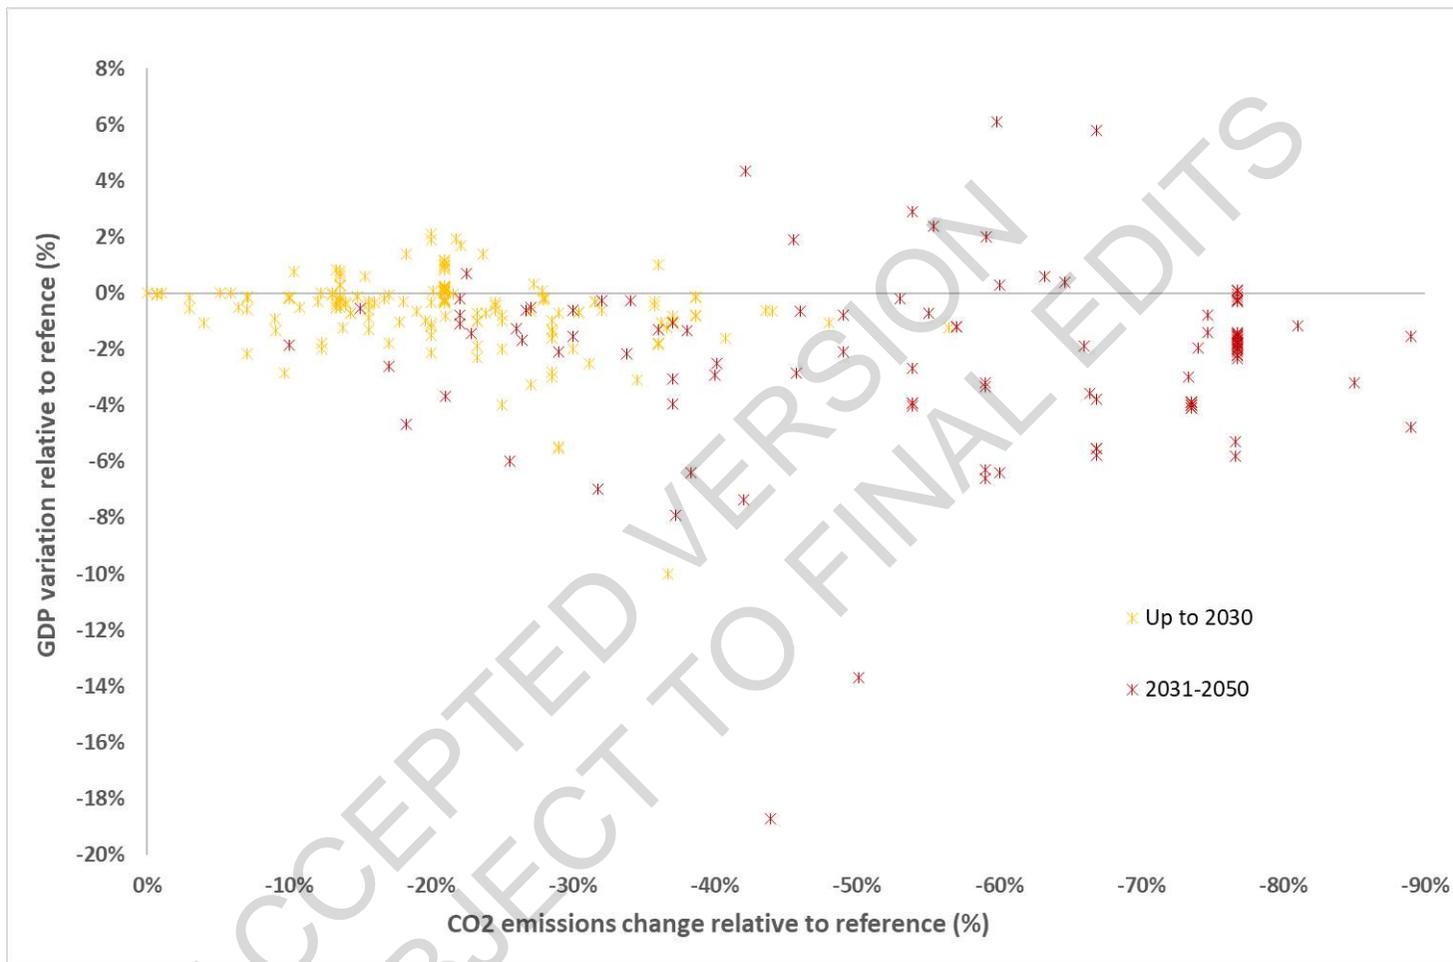

Figure 4.4 GDP against emissions in country-level modelling studies, in variations relative to reference

1
2

1 Two major mechanisms interplay to explain the impact of mitigation on GDP. First, the carbon
 2 constraint imposes reduced use of a production factor (fossil energy), thus reducing GDP. In the
 3 simulations, the mechanism at work is that firms and households reduce their use of GHG-intensive
 4 goods and services in response to higher prices due to reduced fossil energy use. Second, additional
 5 investment required for mitigation partially crowds out productive investment elsewhere (Fujimori et
 6 al. 2019), except in Keynesian models in which increased public investment actually boosts GDP
 7 (Pollitt et al. 2015; Bulavskaya and Reynès 2018; Landa Rivera et al. 2016). Magnitude and duration
 8 of GDP loss depend on the stringency of the carbon constraint, the degree of substitutability with less-
 9 GHG-intensive goods and services, assumptions about costs of low-carbon technologies and their
 10 evolution over time (e.g., (Duan et al. 2018; van Meijl et al. 2018; Cui et al. 2019) and decisions by
 11 trading partners, which influence competitiveness impacts for firms (Alton et al. 2014; Fragkos et al.
 12 2017) (*high evidence, high agreement*).

13 In the near-term, presence of long-lived emissions intensive capital stock, and rigidities in the labour
 14 market (Devarajan et al. 2011) and other areas may increase impacts of mitigation on GDP. In the mid-
 15 term, on the other hand, physical and human capital, technology, institutions, skills or location of
 16 households and activities are more flexible. The development of renewable energy may help create
 17 more employment and demands for new skills, particularly in the high-skill labour market (Hartley et
 18 al. 2019). In addition, cumulative mechanisms such as induced technical change or learning by doing
 19 on low-emissions technologies and process may reduce the impacts of mitigation on GDP.

20

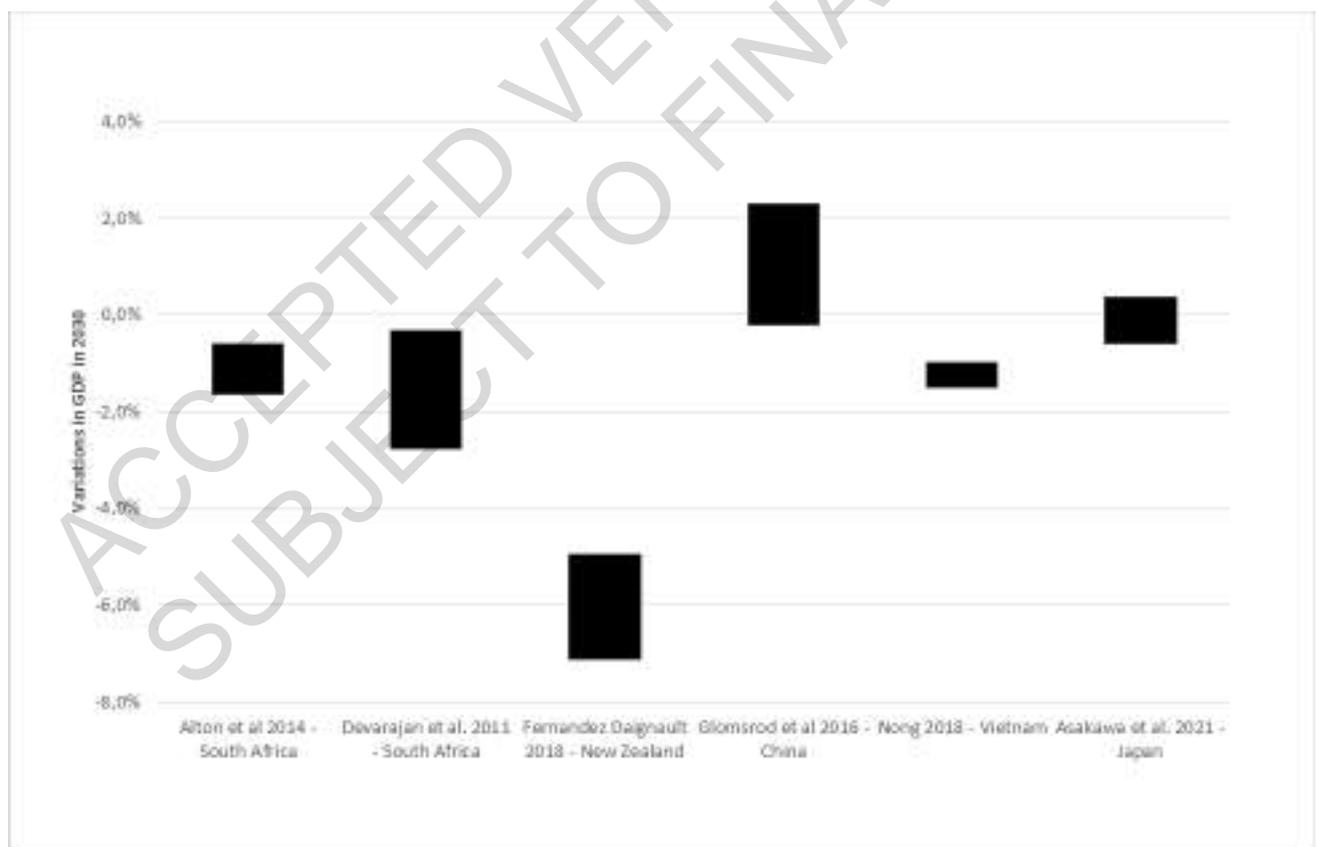

21 **Table 4.9 Examples of country-level modelling studies finding positive short-term outcome of mitigation**
 22 **on GDP relative to baseline**

Reference	Country/region	Explanation for positive outcome of mitigation on GDP
(Antimiani et al. 2016)	European Union	GDP increases relative to reference only in the scenario with global cooperation on mitigation
(Willenbockel et al. 2017)	Kenya	The mitigation scenario introduces cheaper (geothermal) power generation units than in BAU (in which thermal increases). Electricity prices actually decrease.
(Siagian et al. 2017)	Indonesia	Coal sector with low productivity is forced into BAU. Mitigation redirects investment towards sectors with higher productivity.
(Blazquez et al. 2017)	Saudi Arabia	Renewable energy penetration assumed to free oil that would have been sold at publicly subsidised price on the domestic market to be sold internationally at market price
(Wei et al. 2019)	China	Analyse impacts of feed-in tariffs to renewables, find positive short-run impacts on GDP; public spending boost activity in the RE sector. New capital being built at faster rate than in reference increases activity more than activity decreases due to lower public spending elsewhere.
(Gupta et al. 2019)	India	Savings adjust to investment and fixed unemployment is considered target of public policy, thereby limiting impact of mitigation on GDP relative to other economic variables (consumption, terms of trade).
(Huang et al. 2019)	China	Power generation plan in the baseline is assumed not cost minimising

1 Country-level studies find that the negative impacts of mitigation on GDP can be reduced if pre-existing
 2 economic or institutional obstacles are removed in complement to the imposition of the carbon
 3 constraint (*robust evidence, high agreement*). For example, if the carbon constraint takes the form of a
 4 carbon tax or of permits that are auctioned, the way the proceeds from the tax (or the revenues from the
 5 sales of permits) are used is critical for the overall macroeconomic impacts (Chen et al. 2013). (For a
 6 detailed discussion of different carbon pricing instruments, including the auctioning of permits, see
 7 Section 13.6.3).

8 Figure 4.5 shows that depending on the choice of how to implement a carbon constraint, the same level
 9 of carbon constraint can yield very different outcomes for GDP. The potential for mitigating GDP
 10 implications of mitigation through fiscal reform is discussed in 4.4.1.8.

11 More generally, mitigation costs can be reduced by proper policy design if the economy initially is not
 12 on the efficiency frontier (Grubb 2014), defined as the set of configurations within which the quality of
 13 the environment and economic activity cannot be simultaneously improved given current technologies
 14 – such improvements in policy design may include reductions in distortionary taxes. Most of the studies
 15 which find that GDP increases with mitigation in the near-term precisely assume that the economy is
 16 initially not on the frontier. Making the economy more efficient—i.e., lifting the constraints that
 17 maintain the economy in an interior position—creates opportunities to simultaneously improve
 18 economic activity and reduce emissions. Table 4.9 describes the underlying assumptions in a selection
 19 of studies.

21
 22 **Figure 4.5 Illustrative ranges of variations in GDP relative to reference in 2030 associated with**
 23 **introduction of carbon constraint, depending on modality of policy implementation**

1 Based on (Alton et al. 2014; Devarajan et al. 2011; Fernandez and Daigneault 2018; Glomsrød et al. 2016; Nong
2 2018; Asakawa et al. 2021). Stringency of carbon constraint is not comparable across the studies.

3 Finally, *marginal* costs of mitigation are not always reported in studies of national mitigation pathways.
4 Comparing numbers across countries is not straightforward due to exchange rate fluctuations, differing
5 assumptions by modellers in individual country studies, etc. The database of national mitigation
6 pathways assembled for this Report—which covers only a fraction of available national mitigation
7 studies in the literature—shows that marginal costs of mitigation are positive, with a median value of
8 101 USD₂₀₁₀/tCO₂ in 2030, 244 in 2040 and 733 in 2050 for median mitigation efforts of 21%, 46%
9 and 76% relative to business-as-usual respectively. Marginal costs increase over time along accelerated
10 mitigation pathways, as constraints become tighter, with a non-linearity as mitigation reaches 80% of
11 reference emissions or more. Dispersion across and within countries is high, even in the near-term but
12 increases notably in the mid-term (*medium evidence, medium agreement*).

13 **4.2.6.3 Mitigation and employment in the short- and medium-term**

14 Numerous studies have analysed the potential impact of carbon pricing on labour markets. Chateau et
15 al. (2018) and OECD (2017a) find that the implementation of green policies globally (defined broadly
16 as policies that internalise environmental externalities through taxes and other tools, shifting
17 profitability from polluting to green sectors) need not harm total employment, and that the broad skill
18 composition (low-, high- and medium-skilled jobs) of emerging and contracting sectors is very similar,
19 with the largest shares of job creation and destruction at the lowest skill level. To smoothen the labour
20 market transition, they conclude that it may be important to reduce labour taxes, to compensate
21 vulnerable households, and to provide education and training programs, the latter making it easier for
22 labour to move to new jobs. Consistent with this, other studies that simulate the impact of scenarios
23 with more or less ambitious mitigation policies (including 100% reliance on renewable energy by 2050)
24 find relatively small (positive or negative) impacts on aggregate global employment that are more
25 positive if labour taxes are reduced but encompass substantial losses for sectors and regions that today
26 are heavily dependent on fossil fuels (Arndt et al. 2013; Huang et al. 2019; Vandyck et al. 2016;
27 Jacobson et al. 2019). Among worker categories, low-skilled workers tend to suffer wage losses as they
28 are more likely to have to reallocate, something that can come at a cost in the form of a wage cut
29 (assuming that workers who relocate are initially less productive than those who already work in the
30 sector). The results for alternative carbon revenue recycling schemes point to trade-offs: a reduction in
31 labour taxes often leads to the most positive employment outcomes while lump-sum (uniform per-
32 capita) transfers to households irrespective of income yield a more egalitarian outcome.

33 The results from country-level studies using CGE models tend to be similar to those at global level.
34 Aggregate employment impacts are small and may be positive especially if labour taxes are cut, see
35 e.g., (Telaye et al. 2019) for Ethiopia, (Kolsuz and Yeldan 2017) for Turkey, (Fragkos et al. 2017) for
36 the EU, (Mu et al. 2018b) for China. On the other hand, sectoral reallocations away from fossil-
37 dependent sectors may be substantial, see e.g., (Alton et al. 2014) for South Africa or (Huang et al.
38 2019) for China. Targeting of investment to labour-intensive green sectors may generate the strongest
39 employment gains, see, e.g., (Perrier and Quirion 2018) for France, (van Meijl et al. 2018) for the
40 Netherlands, (Patrizio et al. 2018) for the USA. Changes in skill requirements between emerging and
41 declining sectors appear to be quite similar, involving smaller transitions than during the IT revolution
42 (Bowen et al. 2018).

43 In sum, the literature suggests that the employment impact of mitigation policies tends to be limited on
44 aggregate, but can be significant at the sectoral level (*medium evidence, medium agreement*) and that
45 cutting labour taxes may limit adverse effects on employment (*limited evidence, medium agreement*).
46 Labour market impacts, including job losses in certain sectors, can be mitigated by equipping workers

1 for job changes via education and training, and by reducing labour taxes to boost overall labour demand
2 (Stiglitz et al. 2017) (4.5).

3 Like most of the literature on climate change, the above studies do not address gender aspects. These
4 may be significant since the employment shares for men and women vary across sectors and countries.

5 **4.2.6.4 Mitigation and equity in the near- and mid-term**

6 Climate mitigation may exacerbate socio-economic pressures on poorer households (Jakob et al. 2014).
7 First, the price increase in energy-intensive goods and services—including food (Hasegawa et al.
8 2018)—associated with mitigation may affect poorer households disproportionately (Bento 2013), and
9 increase the number of energy-poor (Berry 2019). Second, the mitigation may disproportionately affect
10 low-skilled workers (see previous section). Distributional issues have been identified not only with
11 explicit price measures (carbon tax, emission permits system, subsidy removal), but also with subsidies
12 for renewables (Borenstein and Davis 2016), and efficiency and emissions standards (Davis and Knittel
13 2019; Bruegge et al. 2019; Levinson 2019; Fullerton and Muehlegger 2019).

14 Distributional implications, however, are context specific, depending on consumption patterns (initially
15 and ease of adjusting them in response to price changes) and asset ownership (see for example analysis
16 of energy prices in Indonesia by Renner et al. (2019)). In an analysis of the distributional impact of
17 carbon pricing based on household expenditure data for 87 low- and middle-income countries, Dorband
18 et al. (2019) find that, in countries with a per-capita income of up to USD15,000 per capita (PPP
19 adjusted), carbon pricing has a progressive impact on income distribution and that there may be an
20 inversely U-shaped relationship between energy expenditure shares and per-capita income, rendering
21 carbon pricing regressive in high-income countries, i.e., in countries where the capacity to pursue
22 compensatory policies tends to be relatively strong.

23 The literature finds that the detailed design of mitigation policies is critical for their distributional
24 impacts (*robust evidence, high agreement*). For example, Vogt-Schilb et al. (2019) suggest to turn to
25 cash transfer programs, established as some of the most efficient tools for poverty reduction in
26 developing countries. In an analysis of Latin America and the Caribbean, they find that allocation of 30
27 percent of carbon revenues would suffice to compensate poor and vulnerable households on average,
28 leaving the rest for other uses. This policy tool is not only available in countries with relatively high
29 per-capita incomes: in Sub-Saharan Africa, where per-capita incomes are relatively low, cash transfer
30 programs have been implemented in almost all countries ((Beegle et al. 2018), p. 57), and are found
31 central to the success of energy subsidy reforms (Rentschler and Bazilian 2017). In the same vein,
32 Böhringer et al. (2021) finds that recycling of revenues from emissions pricing in equal amounts to
33 every household appeals as an attractive strategy to mitigate regressive effects and thereby make
34 stringent climate policy more acceptable on societal fairness grounds. However, distributional gains
35 from such recycling may come at the opportunity cost of not reaping efficiency gains from reductions
36 in the taxes that are most distortionary (Goulder et al. 2019).

37 Distributional concerns related to climate mitigation are also prevalent in developed countries, as
38 demonstrated, for instance, by France's recent yellow-vest movement, which was ignited by an increase
39 in carbon taxes. It exemplifies the fact that, when analysing the distributional effects of carbon pricing,
40 it is not sufficient to consider vertical redistribution (i.e., redistribution between households at different
41 incomes levels but also horizontal redistribution (i.e., redistribution between households at similar
42 incomes which is due to differences in terms of spending shares and elasticities for fuel consumption).
43 Compared to vertical redistribution, it is more difficult to devise policies that effectively address
44 horizontal redistribution (Douenne 2020; Cronin et al. 2019; Pizer and Sexton 2019). However, it has
45 been shown ex post that transfer schemes considering income levels and location could have protected
46 or even improved the purchasing power of the bottom half of the population (Bureau et al. 2019).

1 Investments in public transportation may reduce horizontal redistribution if it makes it easier for
 2 households to reduce fossil fuel consumption when prices increase (cf. Section 4.4.1.5 and 4.4.1.9).
 3 Similarly, in relation to energy use in housing, policies that encourage investments that raise energy
 4 efficiency for low-income households may complement or be an alternative to taxes and subsidies as a
 5 means of simultaneously mitigating and reducing fuel poverty (Charlier et al. 2019). From a different
 6 angle, public acceptance of the French increase in the carbon tax could also have been enhanced via a
 7 public information campaign could have raised public acceptance of the carbon tax increase (Douenne
 8 and Fabre 2020). (See section 4.4.1.8 for a discussion of this and other factors that influence public
 9 support for carbon taxation).

11 **4.2.7 Obstacles to accelerated mitigation and how overcoming them amounts to shifts** 12 **in development pathways**

13 As outlined in Sections 4.2.3, 4.2.4, 4.2.5 and 4.2.6 there is improved understanding since AR5 of what
 14 accelerated mitigation would entail in the coming decades. A major finding is that accelerated
 15 mitigation pathways in the near- to mid-term appear technically and economically feasible in most
 16 contexts. Chapter 4, however, cannot stop here. Section 4.2.2 has documented an important policy gap
 17 for current climate pledges, and Cross-Chapter Box 4 shows an even larger ambition gap between
 18 current pledges and what would be needed in the near- term to be on pathways consistent with below
 19 2°C, let alone 1.5°C. In other words, while the implementation of mitigation policies to achieve updated
 20 NDC almost doubles the mitigation efforts, and notwithstanding the widespread availability of the
 21 necessary technologies, this doubling of effort merely narrows the gap to pathways consistent with 2°C
 22 by at most 20%.

23 Obstacles to the implementation of accelerated mitigation pathways can be grouped in four main
 24 categories (Table 4.10). The first set of arguments can be understood through the lens of cost-benefit
 25 analysis of decision-makers, as they revolve around the following question: Are costs too high relative
 26 to benefits? More precisely, are the opportunity costs—in economics terms, what is being forfeited by
 27 allocating scarce resources to mitigation—justified by the benefits for the decision-maker (whether
 28 individual, firm, or nation)? This first set of obstacles is particularly relevant because accelerated
 29 mitigation pathways imply significant effort in the short-run, while benefits in terms of limited warming
 30 accrue later and almost wholly to other actors. However, as discussed in 3.6 and 4.2.6, mitigation costs
 31 for a given mitigation target are not carved in stone. They strongly depend on numerous factors,
 32 including the way mitigation policies have been designed, selected, and implemented, the processes
 33 through which markets have been shaped by market actors and institutions, and nature of socially- and
 34 culturally-determined influences on consumer preferences. Hence, mitigation choices that might be
 35 expressed straightforwardly as techno-economic decisions are, at a deeper level, strongly conditioned
 36 by underlying structures of society.

38 **Table 4.10 Objections to accelerated mitigation and where they are assessed in the WG3 report**

Category	Main dimensions	Location in WGIII report where objection is assessed and solutions are discussed
Costs of mitigation	Marginal, sectoral or macroeconomic costs of mitigation too high; Scarce resources could/should be used for other development priorities; Mitigation	3.6, 4.2.6, 12.2, Chapter 15, Chapter 17

	benefits are not worth the costs (or even non-existent); Lack of financing	
Distributional implications	Risk of job losses; Diminished competitiveness; Inappropriate impact on poor/vulnerable people; negative impact on vested interests	4.5, Chapter 5, Chapter 13, Chapter 14
Lack of technology	Lack of suitable technologies; Lack of technology transfer; unfavourable socio-political environment	4.2.5, Chapter 16
Unsuitable “structures”	Inertia of installed capital stock; Inertia of socio- technical systems; Inertia to behaviour change; Unsuitable institutions	3.5, Chapter 5, Chapter 13

1

2 A second set of likely obstacles in the short-term to accelerated mitigation revolves around undesirable
3 distributional consequences, within and across countries. As discussed in 4.2.6.3, the distributional
4 implications of climate policies depend strongly on their design, the way they are implemented, and on
5 the context into which they are inserted. Distributional implications of climate policies have both ethics
6 and equity dimensions, to determine what is desirable/acceptable by a given society in a given context,
7 notably the relative power of different winners and losers to have their interests taken into account, or
8 not, in the relevant decision-making processes. Like costs, distributional implications of accelerated
9 mitigation are rooted in the underlying socio-political-institutional structures of a society.

10 A third set of obstacles are about technology availability and adoption. Lack of access even to existing
11 cost-effective mitigation technologies remains an important issue, particularly for many developing
12 countries, and even in the short-term. Though it relates most directly to techno-economic costs,
13 technology availability raises broader issues related to the sociotechnical systems within which
14 innovation and adoption are embedded, and issues of technology availability are inherently issues of
15 systemic failure (16.3). The underlying legal, economic and social structures of the economy are central
16 to the different stages of socio-transition processes (Cross-Chapter Box 12).

17 The last set of obstacles revolves around the unsuitability of existing structures to accelerated
18 mitigation. We include here all forms of established structures, material (e.g., physical capital) or not
19 (institutions, social norms, patterns of individual behaviour), that are potentially long-lived and limit
20 the implementation of accelerated mitigation pathways. Typically, such structures exist for reasons
21 other than climate change and climate mitigation, including the distribution of power among various
22 actors. Modifying them in the name of accelerated climate mitigation thus requires to deal with other
23 non-climate issues as well. For example, resolving the landlord-tenant dilemma, an institutional barrier
24 to the deployment of energy efficiency in building, opens fundamental questions on private property in
25 buildings.

1
2 **Figure 4.6 Obstacles to mitigation (top panel) and measures to remove these obstacles and enable shift in**
3 **development pathways (lower panel)**
4

5 A common thread in the discussion above is that the obstacles to accelerated mitigation are to a large
6 degree rooted in the underlying structural features of societies. As a result, transforming those
7 underlying structures can help to remove those obstacles, and thus facilitate the acceleration of
8 mitigation. This remark is all the more important that accelerated mitigation pathways, while very
9 different across countries, all share three characteristics: speed of implementation, breadth of action
10 across all sectors of the economy, and depth of emission reduction achieving more ambitious targets.
11 Transforming those underlying structures amounts to shifting a society's development pathway (Figure
12 4.6). In the following Sections 3 and 4, we argue that it is thus necessary to recast accelerated mitigation
13 in the broader context of shifting development pathways, and that doing so opens up additional
14 opportunities to (i) overcome the obstacles outlined above, and also (ii) combine climate mitigation
15 with other development objectives.
16
17

1 4.3 Shifting Development pathways

2 4.3.1 Framing of development pathways

3 4.3.1.1 What are development pathways?

4 The term development pathway is defined in various ways in the literature, and these definitions
 5 invariably refer to the evolution over time of a society's defining features. A society's development
 6 pathway can be described, analysed, and explained from a variety of perspectives, capturing a range of
 7 possible features, trends, processes, and mechanisms. It can be examined in terms of specific
 8 quantitative indicators, such as population, urbanisation level, life expectancy, literacy rate, GDP,
 9 carbon dioxide emission rate, average surface temperature, etc. Alternately, it can be described with
 10 reference to trends and shifts in broad socio-political or cultural features, such as democratisation,
 11 liberalisation, colonisation, globalisation, consumerism, etc. Or, it can be described in a way that
 12 highlights and details a particular domain of interest; for example, as an "economic pathway",
 13 "technological pathway", "demographic pathway", or others. Any such focused description of a
 14 pathway is more limited, by definition, than the general and encompassing notion of a development
 15 pathway.

16 Development pathways represent societal evolution over time, and can be assessed retrospectively and
 17 interpreted in a historical light, or explored prospectively by anticipating and assessing alternative future
 18 pathways. Development pathways, and prospective development pathways in particular, can reflect
 19 societal objectives, as in "low-emission development pathways", "climate-resilient development
 20 pathways", "sustainable development pathways", "inclusive development pathway", and as such can
 21 embed normative assumptions or preferences, or can reflect potential dystopian futures to be avoided.
 22 A national development plan (4.3.2) is a representation of a possible development pathway for a given
 23 society reflecting its objectives, as refracted through its development planning process.

24 One approach for exploring shifts in future development pathways is through scenarios. Some examples
 25 of scenario exercises in the literature are provided in Table 4.11.

26

27

Table 4.11 Prospective development pathways at global, national and local scale

Scale	Process and publication	Description of development pathways
Global	IPCC Special Report on Emission Scenarios (Nakicenovic et al. 2000)	Four different narrative storylines describing relationships between driving forces and the evolution of emission scenarios over the 21st century.
Global	Shared Socioeconomic Pathways (Riahi et al. 2017; O'Neill et al. 2017)	Five narratives describing alternative socio-economic developments, including sustainable development, regional rivalry, inequality, fossil-fuelled development, and middle-of-the-road development, using alternative long-term projections of demographics, human development, economy and lifestyle, policies and institutions, technology, and environment and natural resources.
Global	(Rao et al. 2019)	Alternative development pathways that explore several drivers of rising or falling inequality.
Global	Futures of Work (World Economic Forum 2018)	Eight possible visions of the future of work in the year 2030, based on different combinations of three core variables: the rate of technological change and its impact on business models, the evolution of learning among the current and

		future workforce, and the magnitude of labour mobility across geographies—all of which are likely to strongly influence the nature of work in the future.
National	Mt Fleur Scenarios (Galer 2004)	Four socio-political scenarios intended to explore possible futures of a newly post-apartheid South Africa, which included three dark prophecies and one bright vision which reportedly influenced the new leadership.
National	Mitigation Action Plans and Scenarios (MAPS) (Winkler et al. 2017; Raubenheimer et al. 2015)	Mitigation and development-focused scenarios for Brazil, Chile, Peru, and Colombia, entailing linked sectoral and economy modelling including socio-economic implications, combined with intensive stakeholder engagement.
National	Deep Decarbonisation Pathways (Bataille et al. 2016a; Waisman et al. 2019)	Mitigation-focused scenarios for sixteen countries from each country’s perspective, carried out by local institutes using national models. The common method is a tool for decision-makers in each context to debate differing concrete visions for deep decarbonisation, seek consensus on near-term policy packages, with aim to contribute to long-term global decarbonisation.
Local	New Lenses on Future Cities (Shell Global 2014)	Six city archetypes used to create scenarios to help understand how cities could evolve through more sustainable urbanisation processes and become more efficient, while coping with major development challenges in the past.

1
2 Different narratives of development pathways can have distinct and even competing focuses such as
3 economic growth, shifts in industrial structure, technological determinism, and can embody alternative
4 framings of development itself (from growth to well-being, see Chapter 5), and of sustainable
5 development in particular (see 1.6 and 17.1). Scenario exercises are structured undertakings to explore
6 alternative future development pathways, often drawing on stakeholder input and accepting the deep
7 and irreducible uncertainty inherent in societal development into the future (Kahane 2019; Schweizer
8 and Kriegler 2012; Raskin and Swart 2020). The results of scenario explorations, including modelling
9 exercises, thus help clarify the characteristics of a particular future pathway, in light of a particular set
10 of assumptions and choice of indicators for assessment. Processes of developing scenarios can inform
11 choices by decision makers of various kinds.

12 Scenarios are useful to clarify societal objectives, understand constraints, and explore future shifts.
13 Scenario exercises are effective when they enable multi-dimensional assessment, and accommodate
14 divergent normative viewpoints (Kowarsch et al. 2017). Such processes might take into account
15 participants’ explicit and implicit priorities, values, disciplinary backgrounds, and world views. The
16 process of defining and describing a society’s development pathway contributes to the ongoing process
17 of understanding, explaining and defining the historical and contemporary meaning and significance of
18 a society. The imagination of facilitated stakeholder process combined with the rigour of modelling
19 helps improve understanding of constraints, trade-offs, and choices. “*Scenario analysis offers a
20 structured approach for illuminating the vast range of possibilities. A scenario is a story, told in words
21 and numbers, describing the way events might unfold. If constructed with rigor and imagination,
22 scenarios help us to explore where we might be headed, but more, offering guidance on how to act now
23 to direct the flow of events toward a desirable future*” (Raskin et al. 2002). Scenario processes are
24 valuable for the quantitative and qualitative insights they can provide, and also for the role they can
25 play in providing a forum and process by which diverse institutions and even antagonistic stakeholders

1 can come together, build trust, improve understanding, and ultimately converge in their objectives
2 (Kane and Boulle 2018; Dubash 2021).

3 **4.3.1.2 Shifting development pathways**

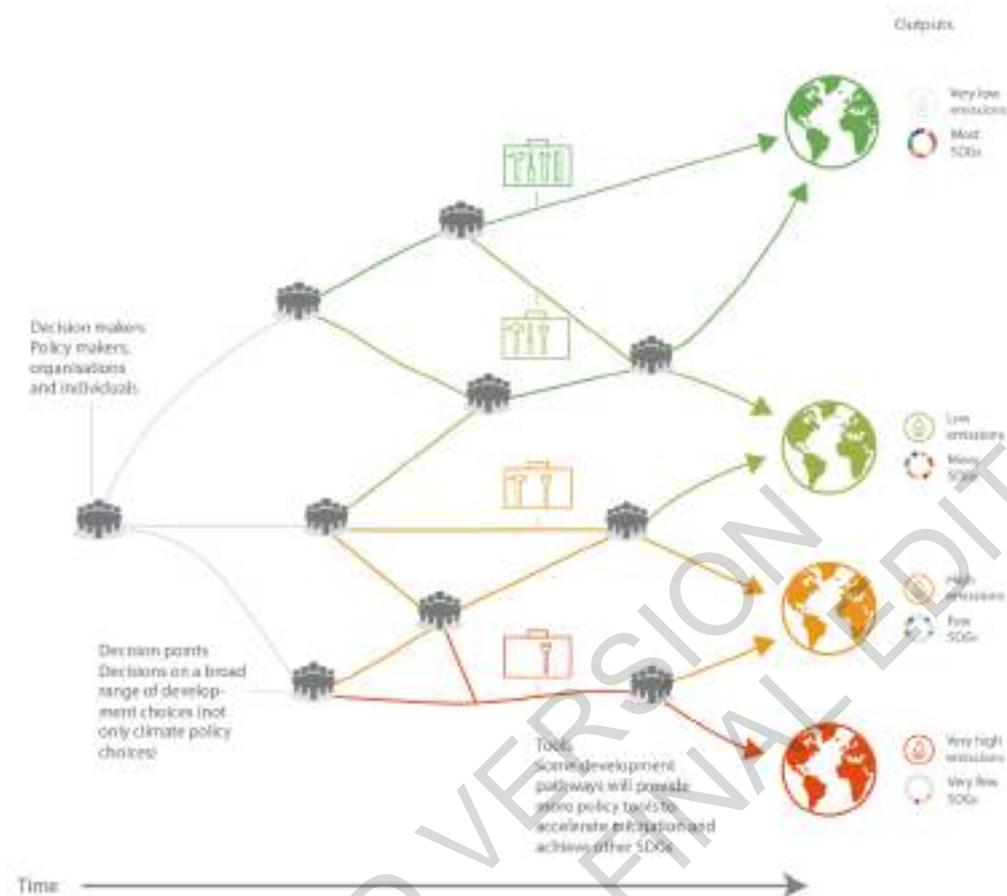

4 Development pathways evolve as the result of the countless decisions and actions at all levels of societal
5 structure, as well due to the emergent dynamics within and between institutions, cultural norms, socio-
6 technological systems, and the biogeophysical environment. Society can choose to make decisions and
7 take actions with the shared intention of influencing the future development pathway toward specific
8 agreed objectives.

9 The SDGs provide a lens on diverse national and local development objectives. Humankind currently
10 faces multiple sustainability challenges that together present global society with the challenge of
11 assessing, deliberating, and attempting to bring about a viable, positive future development pathway.
12 Ecological sustainability challenges include reducing GHG emissions, protecting the ozone, controlling
13 pollutants such as aerosols and persistent organics, managing nitrogen and phosphorous cycles, etc.
14 (Steffen et al. 2015), which are necessary to address the rising risks to biodiversity and ecosystem
15 services on which humanity depends (IPBES 2019a). Socioeconomic sustainability challenges include
16 conflict, persistent poverty and deprivation, various forms of pervasive and systemic discrimination and
17 deprivation, and socially corrosive inequality. The global adoption of the SDGs and their underlying
18 indicators (United Nations 2018) reflect a negotiated prioritisation of these common challenges.

19 Figure 4.7 illustrates the process of shifting development pathways. The lines illustrate different
20 possible development pathways through time, some of which (shown here toward the top of the figure)
21 remove obstacles to the adoption and effective implementation of sustainable development policies,
22 and thus give access to a rich policy toolbox for accelerating mitigation and achieving SDGs. Other
23 development pathways (shown here toward the bottom of the figure) do not overcome, or even reinforce
24 the obstacles to adopting and effectively implementing sustainable development policies, and thus leave
25 decision-makers with more limited policy toolbox (4.2.7; Figure 4.6). A richer tool box enables faster,
26 deeper and broader mitigation.

27 The development pathways branch and branch again, signifying how a diversity of decision-makers
28 (policy makers, organizations, investors, voters, consumers, etc.) are continuously making choices that
29 influence which of many potential development pathways society follows. Some of these choices fall
30 clearly within the domain of mitigation policy. For example, what level carbon price, if any, should be
31 imposed? Should fossil fuel subsidies be removed? Most decisions, of course, fall outside the direct
32 domain of mitigation policy. *Shifting development pathways toward sustainability* involves this broader
33 realm of choices beyond mitigation policy *per se*, and requires identifying those choices that are
34 important determinants of the existing obstacles to accelerating mitigation and meeting other SDGs.
35 Addressing these choices coherently shifts the development pathway away from a continuation of
36 existing trends,

37

1

2 **Figure 4.7 Shifting development pathways to increased sustainability: Choices by a wide range of actors**
 3 **at key decision points on development pathways can reduce barriers and provide more tools to accelerate**
 4 **mitigation and achieve other Sustainable Development Goals**

5 **4.3.1.3 Expanding the range of policies and other mitigative options**

6 Shifting development pathways aims to influence the ultimate drivers of emissions (and development
 7 generally), such as the systemic and cultural determinants of consumption patterns, the political systems
 8 and power structures that govern decision making, the institutions and incentives that guide and
 9 constrain socio-technical innovation, and the norms and information platforms that shape knowledge
 10 and discourse, and culture, values and needs (Raskin et al. 2002). These ultimate drivers determine the
 11 mitigative capacity of a society.

12 Decision-makers might usefully consider a broader palette of policies and measures as part of an overall
 13 strategy to meet climate goals and other sustainable development goals (see 4.3.2; Table 4.12). This is
 14 consistent with the fact that mitigation is increasingly understood to be inseparable from broader
 15 developmental goals, which can be facilitated by policy coherence and integration with broader
 16 objectives and policies sectorally and societally. This is supported by other observations that mitigation
 17 measures based on conventional climate policy instruments, such as emissions taxes or permits, price
 18 incentives such as feed-in tariffs for low-carbon electricity generation, and fuel economy standards, and
 19 building codes, which aim to influence the proximate drivers of emissions alone will not achieve the
 20 long-term goals of the Paris Agreement (IPCC 2018a; Rogelj et al. 2016; UNEP 2018; Méjean et al.

1 2015). An approach of shifting development pathways to increased sustainability (SDPS) broadens the
2 scope for mitigation.

3 **4.3.1.4 An approach of SDPS helps manage trade-offs between mitigation and other SDGs.**

4 Beyond removing structural obstacles to accelerated mitigation, broadening the approach to policies
5 that facilitate shifts in development pathways also helps manage the potential tradeoffs between
6 mitigation and other development objectives discussed in section 4.2.7.

7 Systematic studies of the 17 SDGs have found the interactions among them to be manifold and complex
8 (Pradhan et al. 2017; Nilsson et al. 2016; Weitz et al. 2018; Fuso Nerini et al. 2019). Addressing them
9 calls for interventions affecting fundamental, interconnected, structural features of global society
10 (International Panel on Social Progress 2018; TWI2050 - The World in 2050 2018), such as to our
11 physical infrastructure (e.g., energy, water, industrial, urban infrastructure) (Thacker et al. 2019;
12 Adshead et al. 2019; Waage et al. 2015; Mansell et al. 2019; Chester 2019), our societal institutions
13 (e.g., educational, public health, economic, innovation, and political institutions) (Sachs et al. 2019;
14 Ostrom 2010; Kläy et al. 2015; Messner 2015), and behavioural and cultural tendencies (e.g.,
15 consumption patterns, conventional biases, discriminatory interpersonal and intergroup dynamics, and
16 inequitable power structures) (Esquivel 2016; Sachs et al. 2019). These observations imply that attempt
17 to address each SDG in isolation, or as independent technical challenges, would be insufficient, as
18 would incremental, marginal changes. In contrast, effectively addressing the SDGs is likely to mean
19 significant disruption of long-standing trends and transformative progress to shift development
20 pathways to meet all the SDGs, including climate action, beyond incremental changes targeted at
21 addressing mitigation objectives in isolation. In other words, mitigation conceived as incremental
22 change is not enough. Transformational change has implications for equity in its multiple dimensions
23 (Leach et al. 2018; Klinsky et al. 2017a; Steffen and Stafford Smith 2013) including just transitions
24 (4.5).

25 Working Group II examines *climate resilient development pathways* – continuous processes that imply
26 deep societal changes and/or transformation, so as to strengthen sustainable development, efforts to
27 eradicate poverty and reduce inequalities while promoting fair and cross-scalar capacities for adaptation
28 to global warming and reduction of GHG emissions in the atmosphere. Transformational action in the
29 context of CRD specifically concerns leveraging change in the five dimensions of development (people,
30 prosperity, partnership, peace, planet) (WGII chapter 18).

31 Section 4.3.2 provides more details on the way development pathways influence emissions and
32 mitigative capacity. Section 4.3.3 provides examples of shifts in development pathways, as well as of
33 policies that might facilitate those. Cross-Chapter Box 5 details the links between SDPS and
34 sustainability.

35 **4.3.2 Implications of development pathways for mitigation and mitigative capacity**

36 **4.3.2.1 Countries have different development priorities**

37 At the global level, the SDGs adopted by all the United Nations Member States in 2015 are delineated
38 with a view to end poverty, protect the planet and ensure that all people enjoy peace and prosperity by
39 2030. The 17 SDGs are integrated and imply that development must balance social, economic and
40 environmental sustainability.

41 While all countries share the totality of the SDGs, development priorities differ across countries and
42 over time. These priorities are strongly linked to local contexts, and depend on which dimensions of
43 improvements in the well-being of people are considered the most urgent.

1 Development priorities are reflected in the decisions that actors within societies make, such as policy
2 choices by governments and parliaments at all levels, votes over competing policy platforms by citizens,
3 or selection of issues that non-state actors push for. Multiple objectives range from poverty eradication
4 to providing energy access, addressing concerns of inequality, providing education, improving health,
5 cleaning air and water, improving connectivity, sustaining growth and providing jobs, among others.
6 For example, eradicating poverty and reducing inequality is a key development priority across many
7 countries, such as Brazil (Grottera et al. 2017), Indonesia (Irfany and Klasen 2017), India (GoI, 2015),
8 South Africa (Winkler 2018) and other low- and middle-income countries (Dorband et al. 2019).
9 Reducing inequality relates not only to income, but also to other dimensions such as in access to energy
10 services (Tait 2017), gender, education, racial and ethnic profiles (Andrijevic et al. 2020), and thereby
11 assumes relevance in both developing and developed countries. The development priorities of many
12 poor countries and communities with low capacities to adapt, has been focused more on reducing
13 poverty, providing basic infrastructure, education and improving health, rather than on mitigation
14 (Chimhowu et al. 2019).

15 **4.3.2.2 *The nature of national development plans is changing***

16 Governments are increasingly resorting to the development of national plans to build institutions,
17 resources, and risk/shock management capabilities to guide national development. The number of
18 countries with a national development plan has more than doubled, from about 62 in 2006 (World Bank
19 2007) to 134 plans published between 2012 and 2018 (Chimhowu et al. 2019). The comeback of
20 planning may be linked to increased consideration given to sustainability, which is by construction
21 forward-looking and far ranging, and therefore requires state and civil society to prepare and implement
22 plans at all levels of governance. Governments are increasingly engaging in the development and
23 formulation of national plans in an organised, conscious and continual attempt to select the best
24 available alternatives to achieve specific goals.

25 A systematic assessment of 107 national development plans and 10 country case studies provides useful
26 insights regarding the type and content of the plans (Chimhowu et al. 2019). development plans are
27 increasingly focusing on mobilising action across multiple actors and multiple dimensions to enhance
28 resilience and improve the ability to undertake stronger mitigation actions. Various initiatives such as
29 the World Summit for Children in 1990; the Heavily Indebted Poor Country initiative that started
30 offering debt relief in exchange for commitments by beneficiary states to invest in health, education,
31 nutrition and poverty reduction in 1996; and push towards Comprehensive Development Frameworks
32 seem to have catalysed the development of national actions plans across countries to estimate, measure
33 and track investments and progress towards SDGs.

34 The most recent development plans also tend to differ from the earlier ones in terms of their approach.
35 Complexity science has over the years argued for new forms of planning based on contingency,
36 behaviour change, adaptation and constant learning (Colander and Kupers 2016; Ramalingam, 2013),
37 and new plans have increasingly focused on increasing resilience of individuals, organisations and
38 systems (Hummelbrunner and Jones, 2013). Finally, alongside short-term (typically 5 year) plans with
39 operational purpose, countries have also expressed visions of their development pathways over longer
40 time horizons, via, e.g., Voluntary National Reviews submitted in the context of the UN High Level
41 Political Forum on Sustainable Development.

42 National development plans are also increasingly more holistic in their approach, linking closely with
43 SDGs and incorporating climate action in their agendas. For instance, the Low Carbon Development
44 Initiative (LCDI), launched in 2017 by the Government of Indonesia, seeks to identify the development
45 policies that can help Indonesia achieve multiple (social, economic, and environmental) goals
46 simultaneously along with preserving and improving the country's natural resources (Bappenas 2019).

1 Likewise, Nepal's Fifteenth five-year plan recognises the need for climate mitigation and adaptation
2 and corresponding access to international finance and technologies. The plan suggests mobilization of
3 foreign aid in the climate change domain in line with Nepal's priorities and its inclusion in the country's
4 climate-friendly development programs as the key opportunities in this regard (Nepal 2020).

5 China's development plans have evolved over time from being largely growth oriented, and geared
6 largely towards the objectives of addressing poverty, improving health, education and public well-being
7 to also including modernisation of agriculture, industry and infrastructure, new forms of urbanisation
8 and a clear intent of focusing on innovation and new drivers of development (Central Compilation &
9 Translation Press 2016). China's 14th Five Year Plan not only seeks to promote high quality
10 development in all aspects and focus on strengthening the economy in the global industrial chain, but
11 also includes a vision of an 'ecological civilisation', which had been developed (CPC-CC 2015) and
12 analysed earlier (He 2016; Xiao and Zhao 2017). It seeks to enhance China's climate pledge to peak
13 CO₂ emissions by 2030 and achieve carbon neutrality by 2060 through more vigorous policies and
14 measures. Development plans tie in multiple development priorities that evolve and broaden over time
15 as societies develop, as exemplified inter alia by the history of development plans in India (Box 4.4).

17 **START BOX 4.4 HERE**

19 **Box 4.4 India's national development plan**

20 India's initial national development plans focused on improving the living standards of its people,
21 increasing national income and food self-sufficiency. Accordingly, there was a thrust towards
22 enhancing productivity of the agricultural and industrial sectors. While the main focus was on
23 maintaining high economic growth and industrial productivity, poverty eradication, employment and
24 inclusive growth remained important priorities. The National Action Plan on Climate Change with 8
25 Missions focusing on mitigation as well as adaptation was launched in 2008 integrating climate change
26 considerations in planning and decision making (MoEF 2008). The 12th Five Year Plan (2012-17) also
27 brought in a focus on sustainability and mentioned the need for faster, sustainable and inclusive growth.
28 The National Institution for Transforming India (NITI Aayog) was set up in 2017 replacing the erstwhile
29 Planning Commission, with a renewed focus towards bringing innovation, technology, enterprise and
30 efficient management together at the core of policy formulation and implementation. However, while
31 India has moved away from its Five-Year Plans, decision making is more dynamic, with a number of
32 sector specific initiatives and targets focused on integrating sustainability dimensions through a series
33 of policies and measures supporting resource efficiency, improved energy access, infrastructure
34 development, low carbon options and building resilient communities, among other objectives
35 (MoEFCCC 2021; MoEFCC 2018; GoI 2015). India's overall development pathway currently has a
36 strong focus on achieving robust and inclusive growth to ensure balanced development across all
37 regions and states and across sectors. There is a thrust on embracing new technologies while fostering
38 innovation and upskilling, modernisation of agriculture, improving regional and inter-personal equity,
39 bridging the gap between public and private sector performance, by focusing on efficient delivery of
40 public services, rooting out corruption and black economy, formalising the economy and expanding the
41 tax base, improving the ease of doing business, nursing the stressed commercial banking sector back to
42 a healthy state, and stopping leakages through direct benefit transfers, among other measures
43 (Government of India 2018; MoEFCCC 2021; GoI 2015).

45 **END BOX 4.4 HERE**

1

2 **4.3.2.3 Development pathways shape emissions and capacities to mitigate**

3 Analysis in the mitigation literature often frames mitigation policy as having development co-benefits,
4 the main objective being climate stabilisation. This misses the point that development drives emissions,
5 and not vice versa, and it is the overall development approach and policies that determine mitigation
6 pathways (Munasinghe 2007). A large body of literature supports the fact that development pathways
7 have direct and, just as importantly, indirect implications for GHG emissions (Nakicenovic et al. 2000;
8 Winkler 2017b), through multiple channels, such as the nature of economic activity, spatial patterns of
9 development, degree of inequality, and population growth.

10 **Economic structure:** Chapter 2 notes that overall, affluence (GDP per capita), economic growth and
11 population growth have remained the main upward drivers of CO₂ emissions from fossil-fuel
12 combustion in the past decade, with energy efficiency the main countervailing force (2.4) (Wang and
13 Feng 2017; Lin and Liu 2015). A major component of the development pathway of a country is precisely
14 the nature of the economic activities on which the country relies (e.g., agriculture and mining, heavy
15 industry, services, high-tech products, etc.) as well as the way it articulates its economy with the rest of
16 the World (e.g., export-led growth vs. import substitution strategies). Hence, the development pathway
17 ultimately drives the underlying structure of the economy, and to a large degree the relationship between
18 activity and GHG emissions.

19 At country level, however, the picture is more nuanced. Both India and China show signs of relative
20 decoupling between GDP and emissions because of structural change (Chen et al. 2018a). Sumabat et
21 al. (2016) indicate that economic growth had a negative impact on CO₂ emissions in Philippines. Baek
22 and Gweisah (2013) find that CO₂ emissions tend to drop monotonously as incomes increased. Lantz
23 and Feng (2006) also indicate that per capita GDP is not related to CO₂ emissions in Canada. Other
24 studies point to an emerging consensus that the relationship between CO₂ emissions and economic
25 indicators depends on the level of development of countries (Nguyen and Kakinaka 2019; Sharma
26 2011). While some literature indicates that absolute decoupling of economic growth and GHG
27 emissions has occurred in some countries (Le Quéré et al. 2019), a larger systematic review found
28 limited evidence of this (Haberl et al. 2020).

29 Looking ahead, choices about the nature of economic activities are expected to have significant
30 implications for emissions. For example, a development pathway that focuses on enhancing economic
31 growth based on manufacturing is likely to lead to very different challenges for mitigation compared to
32 one that focuses on services-led growth. (Quéré et al. 2018) find that choices about whether or not to
33 export offshore oil in Brazil will have significant implications for the country's GHG emissions.
34 Similarly, in China, transforming industrial structure towards tertiary sectors (Kwok et al. 2018) and
35 restructuring exports towards higher value-added products (Wu et al. 2019) are expected to have
36 significant implications for GHG emissions.

37 **Spatial patterns of development:** Chapter 2 notes that rapid urbanisation in developing and transition
38 countries leads to increased CO₂ emissions, the substantial migration of rural populations to urban areas
39 in these countries being the main factor leading to increased levels of income and expenditure of new
40 urban dwellers which in turn leads to increased personal carbon footprints and overall emissions (2.4).
41 Urbanisation, and more broadly spatial patterns of development, are in turned driven to a large part by
42 development choices, such as, inter alia, spatial provision of infrastructure and services, choices
43 regarding the agriculture and forestry sector, land-use policies, support to regional/local development,
44 among others (World Bank, 2009). For example, Dorin (2017) points out that if agriculture sectors in
45 Africa and India follow the same development path that developed countries have followed in the past,
46 namely increased labour productivity through enlargement and robotisation of farms, then

1 unprecedented emigrations of rural workers towards cities or foreign countries will ensue, with large-
2 scale social, economic and environmental consequences. Looking ahead, a development pathway that
3 encourages concentrated influx of people to large urban centres will lead to very different energy and
4 infrastructure consumption patterns than a pathway that prioritises the development of smaller, self-
5 contained towns and cities.

6 **Degree of inequality:** Chapter 2 notes that while eradicating extreme poverty and providing universal
7 access to modern energy services to poor populations across the globe has negligible implications for
8 emissions growth, existing studies on the role of poverty and inequality as drivers of GHG emissions
9 provide limited evidence that under certain contexts greater inequality can lead to a deterioration in
10 environmental quality and may be associated with higher GHG emissions (2.4). In fact, factors affecting
11 household consumption based emissions include household size, age, education attainment,
12 employment status, urban vs rural location and housing stock (Druckman and Jackson 2015). There is
13 evidence to indicate that at the household level, the increase in emissions from additional consumption
14 of the lower income households could be larger than the reduction in emissions from the drop in
15 consumption from the high income households (Sager 2019). Accordingly, as countries seek to fulfil
16 the objective of reducing inequality, there are possibilities of higher increase in emissions (Sager 2019).

17 Since reducing inequality, as noted above, is globally one of the main development priorities, a large
18 body of literature focuses on the compatibility of climate change mitigation and reduction in economic
19 inequality (Berthe and Elie 2015; Grunewald et al. 2017; Hao et al. 2016; Wiedenhofer et al. 2017;
20 Auffhammer and Wolfram 2014; Baek and Gweisah 2013). However, the use of narrow approaches or
21 simple methods of studying the relationships of income inequality and emissions by looking at
22 correlations, may miss important linkages. For example, the influence of inequality on social values
23 such as status and civic mindedness and non-political interests that shape environmental policy can
24 influence overall consumption and its environmental impacts (Berthe and Elie 2015). Moreover,
25 inequalities may also be reflected in gender, education, racial and ethnic profiles and could accordingly
26 be associated with the level of emissions and mitigation prospects (Andrijevic et al. 2020).

27 The Illustrative Mitigation Pathways (IMP) developed for this Report (Box 3.1 and section 3.2.5)
28 provide another example of how development pathways influence mitigative capacity. Precisely,
29 IMP1.5-SP (Shifting Pathways) and 1.5-Ren (Renewables) lead to the same long-term temperature, but
30 differ in underlying socio-economic conditions. The former is based on Shared Socio-economic
31 Pathway (SSP) 1 (sustainable development), whereas the latter is based on SSP 2 (middle of the road).
32 Comparing 1.5-Ren to 1.5-SP can thus be interpreted as a numerical translation of trying to reach the
33 same long-term temperature goal without and with shifting development pathways towards
34 sustainability. Data shows that the global price of carbon necessary to remain on target is 40%-50%
35 lower in the latter relative to the former, thus indicating that mitigation is cheaper with a shift in
36 development pathway towards sustainability. Other cost indicators (e.g. consumption loss or GDP loss)
37 tell the same story. Since both IMPs were computed using the same underlying model, the comparison
38 is even more robust.

39 In sum, development pathways can lead to different emission levels and different capacities and
40 opportunities to mitigate (*medium evidence, high agreement*). Thus, focusing on shifting development
41 pathways can lead to larger systemic sustainability benefits.

42 **4.3.2.4 Integrating mitigation considerations requires non-marginal shifts in development** 43 **pathways**

44 Concerns about mitigation are already being introduced in national development plans, as there is
45 evidence that development strategies and pathways can be carefully designed so as to align towards
46 multiple priorities and achieve greater synergistic benefits. For example, India's solar programme is a

1 key element in its NDC that can in the long run, not only provide energy security and contribute to
2 mitigation, but can simultaneously contribute to economic growth, improved energy access and
3 additional employment opportunities, if appropriate policies and measures are carefully planned and
4 implemented. However, the environmental implications of the transition need to be carefully examined
5 with regard to the socio-economic implications in light of the potential of other alternatives like green
6 hydrogen, nuclear or CCUS. Similarly, South Africa National Development Plan (2011) also integrates
7 transition to low-carbon as part of the country development objectives (Box 4.5).

8
9 **START BOX 4.5 HERE**

10
11 **Box 4.5 South Africa’s National Development Plan**

12 South Africa adopted its first National Development Plan (NDP) in 2011 (NPC 2011), the same year in
13 which the country adopted climate policy (RSA 2011) and hosted COP17 in Durban. Chapter 5 of the
14 NDP addresses environmental sustainability in the context of development planning, and specifically
15 “an equitable transition to a low-carbon economy” (NPC 2011). The chapter refers explicitly to the need
16 for a just transition, protecting the poor from impacts and any transitional costs from emissions-
17 intensive to low-carbon. The plan proposes several mitigation measures, including a carbon budgeting
18 approach, reference to Treasury’s carbon tax, use of various low carbon options while maintaining
19 energy security, and the integrated resource plan for electricity. The NDP refers to coal in several
20 chapters, in some places suggesting additional investment (including new rail lines to transport coal and
21 coal to liquids), in others decommissioning coal-fired power “*Procuring at least 20 000MW of
22 renewable electricity by 2030, importing electricity from the region, decommissioning 11 000MW of
23 ageing coal-fired power stations and stepping up investments in energy-efficiency*” (NPC 2011: p.46).
24 Reference to environmental sustainability is not limited to chapter 5 – the introductory vision statement
25 includes acknowledgement “*that each and every one of us is intimately and inextricably of this earth
26 with its beauty and life-giving sources; that our lives on earth are both enriched and complicated by
27 what we have contributed to its condition*” (NPC 2011: p. 21); and the overview of the plan includes a
28 section on climate change, addressing both mitigation and adaptation.

29 **END BOX 4.5 HERE**

30
31 Looking ahead, given that different development pathways can lead to different levels of GHG
32 emissions and to different capacities and opportunities to mitigate, there is increasing research on how
33 to make development pathways more sustainable. Literature is also focusing on the need for a “new
34 normal” as a system capable of achieving higher quality growth while addressing multiple development
35 objectives by focusing on “innovative development pathways”.

36 Literature suggests that if development pathways are to be changed to address the climate change
37 problem, choices that would need to be made about development pathways would not be marginal
38 (Stern and Professor 2009), and would require a new social contract to address a complex set of inter-
39 linkages across sectors, classes and the whole economy (Winkler 2017b). Shifting development
40 pathways necessitates planning in a holistic manner, rather than thinking about discrete and isolated
41 activities and actions to undertake mitigation. Further, the necessary transformational changes can be
42 positive if they are rooted in the development aspirations of the economy and society in which they take
43 place (Dubash 2012; Jones et al. 2013), but they can also lead to carbon colonialism if the
44 transformations are imposed by Northern donors or perceived as such.

1 Accordingly, influencing a societies' development pathways draws upon a broader range of policies
2 and other efforts than narrowly influencing mitigation pathways, to be able to achieve the multiple
3 objectives of reducing poverty, inequality and GHG emissions. The implications for employment,
4 education, mobility, housing and many other development aspects must be integrated and new ways of
5 looking at development pathways which are low carbon must be considered (Bataille et al. 2016b;
6 Waisman et al. 2019). For instance, job creation and education are important elements that could play
7 a key role in reducing inequality and poverty in countries like South Africa and India (Rao and Min
8 2018; Winkler et al. 2015) while these also open up broader opportunities for mitigation.

9 *4.3.2.5 New tools are needed to pave and assess development pathways*

10 Relative to the literature on mitigation pathways described in 4.2.5 and in 4.3.3, the literature on
11 development pathways is limited. The climate research community has developed the Shared Socio-
12 economic pathways (SSPs) that link several socio-economic drivers including equity in relation to
13 welfare, resources, institutions, governance and climate mitigation policies in order to reflect many of
14 the key development directions (O'Neill et al. 2014). In most modelling exercises however,
15 development remains treated as an exogenous input. In addition, models may capture only some
16 dimensions of development that are relevant for mitigation options, thereby not capturing distributional
17 aspects and not allowing consistency checks with broader developmental goals (Valadkhani et al. 2016).
18 Quantitative tools for assessing mitigation pathways could be more helpful if they could provide
19 information on a broader range of development indicators, and could model substantively different
20 alternative development paths, thereby providing information on which levers might shift development
21 in a more sustainable direction.

22 Doing so requires new ways of thinking with interdisciplinary research and use of alternative
23 frameworks and methods suited to deeper understanding of change agents, determinants of change and
24 adaptive management among other issues (Winkler 2018). This includes, inter alia, being able to
25 examine enabling conditions for shifting development pathways (see 4.4.1); re-evaluating the neo-
26 classical assumptions within most models, both on the functioning of markets and on the behaviour of
27 agents, to better address obstacles on the demand side, obstacles on the supply side and market
28 distortions (Ekholm et al. 2013; Staub-Kaminski et al. 2014; Grubb et al. 2015) improving
29 representation of issues related with uncertainty, innovation, inertia and irreversibility within the larger
30 development contexts, including energy access and security ; improving the representation of social and
31 human capital, and of social, technological and governance innovations (Pedde et al. 2019).

32 Tools have been developed in that direction, for example in the Mitigation Action Plans and Scenarios
33 (MAPS) community (La Rovere et al. 2014b), but need to be further mainstreamed in the analysis.
34 Back-casting is often a preferred modelling approach for assessment aiming to align national
35 development goals with global climate goals like CO₂ stabilisation. Back-casting is a normative
36 approach where modellers construct desirable futures and specify upfront targets and then find out
37 possible pathways to attain these targets (IPCC et al. 2001). Use of approaches like back-casting are
38 useful not only in incorporating the long term national development objectives in the models, but also
39 evaluating conflicts and synergies more effectively (van der Voorn et al. 2020). In back casting, the
40 long-term national development objectives remain the key benchmarks guiding the model dynamics
41 and the global climate goal is interfaced to realise the co-benefits. The models then delineate the
42 roadmap of national actions such that the national goals are achieved with a comprehensive
43 understanding of the full costs and benefits of low carbon development (often including the costs of
44 adaptation and impacts from residual climate change). Back-casting modelling exercises show that
45 aligning development and climate actions could result in much lower 'social cost of carbon' (Shukla et
46 al. 2008). Back-casting does not aim to produce blueprints. Rather, it indicates the relative feasibility
47 and the social, environmental, and political implications of different development and climate futures

1 on the assumption of a clear relationship between goal setting and policy planning (Dreborg 1996).
2 Accordingly, back-casting exercises are well suited for preparing local specific roadmaps like for cities
3 (Gomi et al. 2011, 2010).

4

5 **4.3.3 Examples of shifts in development pathways and of supporting policies**

6 As noted in 4.3.1, policy approaches that include a broader range of instruments and initiatives would
7 impact more fundamentally on the actors, institutions and structures of societies and the dynamics
8 among them, aiming to alter the underlying drivers of emissions, opening up a wider range of mitigation
9 opportunities and potential in the process of achieving societal development goals. While the evolution
10 of these drivers is subject to varied influences and complex interactions, there are policy measures by
11 which decision-makers might influence them. Table 4.12 provides some examples of policy measures
12 that can affect key drivers (shown in the row headings).

13

2

3 Policies such as those listed in Table 4.12 are typically associated with broader objectives than GHG
4 mitigation. They are generally conceived and implemented in the pursuit of overall societal
5 development objectives, such as job creation, macro-economic stability, economic growth, and public
6 health and welfare. However, they can have major influence on mitigative capacity, and hence can be
7 seen as necessary tools if mitigation options are to be significantly broadened and accelerated (*medium*
8 *evidence, medium agreement*). The example of the UK shows how accelerated mitigation through
9 dietary changes require a wide set of efforts to shift underlying drivers of behaviour. In this case,
10 multiple forces have interacted to lead to reduced meat consumption, including health attitudes, animal
11 welfare concerns, and an increasing focus on climate and other environmental impacts of livestock
12 production, along with corporate investment in market opportunities, and technological developments
13 in meat alternatives (Box 5.5).

1 Other historic cases that are unrelated to recent mitigation efforts might be more appropriate examples
2 of major socio-technical shifts that were largely driven by intentional, coherent intentional policy
3 initiatives across numerous domains to meet multiple objectives. The modernization of agriculture in
4 various national contexts fits such a mold. In the US, for example, major government investments in
5 agricultural innovation through the creation of agricultural universities and support for research
6 provided advances in the technological basis for modernization. A network of agricultural extension
7 services accelerated the popularization and uptake of modern methods. Infrastructure investments in
8 irrigation and drainage made production more viable, and investment in roadways and rail for transport
9 supported market formation. Agricultural development banks made credit available, and government
10 subsidies improved the profitability for farmers and agricultural corporations. Public campaigns were
11 launched to modify food habits (Ferleger 2000).

12 Further examples of SDPS across many different systems and sectors are elaborated across this report.
13 Concrete examples assessed in this Chapter include high employment and low emissions structural
14 change, fiscal reforms for mitigation and social contract, combining housing policies to deliver both
15 housing and transport mitigation, and change economic, social and spatial patterns of development of
16 the agriculture sector provide the basis for sustained reductions in emissions from deforestation (4.4.1.7-
17 4.4.1.10). These examples differ by context. Examples in other chapters include transformations in
18 energy, urban, building, industrial, transport, and land-based systems, changes in behaviour and social
19 practices, as well as transformational changes across whole economies and societies (Cross Chapter
20 Box 5, 5.8, Box 6.2, 8.2, 8.3.1, 8.4, 9.8.1, 9.8.2, 10.4.1, Cross-Chapter Box 12}. These examples and
21 others can be understood in the context of an explanation of the concept of SDPS, and how to shifting
22 development pathways (Cross-Chapter Box 5).

36

37 **1. What do we mean by development pathways?**

38 In the present report, development pathways refer to patterns of development resulting from multiple
39 decisions and choices made by many actors in the national and global contexts. Each society whether
40 in the Global North or the Global South follows its own pattern of development (Figure 1.6).
41 Development pathways can also be described at smaller scales (e.g., for regions or cities). By extension,
42 the concept can also be applied to sectors and systems (e.g., the development pathway of the agricultural
43 sector or of industrial systems).

44

45 **2. Why do development pathways matter in a report about mitigation?**

1 **2a. Past development pathways determine both today's GHG emissions and the set of opportunities**
2 **to reduce emissions**

3
4 Development pathways drive GHG emissions for a large part (2.4, 2.5 and 2.6). For example, different
5 social choices and policy packages with regard to land use and associated rents will result in human
6 settlements with different spatial patterns, different types of housing markets and cultures, and different
7 degrees of inclusiveness, and thus different demand for transport services and associated GHG
8 emissions (8.3.1, 10.2.1).

9
10 There is compelling evidence to show that continuing along existing development pathways is unlikely
11 to achieve rapid and deep emission reductions (robust evidence, medium agreement). For example,
12 investments in long-lived infrastructure, including energy supply systems, could lock-in high emissions
13 pathways and risk making deep decarbonisation and sustainable policies more difficult and expensive.
14 Development pathways also determine the set of tools available to mitigate climate change (Figure 4.7).
15 For example, the capacity of households to move closer to their workplace, in response to, e.g., a price
16 signal on carbon and thus on gasoline, depends on rents, which themselves depend on the spatial
17 patterns of development of human settlements (8.3.1). Said differently, mitigation costs depend on past
18 development choices. Similarly, development pathways determine the enablers and levers available for
19 adaptation (WGII, Chapter 18) and for achieving other SDGs.

20
21 In the absence of shifts in development pathways, conventional mitigation policy instruments (e.g.,
22 carbon tax, emission quotas, technological norms, etc.) may not be able to limit emissions to a degree
23 sufficient for deep decarbonisation or only at very high economic and social costs.

24
25 Policies to shift development pathways, on the contrary, make mitigation policies more effective. For
26 example, policies that prioritise non-car transit, or limit rents close to work places would make it easier
27 for households to relocate in response to a price signal on transport, and thus makes the same degree of
28 mitigation achievable at lower economic and social cost.

29
30 **2b. Shifting development pathways broadens the scope for synergies between development objectives**
31 **and mitigation**

32 Second, societies pursue a variety of development objectives, of which protecting the Earth's climate
33 is part. The SDGs provide a global mapping of these goals. Absent climate mitigation, our collective
34 ability to achieve the SDGs in 2030 and to sustain them beyond 2030 is likely to be compromised, even
35 if adaptation measures are put in place (WGII).

36
37 There are many instances in which reducing GHG emissions and moving towards the achievement of
38 other development objectives can go hand in hand, in the near-, mid- and long-term (3.7, 6.7.7, 7.6.5,
39 8.2, 9.8, 10.1.1, 11.5.3, 17.3) (Figures 3.40, 12.1). For example, transitions from coal-based power to
40 lower-emissions electricity generation technologies and from Internal Combustion Engine to lower-
41 carbon transport has large mitigation potential and direct benefits for health through reduction in local
42 air pollution (Box 6.2, 10.4.1). Energy efficiency in buildings and energy poverty alleviation through
43 improved access to clean fuels also delivers significant health benefits (9.8.1 and 9.8.2).

44
45 Careful design of mitigation policies is critical to achieving these synergies (13.8). Integrated policies
46 can support the creation of synergies between climate change goals and other SDGs. For example, when
47 measures promoting walkable urban areas are combined with electrification and clean renewable
48 energy, there are several co-benefits to be attained (5.2, Figure SPM.8). These include reduced pressures

1 on agricultural land from reduced urban growth, health co-benefits from cleaner air and benefits from
2 enhanced mobility (8.2; 8.4; 4.4.1.9).

3
4 Policy design can also manage trade-offs, for example through policy measures as part of just transitions
5 (17.4). However, even with good policy design, decisions about mitigation actions, and the timing and
6 scale thereof, may entail trade-offs with the achievement of other national development objectives in
7 the near-, mid- and long-term. In the near-term, for example, regulations may ban vehicles from city
8 centres to reduce congestion and local air pollution, but reduce mobility and choice. Increasing green
9 spaces within cities without caps on housing prices may involve trade-offs with affordable housing and
10 push low income residents outside the city (8.2.2). In the mid- and long-term, large-scale deployment
11 of biomass energy raises concerns about food security and biodiversity conservation (3.7.1, 3.7.5, 7.4.4,
12 9.8.1, 12.5.2, 12.5.3). Conflicts between mitigation and other development objectives can act as an
13 impediment to climate action (13.8). Climate change is the result of decades of unsustainable energy
14 production, land-use, production and consumption patterns, as well as governance arrangements and
15 political economic institutions that lock in resource-intensive development patterns (*robust evidence,*
16 *high agreement*). Reframing development objectives and shifting development pathways towards
17 sustainability can help transform these patterns and practices, allowing space for transitions
18 transforming unsustainable systems (*medium evidence, high agreement*) (Chapter 17 Executive
19 Summary).

20
21 Prioritising is one way to manage trade-offs, addressing some national development objectives earlier
22 than others. Another way is to adopt policy packages aimed at shifting development pathways towards
23 sustainability as they expand the range of tools available to simultaneously achieve multiple
24 development objectives, including mitigation. In the city example of section 2a, a carbon tax alone
25 would run counter to other development objectives if it made suburban households locked into high
26 emissions transport modes poorer or if it restricted mobility choices, in particular for low- and middle-
27 income households. Policy packages combining affordable housing and provision of safe low-carbon
28 mobility could both facilitate equitable access to housing (a major development objective in many
29 countries) and make it easier to mitigate by shifting the urban development pathway.

30
31 Similarly, a fundamental shift in the service provision that helps reduce energy demand (Chapter 5),
32 driven by targeted policies, investment and enabling socio-cultural and behavioural change, would
33 reduce pressure on supply side mitigation need, hence limiting pressure on water and food and the
34 achievement of associated SDGs. Some studies assume Western European lifestyle as a reference for
35 the global North and an improvement in the living standard for the Global South to reduce energy
36 demand and emissions (e.g., (Grubler et al. 2018)), while others explore a transformative change in the
37 global North to achieve a decent living standard for all (Millward-Hopkins et al. 2020; Bertram et al.
38 2018) (3.7.8). For example, in the UK, interaction between multiple behavioural, socio-cultural, and
39 corporate drivers including NGO campaigns, social movements and product innovations resulted in an
40 observed decline in meat consumption (5.4, 5.6.4).

41 42 **3. What does shifting development pathways towards sustainability entail?**

43 Shifting development pathways towards sustainability implies making transformative changes that
44 disrupt existing developmental trends. Such choices would not be marginal (Stern and Professor 2009),
45 but include technology adoption, infrastructure availability and use, and socio-behavioural factors
46 (Chapter 5).

1 These include creating new infrastructure, sustainable supply chains, institutional capacities for
2 evidence-based and integrated decision-making, financial alignment towards low-carbon socially
3 responsible investments, just transitions and shifts in behaviour and norms to support shifts away from
4 fossil-fuel consumption (Green and Denniss 2018). Adopting multi-level governance modes, tackling
5 corruption where it inhibits shifts to sustainability, and improving social and political trust are also key
6 for aligning and supporting long-term environmentally just policies and processes.

7
8 Shifting development pathways entails fundamental changes in energy, urban, building, industrial,
9 transport, and land-based systems. It also requires changes in behaviour and social practices.
10 Overcoming inertia and locked-in practices may face considerable opposition (5.4.5) (Geels et al. 2017).
11 The durability of carbon intensive transport modes and electricity generating infrastructures increase
12 the risk of lock-in to high emissions pathways, as these comprise not just consumer practices, but sunk
13 costs in infrastructure, supporting institutions and rules (Seto et al. 2016; Mattioli et al. 2020). Shifting
14 investments towards low-GHG solutions requires a combination of conducive public policies, attractive
15 investment opportunities, as well as the availability of financing to enable such a transition (15.3).

16 17 **4. How to shift development pathways?**

18 Shifting development paths is complex. If history is any guide, practices that can easily supplant existing
19 systems and are clearly profitable move fastest (Griliches 1957). Changes that involve ‘dissimilar,
20 unfamiliar and more complex science-based components’ take more time, acceptance and legitimation
21 and involve complex social learning (Conley and Udry 2010), even when they promise large gains
22 (Pezzoni et al. 2019).

23
24 Yet despite the complexities of the interactions that result in patterns of development, history also shows
25 that societies can influence the direction of development pathways based on choices made by decision-
26 makers, citizens, the private sector and social stakeholders. For example, fundamentally different
27 responses to the first oil shock shifted then-comparable economies on to different energy sector
28 development and economic pathways in the 1970s and 80s (Sathaye et al. 2009). More recent examples
29 have shown evidence of voluntary transitions for e.g., advanced lighting in Sweden, improved cook-
30 stoves in China, liquefied petroleum gas stoves in Indonesia or ethanol vehicles in Brazil (Sovacool
31 2016).

32
33 There is no one-size-fits-all recipe for shifting development pathways. However, the following insights
34 can be drawn from past experience and scenarios of possible future development pathways (4.4.1). For
35 example, policies making inner-urban neighbourhoods more accessible and affordable reduce transport
36 costs for low- and middle-income households, and also reduce transport emissions (4.4.1.9). Shifts in
37 development pathways result from both sustained political interventions and bottom-up changes in
38 public opinion. No single sector or policy action is enough to achieve this. Coordinated policy mixes
39 would need to coordinate multiple actors – i.e., individuals, groups and collectives, corporate actors,
40 institutions and infrastructure actors – to deepen decarbonisation and shift pathways towards
41 sustainability (Pettifor 2020). One example was the LPG Subsidy ("Zero Kero") Program in Indonesia
42 which harnessed creative policy design to shift to cleaner energy by overcoming existing private
43 interests. The objective of decreasing fiscal expenditures on domestic kerosene subsidies by replacing
44 it with LPG was achieved by harnessing distribution networks of existing providers supported by
45 government subsidized provision of equipment and subsidized pricing (Cross-Chapter Box 9).

46
47 Shifts in one country may spill over to other countries. Collective action by individuals as part of formal
48 social movements or informal lifestyle changes underpins system change (5.2.3, 5.4.1, 5.4.5.3, 13.5).

1 Sectoral transitions that aspire to shift development pathways often have multiple objectives, and deploy
2 a diverse mix or package of policies and institutional measures (Figure 13.6). Context specific
3 governance conditions can significantly enable or disable sectoral transitions, and play a determinative
4 role in whether a sectoral transition leads to a shift in development pathway. For example, if
5 implemented policies to tackle fuel poverty target the most socially vulnerable households, this can help
6 address barriers poor households face in undertaking building retrofits. In the EU-28, it has been shown
7 that accelerated energy efficiency policies coupled with strong social policies targeting the most
8 vulnerable households, can help reduce the energy demand in residential sector, and deliver additional
9 co-benefits of avoided premature deaths and reduced health impacts (9.8.2).

10
11 Literature suggests that through equitable resource distribution, high levels of human development can
12 be provided at moderate energy and carbon levels by changing consumption patterns and redirecting
13 systems in the direction of more sustainable resource use, suggesting that a special effort can be made
14 in the near term for those on higher incomes who account for a disproportionate fraction of global
15 emissions (Millward-Hopkins et al. 2020; Hickel et al. 2021) (5.2.2, Figure 5.14).

16
17 The necessary transformational changes are likely to be more acceptable if rooted in the development
18 aspirations of the economy and society within which they take place (Jones et al. 2013; Dubash 2012)
19 and may enable a new social contract to address a complex set of inter-linkages across sectors, classes
20 and the whole economy (Fleurbaey et al. 2018).

21
22 Taking advantage of windows of opportunity and disruptions to mindsets and socio-technical systems
23 could advance deeper transformations. These might include the globally declining costs of renewables
24 (Fig.1.7, 2.2.5, Box 16.2), emerging social norms for climate mitigation (Green and Denniss 2018), or
25 the COVID-19 pandemic, all of which might be harnessed to centre political action on protecting human
26 and planetary health (Büchs et al. 2020), but if not handled carefully could also risk to undermine the
27 support for transformation.

28 29 ***5. How can shifts in development pathways be implemented by actors in different contexts?***

30 Shifting development pathways to increased sustainability is a shared aspiration. Yet since countries
31 differ in starting points (e.g., social, economic, cultural, political) and history, they have different urgent
32 needs in terms of facilitating the economic, social, and environmental dimensions of sustainable
33 development and, therefore, give different priorities (4.3.2, 17.4). The appropriate set of policies to shift
34 development pathways thus depends on national circumstances and capacities.

35
36 In some developed countries and communities, affluence leads to high levels of consumption and
37 emissions across sectors (Wiedmann et al. 2020; Mazur and Rosa 1974). For some countries, reducing
38 consumption can reduce emissions without compromising on wellbeing. However, some developing
39 countries still face the challenge of escaping “middle-income traps” (Agénor and Canuto 2015), as
40 labour-saving technological change and globalisation have limited options to develop via the
41 manufacturing sector (Altenburg and Rodrik 2017). In least developed countries, infrastructure,
42 industry, and public services are still being established, posing both a challenge to financial support to
43 deploy technologies, and large opportunities to support accelerating low-to-zero carbon options
44 (especially in terms of efficient and sufficient provision, (Millward-Hopkins et al. 2020)). Availability
45 of capital, or lack thereof, is a critical discriminant across countries and requires international
46 cooperation (15.2.2).

1 Shifting development pathways towards sustainability needs to be supported by global partnerships to
2 strengthen suitable capacity, technological innovation (16.6), and financial flows (14.4.1, 15.2.4). The
3 international community can play a particularly key role by helping ensure the necessary broad
4 participation in climate-mitigation efforts, including by countries at different development levels,
5 through sustained support for policies and partnerships that support shifting development pathways
6 towards sustainability while promoting equity and being mindful of different transition capacities
7 (4.3.2, 16.5, 16.6, 14.4, 17.4).

8
9 **END CCB 5 HERE**

10
11 In sum, development pathways unfold over time in response to complex dynamics among various
12 drivers and diverse actors with varying interests and motivations (*high agreement, robust evidence*).
13 The way countries develop determines the nature and degree of the obstacles to accelerating mitigation
14 and achieving other sustainable development objectives (*medium-robust evidence, medium agreement*).
15 Meeting ambitious mitigation and development goals cannot be achieved through incremental change
16 (*robust evidence, medium agreement*). Shifting development pathways thus involves designing and
17 implementing policies where possible to intentionally enhance enabling conditions and reduce obstacles
18 to desired outcomes (*medium evidence, medium agreement*).

19 Section 4.4 elaborates mechanisms through which societies can develop and implement policies to
20 substantially shift development pathways toward securing shared societal objectives. Such policies
21 entail overcoming obstacles (see 4.2.7) by means of favourable enabling conditions: governance and
22 institutions, behaviour, innovation, policy and finance. These enabling conditions are amenable to
23 intentional change – to greater or lesser degrees and over longer or shorter time scales – based on a
24 range of possible measures and processes (see section 4.4).

25 26 **4.4 How to shift development pathways and accelerate the pace and scale** 27 **of mitigation**

28 **4.4.1 Approaches, enabling conditions and examples**

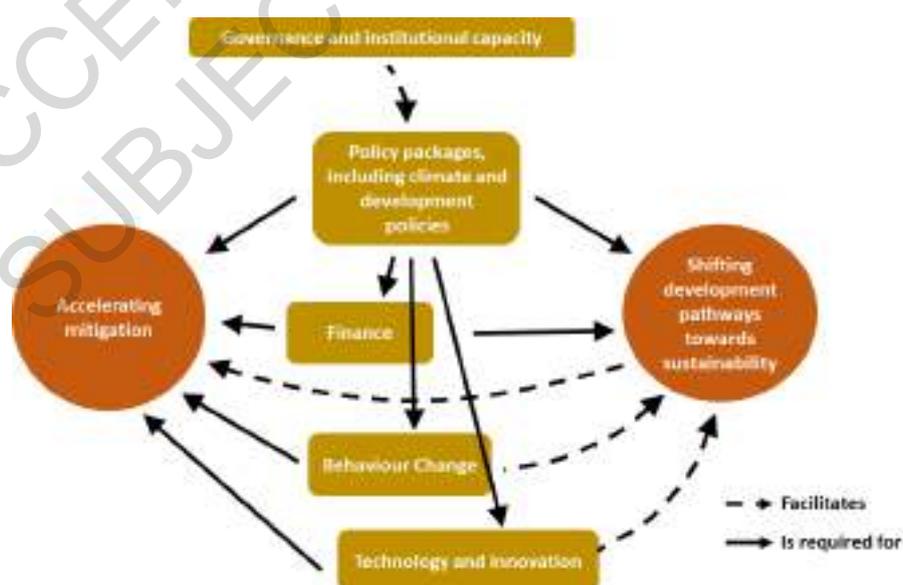

29 **4.4.1.1 Framing the problem**

30 What have we learned so far? As highlighted above, despite 30 years of UNFCCC and growing
31 contributions by non-state actors, the emissions gap keeps growing (4.2.2 and 4.2.3). Mitigation
32 conceived as incremental change is not enough. Meeting ambitious mitigation goals entails rapid, non-
33 marginal changes in production and consumption patterns (4.2.4 and 4.2.5). Taking another approach,
34 we have seen in section 4.3 that shifting development pathways broadens the scope for mitigation (4.3.1,
35 4.3.2) and offers more opportunities than mitigation alone to combine mitigation with the realisation of
36 other SDGs (4.3.1, Cross-Chapter Box 5).

37 A practical way forward is to combine shifting development pathways and accelerating mitigation
38 (*medium evidence, high agreement*). This means introducing multi-objective policy packages and
39 sequences with climate and development components that both target mitigation directly and create the
40 conditions for shifts in development pathways that will help accelerate further mitigation down the line,
41 and meet other development objectives. Since development pathways result from a myriad of decisions
42 from multiple actors (4.3.1), coordination across countries and with non-state actors is essential.

1 The literature does not provide a handbook on how to accomplish the above. However, analysis of past
 2 experience as well as understanding of how societies function yield insights that the present section
 3 aims at presenting. Human history has seen multiple transformation of economies due to path-breaking
 4 innovations (Michaelowa et al. 2018), like the transformation of the energy system from traditional
 5 biomass to fossil fuels or from steam to electricity (Fouquet 2010, 2016a; Sovacool 2016). Fouquet
 6 (2016b) and Smil (2016) argue that even the most rapid global transformations have taken several
 7 decades. Enabling transformational change implies to create now the conditions that lead to that
 8 transformation (Díaz et al. 2019). The starting point is that there is no single factor determining such a
 9 transformation. Rather a range of enabling conditions can combine in a co-evolutionary process.
 10 Amongst the conditions that have been cited in the literature are higher levels of innovation, multilevel
 11 governance, transformative policy regimes or profound behavioural transformation (IPCC 2018a; Geels
 12 et al. 2018; Kriegler et al. 2018; Rockström et al. 2017). It might be possible to put in place some of the
 13 above conditions rapidly, while others may take longer, thereby requiring an early start.

14 The present chapter uses the set of enabling conditions identified in the IPCC SR1.5 report, namely
 15 policy, governance and institutional capacity, finance, behaviour and lifestyles and innovation and
 16 technology (de Coninck et al. 2018). As Figure 4.8 illustrates, *public policies* are required to foster both
 17 accelerating mitigation and shifting development pathways. They are also vital to guide and provide the
 18 other enabling conditions (cf. Table 4.12). Improved governance and enhanced institutional capacity
 19 facilitate the adoption of policies that accelerate mitigation and shift development pathways, with the
 20 potential to achieve multiple mitigation and development objectives. Finance is required both to
 21 accelerate mitigation and to shift development pathways. Chapter 15 argues that near-term actions to
 22 shift the financial system over the next decade (2021-2030) are critically important and feasible, and
 23 that the immediate post-COVID recovery opens up opportunities to scale up financing from billions to
 24 trillions (15.6.7) (Mawdsley 2018). As discussed in section 4.2.5, accelerated mitigation pathways
 25 encompass both rapid deployment of new technologies such as CCS or electric vehicles, as well as
 26 changes in consumption patterns: rapid deployment of mitigation *technology* and *behaviour change* are
 27 thus two enabling conditions to accelerated mitigation. Dynamics of deployment of technologies are
 28 relatively well known, pointing to specific, short-term action to accelerate innovation and deployment
 29 (Cross-Chapter Box 12), whereas dynamics of collective behaviour change is less well understood.
 30 Arguably, the latter also facilitates shifting development pathways.

31

1 **Figure 4.8 Enabling conditions for accelerating mitigation and shifting development pathways towards**
2 **sustainability**

3 Individual enabling conditions are discussed at length in Chapter 5 (behaviour change), 13 (policies,
4 governance and institutional capacity), 15 (Finance) and 16 (Innovation). The purpose of the discussion
5 below is to draw operational implications from these chapters for action, taking into account the focus
6 of the present Chapter on action at the national level in the near- and mid-term, and its special emphasis
7 on shifting development pathways in addition to accelerated mitigation.

8 The rest of the section is organised as follows. Policy packages that combine climate and development
9 policies are first discussed (4.4.1.2). The next sections are dedicated to the conditions that facilitate
10 shifts in development pathways and accelerated mitigation: governance and institutions (4.4.1.3),
11 financial resources (4.4.1.4), behaviour change (4.4.1.5) and innovation (4.4.1.6). Four examples of
12 how climate and development policies can be combined to shift pathways and accelerate mitigation are
13 then presented (4.4.1.7, 4.4.1.8, 4.4.1.9 and 4.4.1.10). Section 4.4.2 focuses specifically on how shifts
14 in development pathways can deliver both mitigation and adaptation. Finally, 4.4.3 discusses risks and
15 uncertainties associated with combining shifting development pathways and accelerating mitigation.

16 **4.4.1.2 Policy packages that include climate and development policies**

17 Although many transformations in the past have been driven by the emergence and diffusion of an
18 innovative technology, policy intervention was frequent, especially in the more rapid ones (Grubb et al.
19 2021; Michaelowa et al. 2018). Likewise, it is not expected that spontaneous behaviour change or
20 market evolution alone yield the type of transformations outlined in the accelerated mitigation pathways
21 described in 4.2.5, or in the shifts in development pathways described in 4.3.3. On the contrary, stringent
22 temperature targets imply bold policies in the short term (Rockström et al. 2017; Kriegler et al. 2018)
23 to enforce effective existing policy instruments and regulations, as well as to reform or remove harmful
24 existing policies and subsidies (Díaz et al. 2019).

25 Policy integration, addressing multiple objectives, is an essential component of shifting development
26 pathways and accelerating mitigation (*robust evidence, high agreement*). A shift in development
27 pathways that fosters accelerated mitigation may best be achieved through integrated actions that
28 comprise policies in support of the broader SDG agenda, based on country-specific priorities (4.3.2,
29 13.8, 13.9). These may include for example, fiscal policies, or integrating industrial (Nilsson et al. 2021)
30 and energy policies (Fragkos et al. 2021) with climate policies. Similarly, sectoral transitions that aspire
31 to shifting development pathways towards sustainability often have multiple objectives, and deploy a
32 diverse mix or package of policies and institutional measures (Cross-Chapter Box 5).

33 Because low-carbon transitions are political processes, analyses are needed *of* policy as well as *for*
34 policy (13.6). Political scientists have developed a number of theoretical models that both *explain*
35 policy-making processes and provide useful insights for *influencing* those processes. Case studies of
36 successes and failures in sustainable development and mitigation offer equally important insights. Both
37 theoretical and empirical analysis reinforce the argument that single policy instruments are not
38 sufficient (*robust evidence, high agreement*). Policymakers might rather mobilise a range of policies,
39 such as financial instruments (taxes, subsidies, grants, loans), regulatory instruments (standards, laws,
40 performance targets) and processual instruments (demonstration projects, network management, public
41 debates, consultations, foresight exercises, roadmaps) (Voß et al. 2007). Policies can be designed to
42 focus on limiting or phasing out high-carbon technology. The appropriate mix is likely to vary between
43 countries and domains, depending on political cultures and stakeholder configurations (Rogge and
44 Reichardt 2016), but is likely to include a combination of: a) standards, nudges and information to
45 encourage low-carbon technology adoption and behavioural change; b) economic incentives to reward
46 low carbon investments; c) supply-side policy instruments including for fossil fuel production (to

1 complement demand-side climate policies) and d) innovation support and strategic investment to
2 encourage systemic change (Grubb 2014). These approaches can be mutually reinforcing. For example,
3 carbon pricing can incentivise low carbon innovation, while targeted support for emerging niche
4 technologies can make them more competitive encourage their diffusion and ultimately facilitate a
5 higher level of carbon pricing. Similarly, the success of feed-in tariffs in Germany only worked as well
6 as it did because it formed part of a broader policy mix including “supply-push” mechanisms such as
7 subsidies for research and “systemic measures” such as collaborative research projects and systems of
8 knowledge exchange (Rogge et al. 2015).

9 **4.4.1.3 Governance and institutional capacity**

10 Governance for climate mitigation and shifting development pathways is enhanced when tailored to
11 national and local contexts. Improved institutions and governance enable ambitious climate action and
12 help bridge implementation gaps (*medium evidence, high agreement*). Improving institutions involve a
13 broad range of stakeholders and multiple regional and temporal scales. It necessitates a credible and
14 trusted process for reconciling perspectives and balancing potential side-effects, managing winners and
15 losers and adopting compensatory measures to ensure an inclusive and just transition (Newell and
16 Mulvaney 2013; Miller and Richter 2014; Diffenbaugh and Burke 2019; Gambhir et al. 2018),
17 managing the risk of inequitable or non-representative power dynamics and avoiding regulatory capture
18 by special interests (Helsinki Design Lab 2014; Kahane 2019; Bouille et al. 2015).

19 Long experience of political management of change demonstrates that managing such risks is not easy,
20 and requires sufficiently strong and competent institutions (Stiglitz 1998). For example, shift away
21 from fossil fuel-based energy economy could significantly disrupt the status quo, leading to a stranding
22 of financial and capital assets and shifting of political-economic power. Ensuring the decision-making
23 process is not unduly influenced by actors with much to lose is key to managing a transformation.
24 Effective governance, as noted in Chapter 13, requires establishing strategic direction, coordination of
25 policy responses, and mediation among divergent interests. Among varieties of climate governance,
26 which institutions emerge is path-dependent, based on the interplay of national political institutions,
27 international drivers, and bureaucratic structures (Dubash 2021). Focused national climate institutions
28 to address these challenges are more likely to emerge, persist and be effective when they are consistent
29 with a framing of climate change that has broad national political support (*medium evidence, medium*
30 *agreement*) (4.5, 13.2, 13.5).

31 Innovative governance approaches can help meet these challenges (Clark et al. 2018; Díaz et al. 2019).
32 *Enabling multilevel governance*—i.e., better alignment across governance scales—and coordination of
33 international organisations and national governments can help accelerate a transition to sustainable
34 development and deep decarbonisation (Tait and Euston-Brown 2017; Michaelowa and Michaelowa
35 2017; Ringel 2017; Revi 2017; Cheshmehzangi 2016; IPCC 2018a). *Participatory and inclusive*
36 *governance*—partnerships between state and non-state actors—, and concerted effort across different
37 stakeholders are crucial in supporting acceleration (Roberts 2016; Hering et al. 2014; Figueres et al.
38 2017; Leal Filho et al. 2018; Burch et al. 2014; Lee et al. 2018; Clark et al. 2018). So do *partnerships*
39 *through transnational climate governance initiatives*, which coordinate nation-states and non-state
40 actors on an international scale (Hsu et al. 2018). Although they are unlikely to close the gap of the
41 insufficient mitigation effort of national governments (Michaelowa and Michaelowa 2017) (4.2.3), they
42 help building confidence in governments concerning climate policy and push for more ambitious
43 national goals (UNEP 2018b).

44 Meeting these challenges also requires enhanced institutional capacity and enhanced institutional
45 mechanisms to strengthen the coordination between multiple actors, improve complementarities and
46 synergies between multiple objectives (Rasul 2016; Ringel 2017; Liu et al. 2018) and pursue climate

1 action and other development objectives in an integrated and coherent way (Rogelj et al. 2018b; Von
2 Stechow et al. 2016; Fuso Nerini et al. 2019; Roy et al. 2018; McCollum et al. 2018), particularly in
3 developing countries (Adenle et al. 2017; Rosenbloom 2017). Institutional capacities to be strengthened
4 include vertical collaboration and interaction within Nation-States and horizontal collaboration (e.g.,
5 transnational city networks) for the development and implementation of plans, regulations and policies.
6 More specifically capacities include: capacity for knowledge harnessing and integration (from multiple
7 perspectives); for integrated policy design and implementation (Scott 2017); for long-term planning
8 (Lecocq et al. 2021) for monitoring and review process; for coordinating multi-actor processes to create
9 synergies and avoid trade-offs. As a result, institutions that enable and improve human capacities and
10 capabilities are a major driver of transformation. To this extent, promoting education, health care and
11 social safety, also are instrumental to undertake climate change mitigation and cope with environmental
12 problems (Winkler et al. 2007; Sachs et al. 2019). Given that strengthening institutions may be a long
13 term endeavour, it needs attention in the near-term.

14 **4.4.1.4 Channelling financial resources**

15 Accelerated mitigation and shifting development pathways necessitate both re-directing existing
16 financial flows from high- to low-emissions technologies and systems and providing additional
17 resources (*robust evidence, high agreement*). An example is changes in investments from fossil fuels to
18 renewable energy, with pressures to disinvest in the former while increasing levels of ‘green finance’
19 (6.7.4, 15.5). While some lower-carbon technologies have become competitive (1.4.3, 2.5), support
20 remains needed for the low-emissions options have higher costs per unit of service provided than high-
21 emission ones. Lack of financial resources is identified as a major barrier to the implementation of
22 accelerated mitigation and of shifts in development pathways. Overcoming this obstacle has two major
23 components. One relates to private capital. The other to public finance.

24 There is substantial amount of research on the redirection of private financial flows towards low-carbon
25 investment and the role of financial regulators and central banks, as detailed in Chapter 15. Financial
26 systems are an indispensable element of a systemic transition (Fankhauser et al. 2016; Naidoo 2020).
27 Policy frameworks can re-direct financial resources towards low-emission assets and services (UNEP
28 2015), mainstreaming climate finance within financial and banking system regulation, and reducing
29 transaction costs for bankable mitigation technology projects (Mundaca et al. 2013; Brunner and Enting
30 2014; Yeo 2019). Shifts in the financial system to finance climate mitigation and other SDGs can be
31 achieved by aligning incentives and investments with multiple objectives (UNEP Inquiry 2016).

32 Different approaches have been explored to improve such alignment (15.6), from national credit
33 policies to directly green mainstream financial regulations (e.g., through modifications in the Basel
34 rules for banks). For all approaches, an essential precondition is to assess and monitor the contribution
35 of financial flows to climate and sustainability goals, with better metrics that clearly link with financial
36 activity (Chenet et al. 2019). Enabling the alignment of investment decision-making with achieving
37 climate and broader sustainability goals includes acknowledgment and disclosure of climate-change
38 related risk and of risks associated with mitigation in financial portfolios. Current disclosures remain
39 far from the scale the markets need to channel investment to sustainable and resilient solutions (UNEP
40 - Finance Initiative 2020; Clark et al. 2018; Task Force on Climate-Related Financial Disclosures 2019;
41 IPCC 2018b). Disclosure, however, is not enough (Ameli et al. 2020). In addition, climate targets can
42 be translated into investment roadmaps and financing needs for financial institutions, both at national
43 and international level. Financing needs are usable for financial institutions, to inform portfolio
44 allocation decisions and financing priorities (Chenet et al. 2019). At the international level, for example,
45 technology roadmaps for key sectors can be translated into investment roadmaps and financing needs,
46 as shown by existing experiences in energy and industrial sectors (Chenet et al. 2019; WBSCD 2018;
47 International Energy Agency 2015)

1 The transition from traditional public climate finance interventions to the market-based support of
2 climate mitigation (Bodnar et al. 2018) demands innovative forms of financial cooperation and
3 innovative financing mechanisms to help de-risk low-emission investments and support new business
4 models. These financial innovations may involve sub-national actors like cities and regional
5 governments in raising finance to achieve their commitments (Cartwright 2015; CCFLA 2017).
6 Moreover, public-private partnerships have proved to be an important vehicle for financing investments
7 to meet the SDGs, including economic instruments for financing conservation (Sovacool 2013; Díaz et
8 al. 2019).

9 Overall, early action is needed to overcome barriers and to adjust the existing incentive system to align
10 national development strategies with climate and sustainable development goals in the medium-term.
11 Steckel et al. (2017) conclude that climate finance could become a central pillar of sustainable
12 development by reconciling the global goal of cost-efficient mitigation with national policy priorities.
13 Without a more rapid, scaled redeployment of financing, in development trajectories that hinder the
14 realisation of the global goals will be locked in (Zadek and Robins 2016). Investment might be designed
15 to avoid trading off the Paris goals against other SDGs, as well as those that simultaneously reduce
16 poverty, inequality, and emissions (Fuso Nerini et al. 2019).

17 At the national level, it is also essential to create public fiscal space for actions promoting the SDG
18 agenda and thereby broadening the scope of mitigation (*medium evidence, medium agreement*). To do
19 so, pricing carbon—either through tax payments based on the level of emissions or cap-and-trade
20 systems that limit total allowable emissions—is an efficient means of discouraging carbon emissions
21 throughout an economy (both in consumption and production) while simultaneously encouraging a
22 switch to non-carbon energy sources and generating revenues for prioritised actions (13.6.3). Regarding
23 to levels, the High-Level Commission on Carbon Prices concluded that “*carbon-price level consistent*
24 *with achieving the Paris temperature target is at least USD40–80/tCO₂ by 2020 and USD50–100/tCO₂*
25 *by 2030, provided a supportive policy environment is in place*” (CPLC 2017; Wall Street Journal 2019).
26 National level models yield median carbon values of carbon values of 733 USD/tCO₂ in 2050 along
27 accelerated mitigation pathways (4.2.6), while global models find a median value of 578 USD/tCO₂ for
28 pathways that reach net zero CO₂ between 2045 and 2055 [interquartile range 405-708] (3.6.1).

29 Carbon pricing, however, is designed to reduce its fiscal base. Fiscal space may therefore also need to
30 stem from other sources, although fiscal reforms are complex endeavours (4.4.1.8). For countries at
31 lower income levels, foreign aid can make an important contribution to the same agenda (Kharas and
32 McArthur 2019). It may also be noted that, according to estimates at the global level, military spending
33 amounted to USD1.748 trillion in 2012 (the last year with data), a figure that corresponded to 2.3
34 percent of GDP, 55 percent of government spending in education, and was 13 times the level of net
35 ODA (World Bank 2020; SIPRI 2020). Given this, moderate reductions in military spending (which
36 may involve conflict resolution and cross-country agreements on arms limitations) could free up
37 considerable resources for the SDG agenda, both in the countries that reduce spending and in the form
38 of ODA. The resolution of conflicts within and between countries before they become violent would
39 also reduce the need for public and private spending repairing human and physical damage. The fact
40 that civil wars are common in the countries that face the severest SDG challenges underscores the
41 importance of this issue (Collier 2007 pp.17-37).

42 **4.4.1.5 Changing behaviour and lifestyles**

43 Changes in behaviour and lifestyles are important to accelerated mitigation. Most global mitigation
44 pathways in line with likely below 2°C and 1.5°C temperature limits assume substantial behavioural
45 and societal change and low-carbon lifestyles (Luderer et al. 2018a; de Coninck et al. 2018; IPCC
46 2018a) (See also 3.3, and Table 4.9 and Figure 4.3 in IPCC SR 1.5). Chapter 5 concludes that

1 behavioural changes within transition pathways offer Gigaton-scale CO₂ savings potential at the global
2 level, an often overlooked strategy in traditional mitigation scenarios.

3 Individual motivation and capacity are impacted by different factors that go beyond traditional social,
4 demographic and economic predictors. However, it is unclear to what extent behavioural factors (i.e.,
5 cognitive, motivational and contextual aspects) are taken into account in policy design (Mundaca et al.
6 2019; Dubois et al. 2019). In fact, while economic policies play a significant role in influencing people's
7 decisions and behaviour, many drivers of human behaviour and values work largely outside the market
8 system (Díaz et al. 2019; Winkler et al. 2015) as actors in society, particularly individuals, do not
9 respond in an economically 'rational' manner based on perfect-information cost-benefit analyses
10 (Shiller 2019; Runge 1984). Rather, compelling narratives can drive individuals to adopt new norms
11 and policies. And norms can be more quickly and more robustly shifted by proposing and framing
12 policies designed with awareness of how framings interact with individual cognitive tendencies (van
13 der Linden et al. 2015). Transformative policies are thus much more likely to be successfully adopted
14 and lead to long-term behavioural change if designed in accordance with principles of cognitive
15 psychology (van der Linden et al. 2015), and with the deep understanding of decision-making offered
16 by behavioural science (UNEP 2017b). Similarly, given that present bias—being motivated by costs
17 and benefits that take effect immediately than those delivered later—significantly shapes behaviour,
18 schemes that bring forward distant costs into the present or that upfront incentives have proved to be
19 more effective (Zauberman et al. 2009; van den Broek et al. 2017; Safarzyńska 2018). Overall,
20 transformational strategies that align mitigation with subjective life satisfaction, and build societal
21 support by positive discourses about economic, social, and cultural benefits of low-carbon innovations,
22 promises far more success than targeting mitigation alone (Asensio and Delmas 2016; WBGU 2011;
23 Geels et al. 2017).

24 Climate actions are related to knowledge but even strongly to motivational factors (Hornsey et al. 2016;
25 Bolderdijk et al. 2013; Boomsma and Steg 2014), which explains the gap between awareness and action
26 (Ünal et al. 2018). Social influences, particularly from peers, affect people's engagement in climate
27 action (Schelly 2014). Role models appear to have a solid basis in people's everyday preferences
28 (WBGU 2011). Social norms can reinforce individuals' underlying motivations and be effective in
29 encouraging sustainable consumption patterns, as many examples offered by behavioural science
30 illustrate. Social networks also influence and spread behaviours (Service et al. 2014; Clayton et al. 2015;
31 Farrow et al. 2017; Shah et al. 2019). These social influences can be harnessed by climate policy.

32 Collective action by individuals as part of formal social movements or informal lifestyle movements
33 underpins system change (*robust evidence, high agreement*) (5.4, 5.5). Organisations are comprised of
34 individuals, but also become actors in their own right. Recent literature has considered the role of
35 coalitions and social movements in energy democracy and energy transitions towards sustainability
36 (Hess 2018). Other scholars have examined the role of women in redistributing power, both in the sense
37 of energy transition and in terms of gender relations (Allen et al. 2019; Routledge et al. 2018).
38 Mitigation and broader sustainable development policies that facilitate active participation by
39 stakeholders can build trust, forge new social contracts, and contribute to a positive cycle building
40 climate governance capacity (5.2.3).

41 However, behavioural change not embedded in structural change will contribute little to climate change
42 mitigation, suggesting that behavioural change is not only a function of individual agency but also
43 depends on other enabling factors, such as the provision of infrastructure and institutions (5.4).
44 Successful shifts towards public transport, for example, involve technologies (buses, trams),
45 infrastructure (light rail, dedicated bus lanes), regulations (operational licenses, performance contracts),

1 institutions (new organisations, responsibilities, oversight), and high-enough density, which in turns
2 depends on such choices as housing or planning policies (4.4.1.9).

3 **4.4.1.6 Fostering Technological Innovation**

4 As outlined in section 4.2.5, rapid, large-scale deployment of improved low-carbon technology is a
5 critical component of accelerated mitigation pathways. As part of its key role in technological change,
6 R&D can make a crucial contribution to accelerated mitigation up to 2030 and beyond, among other
7 things by focusing on closing technology gaps that stand in the way of decarbonising today’s high
8 emitting sectors. Such sectors include shipping, trucking, aviation and heavy industries like steel,
9 cement and chemicals. More broadly, it is increasingly clear that digital changes are becoming a key
10 driving force in societal transformation (Tegmark 2017). Digitalisation is not only an “instrument” for
11 resolving sustainability challenges, it is also a fundamental driver of disruptive, multiscale change
12 (Sachs et al. 2019) that amounts to a shift in development pathway. Information and communication
13 technologies, artificial intelligence, the internet of things, nanotechnologies, biotechnologies, robotics,
14 are not usually categorised as climate technologies, but have a potential impact on GHG emissions
15 (OECD 2017b) (Cross-Chapter Box 11).

16 The direction of innovation matters (*robust evidence, high agreement*). The research community has
17 called for more “responsible innovation” (Pandza and Ellwood 2013), “open innovation” (Rauter et al.
18 2019), “mission-oriented” innovation (Mazzucato and Semieniuk 2017), “holistic innovation” (Chen et
19 al. 2018b), “next-generation innovation policy” (Kuhlmann and Rip 2018) or “transformative
20 innovation” (Schot and Steinmueller 2018) so that innovation patterns and processes are commensurate
21 to our growing sustainability challenges. There is a growing recognition that new forms of innovation
22 can be harnessed and coupled to climate objectives (Fagerberg et al. 2016; Wang et al. 2018). As such,
23 innovation and sociotechnical change can be channelled to intensify mitigation via “deliberate
24 acceleration” (Roberts et al. 2018a) and “coalition building” (Hess 2018).

25 Innovation goes beyond technology. For example, decarbonisation in sectors with long lived capital
26 stock (such as heavy industry, buildings, transport infrastructure) entail technology, policy and
27 financing innovations (Bataille 2020). Similarly, expanding the deployment of photovoltaics can draw
28 upon policies that support specific technical innovations (e.g., to improve photovoltaics efficiency), or
29 innovations in regulatory and market regimes (e.g., net-metering), to innovations in social organisation
30 (e.g., community-ownership). System innovation is a core focus of the transitions literature (Grin et al.
31 2010; Markard et al. 2012; Geels et al. 2017). Accelerating low carbon transitions not only involves a
32 shift of system elements but also underlying routines and rules, and hence transitions shift the
33 directionality of innovation. They hence concern the development of a new paradigm or regime that is
34 more focused on solving sustainability challenges that cannot be solved within the dominant regime
35 they substitute (Cross-Chapter Box 12).

36 Several studies have pointed at the important possible contributions of grassroots innovators for the
37 start-up of sustainability transitions (Seyfang and Smith 2007; Smith et al. 2016; Seyfang et al. 2014).
38 In particular, a range of studies have shown that users can play a variety of roles in promoting system
39 innovation: shielding, nurturing (including learning, networking and visioning) and empowering the
40 niches in relation to the dominant system and regime (Schot et al. 2016; Randelli and Rocchi 2017;
41 Meelen et al. 2019). More fundamentally, innovation regimes can be led and guided by markets driven
42 by monetizable profits (as much of private sector led technological innovation of patentable intellectual
43 property), or prioritise social returns (e.g., innovation structures such as innovation prizes, public sector
44 innovation, investments in human capital, and socially-beneficial intellectual property regimes). In both
45 cases, public policies can play a key role by providing resources and favourable incentives (IEA 2020).
46 Chapter 16 provides more details on ways to foster innovation.

1 **4.4.1.7 Example: Structural change provides a way to keep jobs and mitigate**

2 Developing countries have experienced a period of rapid economic growth in the past two decades.
3 Patterns of growth have differed markedly across regions, with newly emerging East Asian economies
4 building on transition to manufacturing—as China has done in the past—while Latin American
5 countries tend to transition directly from primary sector to services (Rodrik 2016), and African countries
6 tend to rely on productivity improvements in the primary sectors (Diao et al. 2019). Yet many countries
7 still face the challenge of getting out of the “middle-income trap” (Agénor and Canuto 2015), as labour-
8 saving technological change and globalisation have limited options to develop via the manufacturing
9 sector (Altenburg and Rodrik 2017).

10 Looking ahead, several studies have illustrated how structural change towards sustainability could lead
11 to reduced emissions intensity and higher mitigative capacity. In China, for example, the shift away
12 from heavy industry (to light industry and services) has already been identified as the most important
13 force limiting emissions growth (Guan et al. 2018), and as a major factor for future emissions (Kwok
14 et al. 2018).

15 Overall, Altenburg et al. (2017) argue that reallocation of capital and labour from low- to high-
16 productivity sectors—i.e., structural change—remains a necessity, and that it is possible to combine it
17 with reduced environmental footprint (including, but not limited to, mitigation). They argue that this
18 dual challenge calls for structural transformation policies different from those implemented in the past,
19 most importantly through a “systematic steering of investment behaviour in a socially agreed direction”
20 and encompassing policy coordination (*limited evidence, medium agreement*).

21 In order to permit progress on their SDG agendas, it is essential that countries develop visions of their
22 future decarbonised sectoral production structure, including its ability to generate growth in incomes,
23 employment and foreign exchange earnings. as well as the related spatial distribution of production,
24 employment, and housing. To this extent, governance and institutional capacity matter, such as
25 availability of tools to support long-term planning. A sectoral structure that permits strong growth is
26 essential given strong associations between growth in per-capita incomes and progress on most SDGs
27 (including those related to poverty; health; education; and access to water, sanitation, electricity, and
28 roads; but not income equality), in part due to the fact that higher incomes provide both households and
29 governments with resources that at least in part would be used to promote SDGs (Gable et al. 2015).

30 The future viability of sectors will depend on the extent to which they can remain profitable while
31 relying on lower-carbon energy. The challenge to identify alternative sectors of growth is particularly
32 acute for countries that today depend on oil and natural gas for most of their foreign exchange and
33 government revenues (Mirzoev et al. 2020). Changes in economic structure will also have gender
34 implications since the roles of men and women vary across sectors. For example, in many developing
35 countries, sectors in which women play a relatively important role, including agriculture and unpaid
36 household services like collection of water and fuel wood, may be negatively affected by climate change
37 (Roy 2018). It may thus be important to take complementary actions to address the gender implications
38 of changes in economic structure.

39 Given strong complementarities between policies discussed above, an integrated policy approach is
40 crucial. For example, as suggested, the actions that influence the pace at which GHG emissions can be
41 cut with political support may depend on taxation (including carbon taxes), investments in
42 infrastructure, spending on R&D, changes in income distribution (influenced by transfers), and
43 communication. In this light, it is important to consider the demands that alternative policy packages
44 put on government policy-making efficiency and credibility as well as the roles of other enabling
45 conditions. In fact, plans to undertake major reforms may provide governments with impetus to

1 accelerate the enhancement of their capacities as part of the preparations (Karapin 2016; Jakob et al
2 2019; Withana & Sirini 2016).

3 **4.4.1.8 Example: Embedding carbon finance in broader fiscal reforms offers a way to mitigate and** 4 **rethink the social contract**

5 In many countries, fiscal systems are currently under stress to provide resources for the implementation
6 of development priorities, such as, for example, providing universal health coverage and other social
7 services (Meheus and McIntyre 2017) or sustainably funding pension systems in the context of aging
8 populations (Asher and Bali 2017; Cruz-Martinez 2018). Overall, Baum et al. (2017) argue that low-
9 income countries are likely not to have the fiscal space to undertake the investment entailed in reaching
10 the SDGs. To create additional fiscal space, major options include improving tax recovery, reducing
11 subsidies and levying additional taxes.

12 Mitigation offers an opportunity to create additional fiscal space, and thus to serve the objectives
13 outlined above, by creating a new source of revenue for the government via carbon taxation or emissions
14 permit auctioning and by reducing existing expenditures via reduction in subsidies to fossil-fuel. The
15 1991 tax reform in Sweden is an early example in which environmental taxation (including, but not
16 limited to, fossil fuel taxation) was introduced as part of a package primarily aimed at lowering the
17 marginal tax rates (more than 80% at the time), at reducing other taxes, while keeping most of the
18 welfare state. To do so, the tax base was broadened, including through environmental and carbon
19 taxation (Stern 2007). Once in place, the carbon tax rate was substantially ramped up over time, and
20 its base broadened (Criqui et al. 2019).

21 The future potential for using carbon taxation as a way to provide space for fiscal reform has been
22 highlighted in the so-called “green fiscal reform” literature (Vogt-Schilb et al. 2019). The potential is
23 large, since only 13 percent of global GHG emissions were covered by carbon pricing schemes in 2019
24 (Watts et al. 2019) and since many countries price carbon negatively by subsidising fossil fuel use, thus
25 generating effects that are the opposite of those that positive carbon prices hope to promote. In 2018,
26 the global subsidy value amounted to \$427 billion, i.e., some 10 times the payment for carbon use
27 (Watts et al. 2019). However, the size of the potential for creating fiscal space varies strongly across
28 countries given differences in terms of current carbon prices and fuel subsidies.

29 The limited adoption of and political support for carbon pricing may be explained by the fact that most
30 of the gains occur in the future and depend on actions across the globe, making them seem abstract and
31 unpredictable, whereas the costs in the form of higher carbon prices are immediate (Karapin 2016).
32 Furthermore, the links between carbon pricing and emissions may not be clear to the public who, in
33 addition, may not trust that the government will use budgetary savings according to stated plans. The
34 latter may be due to various factors, including a history of limited government commitment and
35 corruption (Maestre-Andrés et al 2019 ; Withana & Sirini 2016; Chadwick 2017).

36 The literature reports limited systematic evidence based on *ex post* analysis of the performance of
37 carbon pricing—carbon taxes and greenhouse gas (GHG) emissions trading systems (ETSs) (Haites
38 2018). Performance assessment is complicated by the effect of other policies and exogenous factors.
39 (Haites 2018) suggests that since 2008, other policies have probably contributed more to emission
40 reductions than carbon taxes, and most tax rates are too low to achieve mitigation objectives. Emissions
41 under ETSs have declined, with the exception of four systems without emissions caps (ibid). Every
42 jurisdiction with an ETS and/or carbon tax also has other policies that affect its GHG emissions.

43 To help policymakers overcome obstacles, research has reviewed the international experience from
44 carbon pricing reforms. Elimination of fossil fuel subsidies, equivalent to the elimination of negative
45 carbon prices, have been more successful when they have included complementary and transparent

1 measures that enjoy popular support, accompanied by a strong communications component that
2 explains the measures and stresses their benefits (Rentschler and Bazilian 2017; Withana & Sirini 2016;
3 Maestre-Andrés et al 2019).

4 Part of the losses (and related calls for compensation or exemptions) due to carbon pricing are related
5 to the fact that it hurts the competitiveness of sectors that face imports from countries with lower carbon
6 prices, leading to “carbon leakage” if carbon-intensive production (and related jobs) migrates from
7 countries with relatively high carbon prices. Research confirms that a border carbon tax (or adjustment),
8 set on the basis of the carbon content of the import, including a downward adjustment on the basis of
9 any carbon payments (taxes or other) already made before entry, could reduce carbon leakage while
10 also raising additional revenue and encouraging carbon pricing in the exporting country (Withana &
11 Sirini 2016; Cosbey et al 2019).

12 The timing of carbon pricing reforms is also important: they are more likely to succeed if they exploit
13 windows of opportunity provided by events that raise awareness of the costs of carbon emissions (like
14 bouts of elevated local air pollution or reports about the role of emissions in causing global warming),
15 as well as momentum from climate actions by other countries and international climate agreements
16 (Karapin 2016; Jakob et al 2019). It is also important to consider the level of international prices of
17 carbon energy: when they are low, consumer resistance would be smaller since prices will remain
18 relatively low, though the tax may become more visible when energy prices increase again. As part of
19 ongoing efforts to accelerate mitigation, such tax hikes may be crucial to avoid a slow-down in the shift
20 to renewable energy sources (Rentschler and Bazilian 2017; Withana & Sirini 2016). In countries that
21 exports carbon energy, carbon taxation may run into additional resistance from producers.

22 There is also considerable literature providing insights on the political and social acceptability of carbon
23 taxes, suggesting for example that political support may be boosted if the revenue is recycled to the tax
24 payers or earmarked for areas with positive environmental effects (e.g., (Bachus et al. 2019) for
25 Belgium, and (Beiser-McGrath and Bernauer 2019) for Germany and the USA), as well as on the
26 difficulties associated with political vagaries (and economic consequences thereof) associated with the
27 introduction of such instruments (Pereira et al. 2016). Similarly, “best practice” have been drawn from
28 past experience on fossil-fuel subsidy reforms (Sovacool 2017; Rentschler and Bazilian 2017). Specific
29 policies, however, depend on societal objectives, endowments, structure of production, employment,
30 and trade, and institutional structure (including the functioning of markets and government capacity)
31 (Kettner et al. 2019). As noted in Section 4.2.6, macroeconomic analysis finds that the overall economic
32 implications of carbon pricing differ markedly depending on the way the proceeds from carbon pricing
33 are used, and thus on the way the fiscal system is reformed, with potential for double dividend if the
34 proceeds from the tax are used to repeal the most distortive taxes in the economy.

35 In the context of this section on development pathways, it is worth emphasising that potential revenues
36 drawn from the climate mitigation component of the fiscal reform varies strongly with the context, and
37 may not be sufficient to address the other objectives pursued. Even if the carbon price is high, the
38 revenue it generates may be moderate as a share of GDP and eventually it will be zero if emissions are
39 eliminated. For example, Jakob et al. (2016) find that the carbon pricing revenues that most countries
40 in Sub-Saharan Africa could expect to generate only would meet a small part of their infrastructure
41 spending needs. In Sweden, the country with the highest carbon tax rate in the world, the tax has not
42 been a significant part of total tax revenues. Moreover, emissions from sectors covered by the tax have
43 shrunk and, as a result, the revenues from the tax, as a share of GDP, have also declined, from a peak
44 of 0.93 percent in 2004, when the rate was USD109 per metric ton of CO₂, to 0.48 per cent in 2018,
45 when the rate had reached USD132 (Jonsson et al. 2020; Statistics Sweden 2020). This means that
46 governments that want to avoid a decline in the GDP share for total tax revenues over time would have

1 to raise the intake from other taxes. However, it is here important to note that domestic tax hikes are
2 likely to involve trade-offs since, at the same time as the spending they fund may provide various
3 benefits, they may also reduce the capacity of households and the private sector to consume and invest,
4 something that may reduce growth over time and reduced resources for spending in support of human
5 development (Lofgren et al. 2013). It is also worth emphasising that restructuring of the fiscal system
6 amount to changes in the social contract of the society (Combet and Hourcade 2017, 2014), and thus
7 represents a major economic and social decision.

8 **4.4.1.9 Example: Combining housing policies with carbon taxation can deliver both housing and** 9 **mitigation in the transport sector**

10 The spatial distribution of households and firms across urban and rural areas is a central characteristic
11 of development pathways. Patterns of urbanisation, territorial development, and regional integration
12 have wide-ranging implications for economic, social and environmental objectives (World Bank 2009).
13 Notably, choices regarding spatial forms of development have large-scale implications for demand for
14 transportation and associated GHG emissions.

15 Exclusionary mechanisms such as decreasing accessibility and affordability of inner-urban
16 neighbourhoods is a major cause of suburbanisation of low- to middle-income households (e.g.,
17 (Hochstenbach and Musterd 2018). Suburbanisation, in turn, is associated with higher transportation
18 demand (Bento et al. 2005) and higher carbon footprints for households (Jones and Kammen 2014).
19 Similarly, other studies find a significant positive link between housing prices and energy demand
20 (Lampin et al. 2013).

21 Reducing emissions from transport in cities through traditional climate policy instruments (e.g., through
22 a carbon tax) is more difficult when inner-urban neighbourhoods are less accessible and less affordable,
23 because exclusionary mechanisms act as a countervailing force to the rising transportation costs induced
24 by the climate policy, pushing households outwards rather than inwards. Said differently, the costs of
25 mitigating intra-city transportation emissions are higher when inner-urban housing prices are higher
26 (Lampin et al. 2013).

27 This suggests that policies making inner-urban neighbourhoods more accessible and more affordable
28 can open up broader opportunities for suburban households to relocate in the face of increasing
29 transportation costs. This is particularly important for low- and middle-income households, who spend
30 a greater portion of their income on housing and transportation, and are more likely to be locked into
31 locations that are distant from their jobs. Making inner-urban neighbourhoods more accessible and more
32 affordable has the potential to reduce both the social costs—e.g., households feeling helpless in front
33 of rising fuel prices—and the economic costs of mitigation policies—as a lower price of carbon is likely
34 to achieve the same amount of emission reductions since households have more capacities to adjust.

35 Making inner-cities neighbourhoods more accessible and more affordable is a complex endeavour
36 (Benner and Karner 2016). At the same time, it is already a policy objective in its own right in many
37 countries, independent of the climate mitigation motivation, for a range of social, health and economic
38 reasons. Revenues derived from climate policies could provide additional resources to support such
39 programs, as some climate policy already have provisions to use their revenues towards low-income
40 groups (Karner and Marcantonio 2018). The mitigation benefits of keeping inner-cities more accessible
41 and affordable for low- and middle-income households often remains out of, or is only emerging in the
42 debates surrounding the planning of fast-developing cities in many developing countries (Grant 2015;
43 IADB 2012; Khosla and Bhardwaj 2019). Finally, from a political economy perspective, it is also
44 interesting to note that (Bergquist et al. 2020) find higher support for climate policy packages in the
45 U.S. when affordable housing programs are included.

1 In addition, investment in infrastructure is critical to the development of decarbonised economic
2 structures that generate growth, employment, and universal access to a wide range of services that are
3 central to the SDG agenda: transportation, water, sanitation, electricity, flood protection, and irrigation.
4 For low- and middle-income countries, annual costs of reaching these goals by 2030 and putting their
5 economies on a path toward decarbonisation may range between 2 and 8 percent of GDP, with the level
6 depending on spending efficiency. Notably, these costs need not exceed those of more polluting
7 alternatives (Rozenberg and Fay 2019). For transportation, this involves a shift toward more public
8 transportation (rail and bus), and decarbonised electricity for vehicles, combined with land-use policies
9 that densify cities and reduce distances between homes and jobs. By influencing the spatial distribution
10 of households and firms and the organisation of transportation, infrastructure has a strong bearing on
11 GHG emissions and the costs of providing services to different populations. Depending on country
12 context, the private sector may play a particularly important role in the financing of infrastructure
13 (World Bank 2009; Klein 2015).

14 Many investments in infrastructure and sectoral capital stocks have long lifetimes. Given this, it may
15 be important to make sure that today's investments be fully decarbonised at the start or that they later
16 can be converted to zero carbon. Today's investments in electric vehicles in settings where electricity
17 is produced with fossil fuels is an example of convertible investments—they will be decarbonised once
18 electricity production has switched to renewable energies. For capital stocks that cannot be
19 decarbonised, countries may face costs of decommissioning well before the end of their useful lifetimes,
20 especially when it is needed to respect country commitments to future full decarbonisation.

21 **4.4.1.10 Example: Changing economic, social and spatial patterns of development of the agriculture**
22 **sector provide the basis for sustained reductions in emissions from deforestation**

23 A growing literature assesses co-benefits of sectoral policies that lead to decarbonisation and
24 simultaneously promote economic development, improve living standards, reduce inequality, and create
25 job opportunities (Bataille et al. 2018; Pye et al. 2016; Maroun and Schaeffer 2012; Richter et al. 2018;
26 Bataille et al. 2016b; La Rovere et al. 2018; Waisman et al. 2019). While this may be particularly
27 challenging in developing countries, given large populations still lacking basic needs, previous
28 development paths show that finding synergies in development and climate objectives in the AFOLU
29 sector is possible. One example is Brazil, which has arguably shifted its development pathway to reduce
30 emissions and make progress towards several SDGs, though progress is not linear. Over the past two
31 decades, Brazil had made remarkable progress in implementing a sequence of policies across multiple
32 sectors. This policy package simultaneously increased minimum wages of low income families,
33 achieved universal energy access, and raised the quality of life and well-being for the large majority of
34 the population (Da Silveira Bezerra et al. 2017; Grottera et al. 2018, 2017; La Rovere et al. 2018). This
35 led to significant social benefits, reduction of income inequality and poverty eradication (Da Silveira
36 Bezerra et al. 2017; Grottera et al. 2017), reflected in a decrease of the Gini coefficient and a rise in the
37 human development index (La Rovere 2017).

38 Regulatory instruments were used to limit deforestation rates, together with implemented economic
39 instruments that provided benefits to those protecting local ecosystems and enhancing land-based
40 carbon sinks (Soterroni et al. 2019, 2018; Bustamante et al. 2018; Nunes et al. 2017). In parallel, public
41 policies reinforced environmental regulation and command-and-control instruments to limit
42 deforestation rates and implemented market-based mechanisms to provide benefits to those protecting
43 local ecosystems and enhancing land-based carbon sinks (Sunderlin et al. 2014; Hein et al. 2018;
44 Simonet et al. 2019; Nunes et al. 2017). The private sector, aligned with public policies and civil society,
45 implemented the Amazon Soy Moratorium, a voluntary agreement that bans trading of soybeans from
46 cropland associated with cleared Amazon rainforest and blacklists farmers using slave labour. This was
47 achieved without undermining production of soybean commodities (Soterroni et al. 2019). As a result,

1 between 2005 and 2012, the country halved its GHG emissions and reduced the rate of deforestation by
2 78 per cent (INPE 2019a,b). This example shows that development delivering well-being can be
3 accompanied by significant mitigation. A long-term and strategic vision was important in guiding
4 enabling policies and mechanisms.

5 In more recent years, some of these shifts in Brazil's development pathways were undone. Political
6 changes have redefined development priorities, with higher priority being given to agricultural
7 development than climate change mitigation. The current administration has reduced the power of
8 environmental agencies and forestry protection laws (including the forest code), while allowing the
9 expansion of cropland to protected Amazon rainforest areas (Ferrante and Fearnside 2019; Rochedo et
10 al. 2018). As a result, in 2020, deforestation exceeded 11,000 km², and reached the highest rate in the
11 last 12 years (INPE 2020). The literature cautions that, if current policies and trends continue, the
12 Amazon may reach an irreversible tipping point beyond which it will be impossible to remediate lost
13 ecosystems and restore carbon sinks and indigenous people knowledge (Nobre 2019; Lovejoy and
14 Nobre 2018; INPE 2019a). In addition, fossil fuel subsidies and other fiscal support of increased
15 exploitation of oil resources may create carbon lock-ins that further inhibit low-carbon investments
16 (Lefèvre et al. 2018).

17 Brazil's progress in mitigation depended significantly on reduced deforestation in the past. If
18 deforestation rates keep on rising, mitigation efforts would need to shift to the energy sector. However,
19 according to Rochedo et al. (2018), mitigation costs in the energy sector in Brazil are three times the
20 costs of reducing deforestation and increasing land-based carbon sinks. Further mitigation strategies
21 may depend on CCS in Brazil as elsewhere (Nogueira de Oliveira et al. 2016; Herreras Martínez et al.
22 2015), though the economic feasibility of deployment is not yet clear (4.2.5.4).

23 **4.4.2 Adaptation, development pathways and mitigation**

24 Mitigation actions are strongly linked to adaptation. These connections come about because mitigation
25 actions can be adaptive (e.g., some agroforestry projects) but also through policy choices (e.g., climate
26 finance is allocated among adaptation or mitigation projects) and even biophysical links (e.g., climate
27 trajectories, themselves determined by mitigation, can influence the viability of adaptation projects).
28 As development pathways shape the levers and enablers available to a society (4.3.1, Figure 4.7), a
29 broader set of enabling conditions also helps with adaptation (*medium evidence, high agreement*).

30 Previous assessments have consistently recognised this linkage. The Paris Agreement includes
31 mitigation and adaptation as key areas of action, through NDCs and communicating adaptation actions
32 and plans. The Agreement explicitly recognises that mitigation co-benefits resulting from adaptation
33 can count towards NDC targets. The IPCC Fifth Assessment Report (IPCC 2014) emphasised that
34 sustainable development is helpful in going beyond a narrow focus on separate mitigation and
35 adaptation options and their specific co-benefits. The IPCC Special Report on climate change and land
36 addresses GHG emissions from land-based ecosystems with a focus on the vulnerability of land-based
37 systems to climate change. The report identifies the potential of changes to land use and land
38 management practices to mitigate and adapt to climate change, and to generate co-benefits that help
39 meet other SDGs (Jian et al. 2019).

40 A substantial literature detailing trade-offs and synergies between mitigation and adaptation exists and
41 is summarised in the IPCC SR15 including energy system transitions; land and ecosystem transitions
42 (including addressing food system efficiency, sustainable agricultural intensification, ecosystem
43 restoration); urban and infrastructure system transitions (including land use planning, transport systems,
44 and improved infrastructure for delivering and using power); industrial system transitions (including
45 energy efficiency, bio-based and circularity, electrification and hydrogen, and industrial Carbon

1 Capture, Utilisation and Storage (CCUS); and carbon dioxide removal (including bioenergy with CCS,
2 afforestation and reforestation, soil carbon sequestration, and enhanced weathering.) (IPCC 2018:
3 supplementary information Table 4.SM.5.1). Careful design of policies to shift development pathways
4 towards sustainability can increase synergies and manage trade-offs between mitigation and adaptation
5 (*robust evidence, medium agreement*).

6 This section examines how development pathways can build greater adaptive and mitigative capacity,
7 and then turns to several examples of mitigation actions with implications for adaptation where there is
8 a notable link to development pathways and policy choices. These examples are in the areas of
9 agriculture, blue carbon and terrestrial ecosystem restoration.

10 **4.4.2.1 Development pathways can build greater capacity for both adaptation and mitigation**

11 Previous IPCC assessments have reflected on making development more sustainable (Fleurbaey et al.
12 2014; Sathaye et al. 2007; IPCC et al. 2001). Other assessments have highlighted how ecosystem
13 functions can support sustainable development and are critical to meeting the goals of the Paris
14 Agreement (IPBES 2019b). IPCC SR15 found that sustainable development pathways to 1.5 °C broadly
15 support and often enable transformations and that “sustainable development has the potential to
16 significantly reduce systemic vulnerability, enhance adaptive capacity, and promote livelihood security
17 for poor and disadvantaged populations (*high confidence*)” (IPCC 2018b: 5.3.1). With careful
18 management, shifting development pathways can build greater adaptive and mitigative capacity, as
19 further confirmed in recent literature (Schramski et al. 2018; Harvey et al. 2014; Ebi et al. 2014;
20 Rosenbloom et al. 2018; Antwi-Agyei et al. 2015; Singh 2018; IPBES 2019b). The literature points to
21 the challenge of design of specific policies and shifts in development pathways to achieve both
22 mitigation and adaptation goals.

23 **Governance and Institutional capacity**

24 Governance and institutional capacity necessary for mitigation actions also enables effective adaptation
25 actions. Implementation of mitigation and adaptation actions can, however, encounter different sets of
26 challenges. Mitigation actions requiring a shift away from established sectors and resources (e.g., fossil
27 fuels) entail governance challenges to overcome vested interests (SEI et al. 2020; Piggot et al. 2020).
28 Mitigation-focused initiatives from non-state actors tend to attain greater completion than adaptation-
29 focused initiatives (NewClimate Institute et al. 2019).

30 **Behaviour and lifestyles**

31 On the level of individual entities, adaptation is reactive to current or anticipated environmental changes
32 but mitigation is undertaken deliberately. Chapter 5 considers behavioural change, including the
33 reconsideration of values and what is meant by well-being, and reflecting on a range of actors addressing
34 both adaptation and mitigation. Shifting development pathways may be disruptive (Cross Chapter Box
35 5), and there may be limits to propensity to change. Some studies report that climate change deniers
36 and sceptics can be induced to undertake pro-environmental action if those actions are framed in terms
37 of societal welfare, not climate change (Bain et al. 2012; Hornsey et al. 2016). Concrete initiatives to
38 change behaviour and lifestyles include the Transition Town movement, which seeks to implement a
39 just transition—both in relation to adaptation and mitigation—in specific localities (Roy et al. 2018).

40 **Finance**

41 Finance and investment of mitigation actions must be examined in conjunction with funding of
42 adaptation actions, due to biophysical linkages and policy trade-offs (Box 15.1). Most climate funding
43 supports mitigation efforts, not adaptation efforts (Buchner et al. 2019) (Halimanjaya and Papyrakis
44 2012). Mitigation projects are often more attractive to private capital (Abadie et al. 2013; Buchner et
45 al. 2019). Efforts to integrate adaptation and mitigation in climate change finance are limited (Locatelli
46 et al. 2016; Kongsager et al. 2016) There is a perception that integration of mitigation and adaptation

1 projects would lead to competition for limited finance available for adaptation (Locatelli et al. 2016).
2 Long-standing debates (Ayers and Huq 2009; Smith et al. 2011) whether development finance counts
3 as adaptation funding remain unresolved. See chapter 15 for more in-depth discussion relating
4 investment in funding mitigation and adaptation actions.

5 ***Innovation and technologies***

6 Systems transitions that address both adaptation and mitigation include the widespread adoption of new
7 and possibly disruptive technologies and practices and enhanced climate-driven innovation (IPCC
8 2018a). See Chapter 16 for an in-depth discussion of innovation and technology transfer. The literature
9 points to trade-offs that developing countries face in investing limited resources in research and
10 development, though finding synergies in relation to agriculture (Adenle et al. 2015). Other studies
11 point to difference in technology transfers for adaptation and mitigation (Biagini et al. 2014).
12 Adaptation projects tend to use existing technologies whereas mitigation climate actions are more likely
13 to rely on novel technologies. Innovations for mitigation are typically technology transfers from
14 developed to less-developed countries (Biagini et al. 2014), however this so-called North-South
15 technology transfer pathway is not exclusive (Biagini et al. 2014), and is increasingly challenged by
16 China's global role in implementing mitigation actions (Chen 2018; Urban 2018). Indigenous
17 knowledge can be a unique source for techniques for adaptation (Nyong et al. 2007) and may be
18 favoured over externally generated knowledge (Tume et al. 2019).

19 ***Policy***

20 Adaptation-focused pathways might reduce inequality, if adequate support is available and well-
21 distributed (Pelling and Garschagen 2019). Some studies suggest that cities might plan for possible
22 synergies in adaptation and mitigation strategies, currently done independently (Grafakos et al. 2019).
23 The literature suggests that cities might identify both mitigation and adaptation as co-benefits of
24 interventions targeted at developmental goals (Dulal 2017).

25 ***4.4.2.2 Specific links between mitigation and adaptation***

26 Mitigation actions can be adaptive and vice-versa. In particular, many nature-based solutions (NBS) for
27 climate mitigation are adaptive (*medium evidence, medium agreement*). Multiple NBS are being
28 pursued under current development pathways (see Chapter 7), but shifting to sustainable development
29 pathways may enable a wider set of nature-based mitigation solutions with adaptation benefits. An
30 example of this would be a shift to more sustainable diets through guidelines, carbon taxes, or
31 investment in R&D of animal product substitutes (Figure 13.2) which could reduce pressure on land
32 and allow for implementation of multiple NBS. Many of these solutions are consistent with meeting
33 other societal goals, including biodiversity conservation and other sustainable development goals
34 (Griscom et al. 2017; Tallis et al. 2018; Fargione et al. 2018). However, there can be synergies and
35 trade-offs in meeting a complex set of sustainability goals (e.g., biodiversity, see 7.6.5 and 3.1.5).

36 Development is a key factor leading to land degradation in many parts of the world (IPBES 2019b).
37 Shifting development pathways to sustainability can include restoration and protection of ecosystems,
38 which can enhance capacity for both mitigation and adaptation actions (IPBES 2019b).

39 In this section, we explore mitigation actions related to sustainable agriculture, coastal ecosystems
40 ("blue carbon"), and restoration and protection of some terrestrial ecosystems. These mitigation actions
41 are exemplary of trade-offs and synergies with adaptation, sensitivity to biophysical coupling, and
42 linkages to development pathways. Other specific examples can be found in Chapters 6 to 11.

43 ***Farming system approaches can benefit mitigation and adaptation***

44 Farming system approaches can be a significant contributor to mitigation pathways. These practices
45 (which are not mutually exclusive) include agroecology, conservation agriculture, integrated production

1 systems and organic farming (Box 7.5). Such methods have potential to sequester significant amounts
2 of soil carbon (7.4.3.1) as well as reduce emissions from on-field practices such as rice cultivation,
3 fertilizer management, and manure management (7.4.3) with total mitigation potential of 3.9 ± 0.2
4 $\text{GtCO}_2\text{-eq yr}^{-1}$ (Chapter 7). Critically, these approaches may have significant benefits in terms of
5 adaptation and other development goals.

6 Farming system approaches to agricultural mitigation have a wide variety of co-benefits and tradeoffs.
7 Indeed, there are conceptual formulations for these practices in which the co-benefits are more of a
8 focus, such as climate-smart agriculture (CSA) which ties mitigation to adaptation through its three
9 pillars of increased productivity, mitigation, and adaptation (Lipper et al. 2014). The ‘4 per 1000’ goal
10 to increase soil carbon by 0.4% per year (Soussana et al. 2019) is compatible with the three pillars of
11 CSA. Sustainable intensification, a framework which centers around a need for increased agricultural
12 production within environmental constraints also complements CSA (Campbell et al. 2014). The
13 literature reports examples of mitigation co-benefits of adaptation actions, with evidence from various
14 regions (Chapter 7, Thornton and Herrero (2015), Thornton et al. (2018)).

15 Conservation agriculture, promoted for improving agricultural soils and crop diversity (Powlson et al.
16 2016) can help build adaptive capacity (Smith et al. 2017; Pradhan et al. 2018a) and yield mitigation
17 co-benefits through improved fertiliser use or efficient use of machinery and fossil fuels (Cui et al.
18 2018; Harvey et al. 2014; Pradhan et al. 2018a).

19 There is a complex set of barriers to implementation of farming-system approaches for climate
20 mitigation (7.6.4), suggesting a need for deliberate shifts in development pathways to achieve
21 significant progress in this sector. The link between NDCs and mitigation in the land use sector can
22 provide impetus for such policies. For example, there are multiple agricultural mitigation options that
23 southeast Asian countries could use to meet NDCs that would have an important adaptive impact
24 (Amjath-Babu et al. 2019).

25 Some agricultural practices considered sustainable have trade-offs, and their implementation can have
26 negative effects on adaptation or other ecosystem services. Fast-growing tree monocultures or biofuel
27 crops may enhance carbon stocks but reduce downstream water availability and decrease availability of
28 agricultural land (Windham-Myers et al. 2018; Kuwae and Hori 2019). In some dry environments
29 similarly, agroforestry can increase competition with crops and pastures, decreasing productivity, and
30 reduce catchment water yield (Schroback et al. 2011).

31 Agricultural practices can adapt to climate change while decreasing CO_2 emissions on the farm field.
32 However, if such a practice leads to lower yields, interconnections of the global agricultural system can
33 lead to land use change elsewhere and a net increase in GHG emissions (Erb et al. 2016).
34 Implementation of sustainable agriculture can increase or decrease yields depending on context (Pretty
35 et al. 2006).

36 ***Blue carbon and mitigation co-benefits of adaptation actions***

37 The Paris Agreement recognises that mitigation co-benefits resulting from Parties’ adaptation actions
38 and/or economic diversification plans can contribute to mitigation outcomes (UNFCCC 2015: Article
39 4.7). Blue carbon refers to biologically-driven carbon flux or storage in coastal ecosystems such as
40 seagrasses, salt marshes, and mangroves (Wylie et al. 2016; Fennessy et al. 2019; Fourqurean et al.
41 2012; Tokoro et al. 2014) (see Cross-Chapter Box 8 on blue carbon as a storage medium and removal
42 process).

43 Restoring or protecting coastal ecosystems is a mitigation action with synergies with adaptation and
44 development. Such restoration has been described as a ‘no regrets’ mitigation option in the Special
45 Report on the Ocean and Cryosphere in a Changing Climate (Bindoff et al. 2019) and advocated as a

1 climate solution at national scales (Bindoff et al. 2019; Taillardat et al. 2018; Fargione et al. 2018) and
2 global scales (Howard et al. 2017). On a per-area basis, carbon stocks in coastal ecosystems can be
3 higher than in terrestrial forests (Howard et al. 2017), with below-ground carbon storage up to 1000 tC
4 ha⁻¹ (Crooks et al. 2018; McLeod et al. 2011; Bindoff et al. 2019). Overall, coastal vegetated systems
5 have a mitigation potential of around 0.5% of current global emissions, with an upper limit of less than
6 2% (Bindoff et al. 2019).

7 Restoration or protection of coastal ecosystems is an important adaptation action with multiple benefits,
8 with bounded global mitigation benefits (Gattuso et al. 2018; Bindoff et al. 2019). Such
9 restoration/preservation reduces coastal erosion and protects from storm surges, and otherwise mitigates
10 impacts of sea level rise and extreme weather along the coast line (Siikamäki et al. 2012; Romañach et
11 al. 2018; Alongi 2008). Restoration of tidal flow to coastal wetlands inhibits methane emissions which
12 occur in fresh and brackish water (Kroeger et al. 2017) (7.4.2.8 describes a more inclusive set of
13 ecosystem services provided by coastal wetlands). Coastal habitat restoration projects can also provide
14 significant social benefits in the form of job creation (through tourism and recreation opportunities), as
15 well as ecological benefits through habitat preservation (Edwards et al. 2013; Sutton-Grier et al. 2015;
16 Sutton-Grier and Moore 2016; Kairo et al. 2018; Wylie et al. 2016; Bindoff et al. 2019).

17 Coastal ecosystem-based mitigation can be cost-effective, but interventions should be designed with
18 care. One concern is to assure that actions remain effective at higher levels of climate change (Alongi
19 2015; Bindoff et al. 2019). Also, methane emissions from ecosystems may partially reduce the benefit
20 of the carbon sequestration (Rosentreter et al. 2018) depending on the salinity (Poffenbarger et al. 2011;
21 Kroeger et al. 2017). As the main driver of mangrove forest loss is aquaculture/agriculture (Thomas et
22 al. 2017), there may be entrenched interests opposing restoration and protection actions.

23 ***Restoration and protection of terrestrial ecosystems***

24 Restoration of terrestrial landscapes can be a direct outcome of development pathways, and can be
25 critical to achieving a variety of SDGs (especially 1, 2, 6, 8, 13, 15) (Lapola et al. 2018; Vergara et al.
26 2016) although it also presents risks and can have trade-offs with other SDGs (Cao et al. 2010; Dooley
27 and Kartha 2018). Landscape restoration is nearly always a mitigation action, and can also provide
28 adaptive capacity. While policy in Brazil has tended to focus on the Amazon as a carbon sink, the
29 mitigation co-benefits of ecosystem-based adaptation actions have been highlighted in the literature (Di
30 Gregorio et al. 2016; Locatelli et al. 2011). A study of potential restoration of degraded lands in Latin
31 America (Vergara et al. 2016) indicates that substantial benefits for mitigation, adaptation, and
32 economic development accrue after several years, underscoring a reliance on deliberate development
33 choices. In agricultural contexts, restoration is a development choice that can enhance adaptive and
34 mitigative capacity via impact on farmer livelihoods.

35 Preventing degradation of landscapes can support both mitigation and adaptation (IPCC 2019).
36 Restoration of ecosystems is associated with improved water filtration, ground water recharge and flood
37 control and multiple other ecosystem services (Ouyang et al. 2016).

38 Restoration projects must be designed with care. There can be trade-offs in addition to the synergies
39 noted above (7.6.4.3). Restorations may be unsuccessful if not considered in their socio-economic
40 context (Lengefeld et al. 2020; Iftekhar et al. 2017; Jellinek et al. 2019). Restoration projects for
41 mitigation purposes can be more effective if done with adaptation in mind (Gray et al. 2011) as a
42 changing climate may render some mitigation actions biophysically infeasible (Arneth et al. 2021).
43 Landscape restoration projects intended for CDR may underperform due to future release of stored
44 carbon, or deferral of storage until after irreversible climate change effects (e.g. extinctions) (Dooley
45 and Kartha 2018).

1 Afforestation plans have received substantial attention as a climate mitigation action, with ongoing
2 unresolved debate on the feasibility and tradeoffs of such plans. Such afforestation programs can fail
3 for biophysical reasons (7.4.2.2, Fleischman et al. 2020) but also lack of consideration of socioeconomic
4 and development contexts (Fleischman et al. 2020).

5 **4.4.3 Risks and uncertainties**

6 Shifting development pathways and accelerating mitigation are complex endeavours that carry risks.
7 Some of these risks can be easily captured by quantitative models. Others are better understood via
8 qualitative approaches, such as qualitative narrative storylines (told in words) and methods mixing
9 qualitative and quantitative models (Kemp-Benedict 2012; Hanger-Kopp et al. 2019). The following
10 outline key risks and relevant hedging strategies identified in the literature.

11 **4.4.3.1 Actions by others not consistent with domestic efforts**

12 The international context is a major source of uncertainty for national-level planning, especially for
13 small- or medium-sized open economies, because the outcome of domestic choices may significantly
14 depend on decisions made by other countries and actor, over which national governments have limited
15 or no control (Lachapelle and Paterson 2013). Availability of foreign financial resources in countries
16 with limited domestic savings (Baum et al. 2017) and availability of technology transfers (Glachant and
17 Dechezleprêtre 2017) are some examples. Other external decisions with significant bearing on domestic
18 action include mitigation policies in other countries (Dai et al. 2017), and especially in major trading
19 partners, the lack of which can result in competitive disadvantage for sectors exposed to international
20 competition (Alton et al. 2014). The international prices of the key commodities (notably energy), goods
21 and services are important, notably when shifting development pathway is based on structural change
22 (e.g., Willenbockel et al. (2017) for Ghana and Kenya).

23 Remedies include first devising policy packages that are, to the extent possible, robust to uncertainty
24 regarding external decisions. For example, mitigation in the building sector is considered less
25 problematic for competitiveness since the construction sector is less exposed to international
26 competition. Remedies also include securing international cooperation to reduce the uncertainty that
27 domestic decision-makers face about the international context. Shifting investments towards low-GHG
28 solutions requires a combination of conducive public policies, attractive investment opportunities and
29 financing of transitions (15.6), which can enable shifting development pathways. Cooperation can
30 generate positive spill overs through technology diffusion (13.6.6). Third, cooperation is not limited to
31 governments. As discussed in section 4.2.3, international cooperative initiatives among non-State actors
32 (cities, economic branches, etc.) can also provide know-how, resources and stable cooperative
33 frameworks that reduce uncertainty for individual actors (14.5.5).

34 **4.4.3.2 Parts of complex policy packages fail**

35 As outlined in the examples in section 4.4.1 above, shifting development pathways and accelerating
36 mitigation are complex endeavours, on which there is limited experience and know-how from the past.
37 An uncertainty is that parts of these policy packages may fail, i.e., under-deliver relative to the amount
38 of mitigation and of transformations initially expected. For example, France has failed to meet its 2015-
39 2018 carbon budget as housing retrofitting programs, in particular, have failed to deliver the expected
40 amount of emission reductions (Haut Conseil pour le Climat 2019). There are two main options to tackle
41 this risk. The first is to build in redundancy. The second is to anticipate that some parts of the policies
42 will inevitably fail, and build-in monitoring and corrective mechanisms in a sequential decision-making
43 process. To this regard, building institutions that can properly monitor, learn from and improve over
44 time is critical (Nair and Howlett 2017).

1 **4.4.3.3 New information becomes available**

2 The science on climate change, its impacts and the opportunities to mitigate is continuously being
3 updated. Even though decisions are no longer made “in a sea of uncertainty” (Lave 1991), we know
4 that new information will come over time, that may have significant bearing on the design and
5 objectives of policies to shift development pathways and accelerate mitigation. New information may
6 come from climate sciences (e.g., updated GWP values or available carbon budgets) (Quéré et al. 2018),
7 impact sciences (e.g., re-evaluation of climate impacts associated with given emission pathways) (Ricke
8 et al. 2018) or mitigation sciences (e.g., on availability of given technologies) (Lenzi et al. 2018;
9 Giannousakis et al. 2020).

10 At the same time, economic and social systems are characterised by high degree of inertia, via long-
11 lived capital stock or urban forms (Lecocq and Shalizi 2014), or more broadly mutually reinforcing
12 physical, economic, and social constraints (Seto et al. 2016) that may lead to carbon lock-ins (Erickson
13 et al. 2015). Risks associated with long-lasting fossil-fuel power plants have been the object of particular
14 attention. For example, Pfeiffer et al. (2018) estimate that even if the current pipeline of power plants
15 was cancelled, about 20% of the existing capacity might be stranded to remain compatible with 1.5°C
16 or 2°C pathways—implying that additional capital accumulation would lead to higher sunk costs
17 associated with stranded assets (Luderer et al. 2018b; Johnson et al. 2015; Ansar et al. 2013; Kriegler
18 et al. 2018).

19 In the presence of uncertainty and inertia (or irreversibilities), hedging strategies may be considered,
20 that include selection of risk-hedging strategies and processes to adjust decisions as new information
21 becomes available. The notion of hedging against risks is also prominent in the adaptation literature, as
22 exemplified by the terminology of “climate resilient development” (Fankhauser and McDermott 2016)
23 (WGII, Ch.18). There is also a growing literature on hedging strategies for individual actors (e.g., firms
24 or investors) in the face of the uncertainties associated with mitigation (e.g., policy uncertainty or the
25 associated carbon price uncertainty) (e.g., (Morris et al. 2018) or (Andersson et al. 2016)). On the other
26 hand, there is often limited discussion of uncertainty and of its implication for hedging strategies in the
27 accelerated mitigation pathway literature. Exceptions include (Capros et al. 2019), who elicit “no-
28 regret” and “disruptive” mitigation options for the EU through a detailed sensitivity analysis, and
29 (Watson et al. 2015) who discuss flexible strategies for the U.K. energy sector transition in the face of
30 multiple uncertainties.

31 **4.4.3.4 Black swans (e.g., COVID-19 crisis)**

32 As the current COVID-19 crisis demonstrates, events happen that can derail the best-laid plans.
33 Unexpected events beyond the range of human experience until then are called ‘black swans’, given the
34 expectation that all swans are white. The only point to note here is that such events may also provide
35 opportunities. In the COVID-19 case, for example, the experience of conducting many activities on-
36 line, which reduces emissions from transport, may leave an imprint on how some of these activities are
37 carried out in the post-COVID-19 world. Similarly, reduced air pollution seen during the pandemics
38 may increase support for mitigation and strengthen the case for climate action. However, the emissions
39 implications of recovery packages depend on choosing policies that support climate action while
40 addressing the socio-economic implications of COVID-19 (Hepburn et al. 2020). Governments may be
41 in a stronger position to do so due to their pivotal role in assuring the survival of many businesses during
42 the pandemics. Given the magnitude of recovery packages and their implications (Pollitt et al. 2021),
43 choosing the direction of recovery packages amounts to choosing a development pathway (Cross-
44 Chapter Box 1).

1 **4.4.3.5 Transformations run into oppositions**

2 As noted above, shifting development pathways and accelerating mitigation involve a broad range of
3 stakeholders and decision-makers, at multiple geographical and temporal scales. They require a credible
4 and trusted process for reconciling perspectives and balancing potential side-effects, managing winners
5 and losers and implementing compensatory measures to ensure an inclusive just transition (Newell and
6 Mulvaney 2013; Miller and Richter 2014; Gambhir et al. 2018; Diffenbaugh and Burke 2019). Such
7 processes are designed to manage the risk of inequitable or non-representative power dynamics
8 (Helsinki Design Lab 2014; Kahane 2019; Boulle et al. 2015). More generally, stakeholder processes
9 can be subject to regulatory capture by special interests, or outright opposition from a variety of
10 stakeholders. Information asymmetry between government and business may shape the results of
11 consultative processes. Long experience of political management of change demonstrates that managing
12 such risks is not easy, and requires sufficiently strong and competent institutions (Stiglitz 1998). The
13 next section on Just Transition (4.5) addresses this issue.

14

15

16 **4.5 Equity, including just transitions**

17 Equity is an ethical and at times economic imperative, but it is also instrumentally an enabler of deeper
18 ambition for accelerated mitigation (Hoegh-Guldberg et al. 2019). The literature supports a range of
19 estimates of the net benefits—globally or nationally—of low-carbon transformation, and it identifies a
20 number of difficulties in drawing definitive quantitative conclusions (e.g., comparisons of costs &
21 benefits among different actors, the existence of non-economic impacts, comparison across time,
22 uncertainty in magnitude, 3.6). One of the most important of these dimensions is the distributional
23 consequences of mitigation, as well as a range of equity considerations arising from the uncertainty in
24 net benefits, as well as from the distribution of costs and benefits among winners and losers (Rendall
25 2019; Caney 2016; Lahn and Bradley 2016; Lenferna 2018a; Kartha et al. 2018b; Robiou Du Pont et
26 al. 2017). Some equity approaches are even just seeking corrective justice including for historical
27 emissions (Adler 2007). For an assessment of literature on fairness in NDCs, see 4.2.2.7.

28 Equity issues are often discussed in the literature via frameworks that are well-founded in the ethical
29 literature and that have a strong bearing on effort-sharing, but have not yet been quantitatively modelled
30 and expressed in the form of an emissions allocation quantified framework. These include, for example,
31 ethical perspectives based in human rights (Johl and Duyck 2012), human capabilities (Klinsky et al.
32 2017b), environmental justice (Mohai et al. 2009; Schlosberg 2009), ecological debt (Srinivasana et al.
33 2008; Warlenius et al. 2015), transitional justice (Klinsky 2017; Klinsky and Brankovic 2018), and
34 planetary boundaries (Häyhä et al. 2016).

35 While there is extensive literature on equity frameworks for national emissions allocations (CSO Equity
36 Review 2018, 2015, 2017; Kemp-Benedict et al. 2018; Pye et al. 2020; Robiou du Pont and
37 Meinshausen 2018; Fyson et al. 2020; Holz et al. 2018; Pozo et al. 2020), such studies have tended to
38 focus on allocation of a global carbon budget among countries based on quantified equity frameworks.
39 The implicit normative choices made in these analysis have limitations (Kartha et al. 2018a). Moreover,
40 there are many ethical parameters that could be introduced to enrich the existing quantitative
41 frameworks, such as progressivity (Holz et al. 2018), consumption-based accounting (Afionis et al.
42 2017), prioritarianism (Adler and Treich 2015), and a right to development (Moellendorf 2020).
43 Introducing these ethical frames into conventional quantification approaches generally implies greater
44 allocations for poorer and lower-emitting populations, suggesting that the approaches that are typically

1 highlighted in emissions allocation analyses tends to favour wealthier and higher-emitting countries.
2 Broader, more inclusive sharing of costs and burdens is seen as a way to enhance equity in procedures
3 and outcomes.

4 Ultimately, equity consequences depend on how costs and benefits are initially incurred and how they
5 are shared as per social contracts (Combet and Hourcade 2017), national policy, and international
6 agreements. The literature suggests a relationship between the effectiveness of cooperative action and
7 the perception of fairness of such arrangements. Winkler et al. (2018) demonstrate that countries have
8 put forward a wide variety of indicators and approaches for explaining the fairness and ambition of their
9 NDCs, reflecting the broader range of perspectives found in the moral philosophical literature cited
10 above. Mbeva and Pauw (2016) further find that adaptation and financing issues take on greater salience
11 in the national perspectives reflected in the NDCs.

12 Topics of equity and fairness have begun to receive a greater amount of attention within the energy and
13 climate literature, namely through the approaches of gender and race (Pearson et al. 2017; Lennon 2017;
14 Allen et al. 2019), climate justice (Roberts and Parks 2007; Routledge et al. 2018) (Roberts & Parks,
15 2006; Routledge et al. 2018), and energy justice (Sovacool and Dworkin 2014). While such approaches
16 frequently envision justice and equity as an ethical imperative, justice also possesses the instrumental
17 value of enabling deeper and more socially acceptable mitigation efforts (Klinsky and Winkler 2018).

18 A concrete focal point on these issues has been that of “just transition”. Getting broad consensus for the
19 transformational changes entailed in moving from a high- to a low-carbon economy means ‘leaving no
20 one behind’, i.e., ensuring (sufficiently) equitable transition for the relevant affected individuals,
21 workers, communities, sectors, regions and countries (Newell & Mulvaney, 2013; Jasanoff 2018). The
22 concept of a “just transition” owes its origin to the US trade union movement of the 1980s. The earliest
23 version of a just transition was called the “Superfund for Workers” modelled on the 1980 Superfund
24 program that designed federal funds for the clean-up of toxic substances from chemicals, mining and
25 energy production (Stavis and Felli 2015). It was further taken up, for example in the collaboration of
26 the International Trade Union Confederation (ITUC), the International Labour Organization (ILO) and
27 the UN Environmental Programme (UNEP) in promoting “green jobs” as integral elements of a just
28 transition (ILO 2015; Rosemberg 2015). In recent years the concept of a “just transition” has gained
29 increased traction, for example incorporated in the outcome of the Rio+20 Earth Summit and more
30 recently recognised in the preamble of the Paris Agreement, which states “the imperative of a just
31 transition of the workforce and the creation of decent work and quality jobs in accordance with
32 nationally defined development priorities” (UNFCCC 2015c). Some heads of state and government
33 signed a *Solidarity and Just Transition Silesia Declaration* first introduced at COP24 in Poland (HoSG
34 2018).

35 The literature identifies targeted and proactive measures from governments, agencies, and authorities
36 to ensure that any negative social, environmental or economic impacts of economy-wide transitions are
37 minimised, whilst benefits are maximised for those disproportionately affected (Healy and Barry 2017).
38 While the precise definition varies by source, core elements tend to include: (1) investments in
39 establishing low-emission and labour-intensive technologies and sectors (Mijn Cha et al. 2020); (2)
40 research and early assessment of the social and employment impacts of climate policies (Green and
41 Gambhir 2020; Mogomotsi et al. 2018); (3) social dialogue and democratic consultation of social
42 partners and stakeholders (Smith 2017; Swilling and Annecke 2012); (4) the creation of decent jobs;
43 active labour markets policies; and rights at work (UNFCCC 2016c; ILO 2015); (5) fairness in energy
44 access and use (Carley and Konisky 2020); (6) economic diversification based on low-carbon
45 investments; (7) realistic training/retraining programs that lead to decent work; (8) gender specific
46 politics that promote equitable outcomes (Allwood 2020); (9) the fostering of international cooperation

1 and coordinated multilateral actions (Lenferna 2018b; Newell and Simms 2020); (10) redressing of past
 2 harms and perceived injustices (UNHRC 2020; Setzer and Vanhala 2019); and (11) consideration of
 3 inter-generational justice concerns, such as the impacts of policy decisions on future generations
 4 (Newell & Mulvaney, 2013).

5 A just transition could therefore entail that the state intervenes more actively in the eradication of
 6 poverty, and creates jobs in lower-carbon sectors, in part to compensate for soon-to-be abandoned
 7 fossil-fuel-based sectors, and that governments, polluting industries, corporations and those more able
 8 to pay higher associated taxes pay for transition costs, provide a welfare safety net and adequate
 9 compensation for people, communities, places, and regions that have been impacted by pollution,
 10 marginalised or negatively impacted by a transition from a high- to low-carbon economy and society
 11 (Muttitt and Kartha 2020; Le Billon and Kristoffersen 2020; Kartha et al. 2018b). Reducing climate
 12 impacts is another important dimension of equity, in that the poor who are least responsible for climate
 13 change are most vulnerable to its impacts (WGII, Chapter 8). Focusing on financial losses alone
 14 however can obscure an important distinction between losses incurred by corporations and states and
 15 losses experienced by workers and communities. Processes established in the name of a just transition
 16 are also at risk of being co-opted by incumbent interests and powerful/wealthy agents (Green and
 17 Gambhir, 2020). Policy interventions associated with good governance, democratic oversight, and legal
 18 recourse can help overcome attempted co-optation of just transition, or use of COVID-19 recovery
 19 packages for continued carbon lock-in (Hepburn et al. 2020; SEI et al. 2020).

20 The just transition concept has thus become an international focal point tying together social
 21 movements, trade unions, and other key stakeholders to ensure equity is better accounted for in low-
 22 carbon transitions and to seek to protect workers and communities. It also forms a central pillar of the
 23 growing movement for a ‘Green New Deal’—a roadmap for a broad spectrum of policies, programs,
 24 and legislation that aims to rapidly decarbonise the economy while significantly reducing economic
 25 inequality (Galvin and Healy 2020)(Allam et al. 2021) The US Green New Deal Resolution (Ocasio-
 26 Cortez 2019) for example positions structural inequality, poverty mitigation, and a just transition at its
 27 centre. The European Green Deal proposed in 2019 (European Commission 2019), including a UDF100
 28 billion “Just Transition Mechanism” to mitigate the social effects of transitioning away from jobs in
 29 fossil based industries. National level green new deals with strong just transition components have been
 30 proposed in South Korea, Australia, Spain, UK, Puerto Rico, Canada, as well as regional proposals
 31 across Latin America and the Caribbean (Pollin 2020). .

3

4 A just transition at national, regional and local scales can help to ensure that workers, communities,
5 frontline communities and the energy-poor are not left behind in the transition. Moreover, a just
6 transition necessitates that rapid decarbonisation does not perpetuate asymmetries between richer and
7 poorer states and people (UNHRC 2020). Alliances around a just transition in countries across the world
8 take many forms (Box 4.6).

Figure 4.9 Just Transitions around the world, 2020

Panel A shows commissions, task forces, dialogues behind a just transition in many countries ((Snell 2018; Government of Canada 2019; Piggot et al. 2019; Harrison 2013; Government of Costa Rica 2019; Ng et al. 2016; van Asselt and Moerenhout 2018; European Union 2019, 2020; Galgóczi 2019; Finnish Government 2020; Commission on Growth Structural Change and Employment 2019; Ministry of Employment and Labour Relations of Ghana 2018; Popp 2019; Galgóczi 2014; Adeoti et al. 2016; Gass and Echeverria 2017; Ministry of Business Innovation & Employment New Zealand 2019; Mendoza 2014; Szpor, A. and Ziółkowska 2018; Government of Scotland 2020; Bankwatch 2019; NPC (National Planning Commission) 2019; Strambo et al.

1 2019; Thalmann 2004; White House 2016; Schweitzer, M. and Tonn 2003; International Labor Organization
2 2018; Mijn Cha et al. 2020); **Panel B shows the funds related to the Just Transition within the European**
3 **Union Green Deal, and Panel C shows the European Union’s Platform for Coal Regions in Transition.**

4 As Figure 4.9 shows, no fewer than 7 national commissions or task forces on a just transition existed as
5 of 2020 as well as 7 other sets of national policies and a multitude of other actors, networks, and
6 movements. For instance, the German phase-out of coal subsidies involved a savings package for
7 unemployed miners. Subsidy reform packages introduced by Iran, Namibia, the Philippines, Turkey,
8 and the United Kingdom provide similar compensating measures to affected groups (Sovacool 2017).
9 Spain’s just transition plan for coal miners includes early retirement, redundancy packages, silicosis
10 compensation, retraining for green jobs, and priority job placement for former miners.

11

12 **4.6 Knowledge gaps**

13 This section summarises knowledge gaps that require further research:

- 14 • Literature on mitigation pathways at the national level remains skewed towards large emitters.
15 Many low-income countries have very few or no studies at all (Lepault and Lecocq 2021) (4.2)
16 (Annex III). Development of new studies and inclusion of associated scenarios in updated
17 mitigation national mitigation pathway database would enhance understanding of mitigation at
18 national level.
- 19 • Ex ante and ex post analysis of mitigation action and of mitigation plans by non-state actors,
20 and their relationship with mitigation action and plans by governments is limited (4.2.3).
- 21 • System analysis solutions are only beginning to be recognised in current literature on deep
22 mitigation pathways, and rarely included in existing national policies or strategies (4.2.5).
- 23 • While the technology elements of accelerated mitigation pathways at national level are
24 generally well documented, studies of the economic and social implications of such pathways
25 remain scarce (4.2.6).
- 26 • Literature on the implication of development choices for emissions and for capacity to mitigate
27 is limited (4.3.2). In particular, more contributions from the research community working on
28 development issues would be very useful here.
- 29 • Literature describing shifts in development pathways, and the conditions for such shifts (based
30 on past experience or on models) remains scarce (4.3.1, 4.3.3, 4.4.1). Studying shifts in
31 development pathways requires new ways of thinking with interdisciplinary research and use
32 of alternative frameworks and methods suited for understanding of change agents, determinants
33 of change and adaptive management among other issues (Winkler 2018). Research is not only
34 expected to produce knowledge and boost innovation, but also to help identify transformation
35 pathways and to enlighten public debate and public decision making on related political
36 choices.
- 37 • Other research gaps concern the open ocean and blue carbon. There is limited knowledge about
38 quantification of the blue carbon stocks. Research is required into what happens if the
39 sequestration capacity of the ocean and marine ecosystems is damaged by climate change to
40 the tipping point until the sink becomes an emitter, and on how to manage blue carbon (4.4.2).
- 41 • Knowledge is limited on: i) linking equity frameworks on mitigation with adaptation and most
42 importantly with loss and damage, ii) applying ethical parameters to enrich many of the existing
43 quantitative frameworks, to assess fairness and ambition of NDCs; iii) extending equity

1 frameworks to quantify equitable international support, as the difference between equity-based
2 national emissions scenarios and national domestic emissions scenarios (4.2.2.7, 4.5).

4 Frequently asked questions

5 **FAQ 4.1 What is to be done over and above countries existing pledges under the Paris Agreement 6 to keep global warming well below 2°C?**

7 Current pledges and efforts under the PA aimed at keeping global warming below 2°C are not enough,
8 falling short by 14-23 GtCO₂-eq (Cross-Chapter Box 4). There is a further shortfall of about 4 to 7
9 GtCO₂-eq in 2030 if the conditions are not fulfilled for those Parties that have made their pledges with
10 conditions for support (4.2.2.3). To cover up for these shortfalls will require taking actions across all
11 sectors that can substantially reduce GHG emissions. Examples of such actions include shifting to low-
12 or zero-emission power generation, such as renewables; changing food systems, such as diet changes
13 away from land-intensive animal products; electrifying transport and developing ‘green infrastructure’,
14 such as building green roofs, or improving energy efficiency by smart urban planning, which will
15 change the layout of many cities. Because these different actions are connected, it means all relevant
16 companies, industries and stakeholders would need to be involved to increase the support and chance
17 of successful implementation (4.2.5). The deployment of low-emission technology depends upon
18 economic conditions (e.g., employment generation or capacity to mobilize investment), but also on
19 social/cultural conditions (e.g., awareness and acceptability) and institutional conditions (e.g., political
20 support and understanding), and the provision of relevant enabling conditions (4.4.1). Encouraging
21 stronger and more ambitious climate action by non-government and subnational stakeholders, as well
22 as international cooperative initiatives (ICIs) could make significant contributions to emissions
23 reduction (4.2.3).

24 **FAQ 4.2 Option 1: What is to be done in the near-term to accelerate mitigation and shift 25 development pathways?**

26 Increasing speed of implementation, breadth of action across all sectors of the economy, and depth of
27 emission reduction faces important obstacles, that are rooted in the underlying structure of societies
28 (4.2.7). Addressing these obstacles amounts to shifting away from existing developmental trends (i.e.,
29 shifting development pathways, Cross-Chapter Box 5). This can be done by strengthening governance
30 and institutional capacity, aligning technology and innovation systems with low-carbon development,
31 facilitating behaviour change and providing adequate finance within the context of multi-objective
32 policy packages and sequences (4.4.1). Shifting development pathways towards sustainability broadens
33 the scope for, and is thus a complement to, accelerated mitigation (4.3).

34 **FAQ 4.3 Is it possible to accelerate mitigation in the near-term while there are so many other 35 development priorities? (education, health, employment, etc.)**

36 It is possible to accelerate mitigation while addressing other developmental priorities by implementing
37 measures that simultaneously address both climate and development goals. Casting mitigation in the
38 broader context of development pathways provides additional opportunities to articulate both (4.3.1.4).
39 Policies such as progressive taxation, investment in public transport, regulatory transparency,
40 commitment to multi-lateral environmental governance, fiscal incentives for private investments,
41 international technology development and transfer initiatives, and risk disclosure and efforts to improve
42 underlying enabling conditions (improving governance and institutional capacity, fostering behavioural
43 change and technological innovation, and provision of finance) address multiple objectives beyond
44 mitigation, such as job creation, macro-economic stability, economic growth, public health and welfare,
45 providing energy access, providing formal housing, and providing mobility. How we manage our land
46 and agriculture, growing cities, transport needs, our industries, and the way people are trained and

1 employed all impact on GHG emissions and the options we have to reduce them. In turn, reducing GHG
2 emissions can also contribute to reducing poverty, preventing hunger, improving health and wellbeing,
3 and providing clean water and clean energy. Implementing right policies and investments can help to
4 address the challenges of how to reduce emissions without constraining development. For example, in
5 land use, widespread planting of a single tree species or crops for bioenergy (organic matter turned into
6 renewable energy) could affect food and water supplies. Therefore, if bioenergy is to be relied upon to
7 offset emissions, the right policies and investments are needed (see also Chapter 17).

35		

1 **Executive summary**

2 Assessment of the social science literature and regional case studies reveals how social norms, culture,
3 and individual choices, interact with infrastructure and other structural changes over time. This provides
4 new insight into climate change mitigation strategies, and how economic and social activity might be
5 organised across sectors to support emission reductions. To enhance well-being, people demand
6 services and not primary energy and physical resources per se. Focusing on demand for services and
7 the different social and political roles people play broadens the participation in climate action.

8 **Potential of demand-side actions and service provisioning systems**

9 **Demand-side mitigation and new ways of providing services can help *avoid, shift, and improve***
10 **final service demand. Rapid and deep changes in demand make it easier for every sector to reduce**
11 **GHG emissions in the short and medium term (*high confidence*). {5.2, 5.3}**

12 **The indicative potential of demand-side strategies across all sectors to reduce emissions is 40-70%**
13 **by 2050 (*high confidence*).** Technical mitigation potentials compared to the IEA WEO, 2020 STEPS
14 baseline amounts up to 5.7 GtCO₂eq for building use and construction, 8 GtCO₂eq for food demand,
15 6.5 GtCO₂eq for land transport, and 5.2 GtCO₂eq for industry. Mitigation strategies can be classified as
16 *Avoid-Shift-Improve* (ASI) options, that reflect opportunities for socio-cultural, infrastructural, and
17 technological change. The greatest *Avoid* potential comes from reducing long-haul aviation and
18 providing short-distance low-carbon urban infrastructures. The greatest *Shift* potential would come from
19 switching to plant-based diets. The greatest *Improve* potential comes from within the building sector,
20 and in particular increased use of energy efficient end-use technologies and passive housing. {5.3.1,
21 5.3.2, Figure 5.7, Figure 5.8, Table 5.1, Table SM.2}

22 **Socio-cultural and lifestyle changes can accelerate climate change mitigation (*medium***
23 ***confidence*).** Among 60 identified actions that could change individual consumption, individual
24 mobility choices have the largest potential to reduce carbon footprints. Prioritizing car-free mobility by
25 walking and cycling and adoption of electric mobility could save 2 tCO₂eq cap⁻¹ yr⁻¹. Other options with
26 high mitigation potential include reducing air travel, cooling setpoint adjustments, reduced appliance
27 use, shifts to public transit, and shifting consumption towards plant-based diets. {5.3.1, 5.3.1.2, Figure
28 5.8}

29 **Leveraging improvements in end-use service delivery through behavioural and technological**
30 **innovations, and innovations in market organisation, leads to large reductions in upstream**
31 **resource use (*high confidence*).** Analysis of indicative potentials range from a factor 10 to 20 fold
32 improvement in the case of available energy (exergy) analysis, with the highest improvement potentials
33 at the end-user and service-provisioning levels. Realisable service level efficiency improvements could
34 reduce upstream energy demand by 45% in 2050. {5.3.2, Figure 5.10}

35 **Alternative service provision systems, for example those enabled through digitalisation, sharing**
36 **economy initiatives and circular economy initiatives, have to date made a limited contribution to**
37 **climate change mitigation (*medium confidence*).** While digitalisation through specific new products
38 and applications holds potential for improvement in service-level efficiencies, without public policies
39 and regulations, it also has the potential to increase consumption and energy use. Reducing the energy
40 use of data centres, networks, and connected devices is possible in managing low-carbon digitalisation.
41 Claims on the benefits of the circular economy for sustainability and climate change mitigation have
42 limited evidence. {5.3.4, 5.3.4.1, 5.3.4.2, Figure 5.12, Figure 5.13}

1 **Social aspects of demand-side mitigation actions**

2
3 **Decent living standards (DLS) and well-being for all are achievable through the implementation**
4 **of high-efficiency low demand mitigation pathways (medium confidence).** Decent Living Standards
5 (DLS) – a benchmark of material conditions for human well-being – overlaps with many Sustainable
6 Development Goals (SDGs). Minimum requirements of energy use consistent with enabling well-being
7 for all is between 20 and 50 GJ cap⁻¹ yr⁻¹ depending on the context. {5.2.2.1, 5.2.2.2, Box 5.3}

8
9 **Providing better services with less energy and resource input has high technical potential and is**
10 **consistent with providing well-being for all (medium confidence).** Assessment of 19 demand-side
11 mitigation options and 18 different constituents of well-being show that positive impacts on well-being
12 outweigh negative ones by a factor of 11. {5.2, 5.2.3, Figure 5.6,}

13
14 **Demand-side mitigation options bring multiple interacting benefits (high confidence).** Energy
15 services to meet human needs for nutrition, shelter, health, etc. are met in many different ways with
16 different emissions implications that depend on local contexts, cultures, geography, available
17 technologies, social preferences. In the near term, many less-developed countries and poor people
18 everywhere require better access to safe and low-emissions energy sources to ensure decent living
19 standards and increase energy savings from service improvements by about 20-25%. {5.2, 5.4.5, Figure
20 5.3, Figure 5.4, Figure 5.5, Figure 5.6, Box 5.2, Box 5.3}

21
22 **Granular technologies and decentralized energy end-use, characterised by modularity, small unit**
23 **sizes and small unit costs, diffuse faster into markets and are associated with faster technological**
24 **learning benefits, greater efficiency, more opportunities to escape technological lock-in, and**
25 **greater employment (high confidence).** Examples include solar photovoltaic systems, batteries, and
26 thermal heat pumps. {5.3, 5.5, 5.5.3}

27
28 **Wealthy individuals contribute disproportionately to higher emissions and have a high potential**
29 **for emissions reductions while maintaining decent living standards and well-being (high**
30 **confidence).** Individuals with high socio-economic status are capable of reducing their GHG emissions
31 by becoming role models of low-carbon lifestyles, investing in low-carbon businesses, and advocating
32 for stringent climate policies. {5.4.1, 5.4.3, 5.4.4, Figure 5.14}

33
34 **Demand-side solutions require both motivation and capacity for change (high confidence).**
35 Motivation by individuals or households worldwide to change energy consumption behaviour is
36 generally low. Individual behavioural change is insufficient for climate change mitigation unless
37 embedded in structural and cultural change. Different factors influence individual motivation and
38 capacity for change in different demographics and geographies. These factors go beyond traditional
39 socio-demographic and economic predictors and include psychological variables such as awareness,
40 perceived risk, subjective and social norms, values, and perceived behavioural control. Behavioural
41 nudges promote easy behaviour change, e.g., “improve” actions such as making investments in energy
42 efficiency, but fail to motivate harder lifestyle changes. (high confidence) {5.4}

43
44 **Meta-analyses demonstrate that behavioural interventions, including the way choices are**
45 **presented to consumers¹, work synergistically with price signals, making the combination more**
46 **effective (medium confidence).** Behavioural interventions through nudges, and alternative ways of
47 redesigning and motivating decisions, alone provide small to medium contributions to reduce energy

FOOTNOTE ¹ The way choices are presented to consumers is known as ‘choice architecture’ in the field of behavioural economics.

1 consumption and GHG emissions. Green defaults, such as automatic enrolment in “green energy”
2 provision, are highly effective. Judicious labelling, framing, and communication of social norms can
3 also increase the effect of mandates, subsidies, or taxes. {5.4, 5.4.1, Table 5.3a, Table 5.3b}

4
5 **Coordinated change in several domains leads to the emergence of new low-carbon configurations**
6 **with cascading mitigation effects (*high confidence*)**. Demand-side transitions involve interacting and
7 sometimes antagonistic processes on the behavioural, socio-cultural, institutional, business, and
8 technological dimensions. Individual or sectoral level change may be stymied by reinforcing social,
9 infrastructural, and cultural lock-ins. Coordinating the way choices are presented to end users and
10 planners, physical infrastructures, new technologies and related business models can rapidly realise
11 system-level change. {5.4.2, 5.4.3, 5.4.4, 5.4.5, 5.5}

12
13 **Cultural change, in combination with new or adapted infrastructure, is necessary to enable and**
14 **realise many *Avoid* and *Shift* options (*medium confidence*)**. By drawing support from diverse actors,
15 narratives of change can enable coalitions to form, providing the basis for social movements to
16 campaign in favour of (or against) societal transformations. People act and contribute to climate change
17 mitigation in their diverse capacities as consumers, citizens, professionals, role models, investors, and
18 policymakers. {5.4, 5.5, 5.6}

19
20 **Collective action as part of social or lifestyle movements underpins system change (*high***
21 ***confidence*)**. Collective action and social organising are crucial to shift the possibility space of public
22 policy on climate change mitigation. For example, climate strikes have given voice to youth in more
23 than 180 countries. In other instances, mitigation policies allow the active participation of all
24 stakeholders, resulting in building social trust, new coalitions, legitimising change, and thus initiate a
25 positive cycle in climate governance capacity and policies. {5.4.2, Figure 5.14}

26
27 **Transition pathways and changes in social norms often start with pilot experiments led by**
28 **dedicated individuals and niche groups (*high confidence*)**. Collectively, such initiatives can find
29 entry points to prompt policy, infrastructure, and policy reconfigurations, supporting the further uptake
30 of technological and lifestyle innovations. Individuals’ agency is central as social change agents and
31 narrators of meaning. These bottom-up socio-cultural forces catalyse a supportive policy environment,
32 which enables changes. {5.5.2}

33
34 **The current effects of climate change, as well as some mitigation strategies, are threatening the**
35 **viability of existing business practices, while some corporate efforts also delay mitigation action**
36 **(*medium confidence*)**. Policy packages that include job creation programs help to preserve social trust,
37 livelihoods, respect, and dignity of all workers and employees involved. Business models that protect
38 rent extracting behaviour may sometimes delay political action. Corporate advertisement and
39 brand building strategies may also attempt to deflect corporate responsibility to individuals or aim to
40 appropriate climate care sentiments in their own brand-building. {5.4.3, 5.6.4}

41
42 **Middle actors -professionals, experts, and regulators- play a crucial albeit underestimated and**
43 **underutilised role in establishing low-carbon standards and practices (*medium confidence*)**.
44 Building managers, landlords, energy efficiency advisers, technology installers, and car dealers
45 influence patterns of mobility and energy consumption by acting as middle actors or intermediaries in
46 the provision of building or mobility services and need greater capacity and motivation to play this role.
47 {5.4.3}

48
49 **Social influencers and thought leaders can increase the adoption of low-carbon technologies,**
50 **behaviours, and lifestyles (*high confidence*)**. Preferences are malleable and can align with a cultural

1 shift. The modelling of such shifts by salient and respected community members can help bring about
2 changes in different service provisioning systems. Between 10% and 30% of committed individuals are
3 required to set new social norms. {5.2.1, 5.4}

5 **Preconditions and instruments to enable demand-side transformation**

7 **Social equity reinforces capacity and motivation for mitigating climate change (*medium***
8 ***confidence*)**. Impartial governance such as fair treatment by law and order institutions, fair treatment
9 by gender, and income equity, increases social trust, thus enabling demand-side climate policies. High
10 status (often high carbon) item consumption may be reduced by taxing absolute wealth without
11 compromising well-being. {5.2, 5.4.2, 5.6}

13 **Policies that increase the political access and participation of women, racialized, and marginalised**
14 **groups, increase the democratic impetus for climate action. (*high confidence*)**. Including more
15 differently situated knowledge and diverse perspectives makes climate mitigation policies more
16 effective. {5.2, 5.6}

18 **Carbon pricing is most effective if revenues are redistributed or used impartially (*high***
19 ***confidence*)**. A carbon levy earmarked for green infrastructures or saliently returned to taxpayers
20 corresponding to widely accepted notions of fairness increases the political acceptability of carbon
21 pricing. {5.6, Box 5.11}

23 **Greater contextualisation and granularity in policy approaches better addresses the challenges**
24 **of rapid transitions towards zero-carbon systems (*high confidence*)**. Larger systems take more time
25 to evolve, grow, and change compared to smaller ones. Creating and scaling up entirely new systems
26 takes longer than replacing existing technologies and practices. Late adopters tend to adopt faster than
27 early pioneers. Obstacles and feasibility barriers are high in the early transition phases. Barriers decrease
28 as a result of technical and social learning processes, network building, scale economies, cultural
29 debates, and institutional adjustments. {5.5, 5.6}

31 **The lockdowns implemented in many countries in response to the COVID-19 pandemic**
32 **demonstrated that behavioural change at a massive scale and in a short time is possible (*high***
33 ***confidence*)**. COVID-19 accelerated some specific trends, such as an uptake in urban cycling. However,
34 the acceptability of collective social change over a longer term towards less resource-intensive lifestyles
35 depends on social mandate building through public participation, discussion and debate over
36 information provided by experts, to produce recommendations that inform policy-making. {Box 5.2}

38 **Mitigation policies that integrate and communicate with the values people hold are more**
39 **successful (*high confidence*)**. Values differ between cultures. Measures that support autonomy, energy
40 security and safety, equity and environmental protection, and fairness resonate well in many
41 communities and social groups. Changing from a commercialised, individualised, entrepreneurial
42 training model to an education cognizant of planetary health and human well-being can accelerate
43 climate change awareness and action {5.4.1, 5.4.2}

45 **Changes in consumption choices that are supported by structural changes and political action**
46 **enable the uptake of low-carbon choices (*high confidence*)**. Policy instruments applied in
47 coordination can help to accelerate change in a consistent desired direction. Targeted technological
48 change, regulation, and public policy can help in steering digitalization, the sharing economy, and
49 circular economy towards climate change mitigation. {5.3, 5.6}

- 1 **Complementarity in policies helps in the design of an optimal demand-side policy mix (*medium***
2 ***confidence*)**. In the case of energy efficiency, for example, this may involve CO₂ pricing, standards and
3 norms, and information feedback. {5.3, 5.4, 5.6}

SUBJECT TO FINAL EDITS

1 5.1 Introduction

2 The Sixth Assessment Report of the IPCC (AR6), for the first time, features a chapter on demand,
3 services, and social aspects of mitigation. It builds on the AR4, which linked behaviour and lifestyle
4 change to mitigating climate change (IPCC 2007; Roy and Pal 2009; IPCC 2014a), the Global Energy
5 Assessment (Roy et al. 2012), and the AR5, which identified sectoral demand-side mitigation options
6 across chapters (IPCC 2014b; Creutzig et al. 2016b; IPCC 2014a). The literature on the nature, scale,
7 implementation and implications of demand-side solutions, and associated changes in lifestyles, social
8 norms, and well-being, has been growing rapidly (Creutzig et al. 2021a) (Box 5.2). Demand-side
9 solutions support near-term climate change mitigation (Méjean et al. 2019; Wachsmuth and Duscha
10 2019) and include consumers' technology choices, behaviours, lifestyle changes, coupled production-
11 consumption infrastructures and systems, service provision strategies, and associated socio-technical
12 transitions. This chapter's assessment of the social sciences (also see Supplementary Materials I Chapter
13 5) reveals that social dynamics at different levels offer diverse entry points for acting on and mitigating
14 climate change (Jorgenson et al. 2018).

15
16 Three entry points are relevant for this chapter. First, well-designed demand for services scenarios are
17 consistent with adequate levels of well-being for everyone (Rao and Baer 2012; Grubler et al. 2018;
18 Mastrucci et al. 2020; Millward-Hopkins et al. 2020), with high and/or improved quality of life (Max-
19 Neef 1995), improved levels of happiness (Easterlin et al. 2010) and sustainable human development
20 (Arrow et al. 2013; Dasgupta and Dasgupta 2017).

21
22 Second, demand-side solutions support staying within planetary boundaries (Haberl et al. 2014; Matson
23 et al. 2016; Hillebrand et al. 2018; Andersen and Quinn 2020; UNDESA 2020; Hickel et al. 2021;
24 Keyßer and Lenzen 2021); they entail fewer environmental risks than many supply side technologies
25 (Von Stechow et al. 2016) and make carbon dioxide removal technologies, such as Bio-Energy with
26 Carbon Capture and Storage (BECCS) less relevant (Van Vuuren et al. 2018) or possibly irrelevant in
27 modelling studies (Grubler et al. 2018; Hickel et al. 2021; Keyßer and Lenzen 2021) still requiring
28 ecosystem based carbon dioxide removal. In the IPCC's SR1.5C (IPCC 2018), four stylised scenarios
29 have explored possible pathways towards stabilising global warming at 1.5°C (SPM SR.15 Figure 3a
30 (IPCC 2014a), (Figure 5.1) One of these scenarios, LED-19, investigates the scope of demand-side
31 solutions (Figure 5.1). The comparison of scenarios reveals that such low-energy demand pathways
32 eliminate the need for technologies with high uncertainty, such as BECCS.

33
34 Third, interrogating demand for services from the well-being perspective also opens new avenues for
35 assessing mitigation potentials (Brand-Correa and Steinberger 2017; Mastrucci and Rao 2017; Rao and
36 Min 2018a; Mastrucci and Rao 2019; Balruszewicz et al. 2021). Arguably, demand-side interventions
37 often operate institutionally or in terms of restoring natural functioning and have so far been politically
38 side lined but COVID-19 revealed interesting perspectives (Box 5.2). Such demand-side solutions also
39 support near-term goals towards climate change mitigation and reduce the need for politically
40 challenging high global carbon prices (Méjean et al. 2019) (Box 5.11). The well-being focus emphasises
41 equity and universal need satisfaction, compatible with Sustainable Development Goals (SDGs)
42 progress (Lamb and Steinberger 2017).

43
44 The requisites for well-being include collective and social interactions as well as consumption-based
45 material inputs. Moreover, rather than material inputs *per se*, people need and demand services for
46 dignified survival, sustenance, mobility, communication, comfort and material well-being (Nakićenović
47 et al. 1996b; Johansson et al. 2012; Creutzig et al. 2018). These services may be provided in many
48 different context-specific ways using physical resources (biomass, energy, materials, etc.) and available
49 technologies (e.g. cooking tools, appliances). Here we understand demand as demand for services

1 (often requiring material input), with particular focus on services that are required for well-being (such
2 as lighting, accessibility, shelter, etc.), and that are shaped by culturally and geographically
3 differentiated social aspects, choice architectures and the built environment (infrastructures).

4
5 Focusing on demand for services broadens the climate solution space beyond technological switches
6 confined to the supply side, to include solutions that maintain or improve well-being related to nutrition,
7 shelter and mobility while (sometimes radically) reducing energy and material input levels (Creutzig et
8 al. 2018; Cervantes Barron 2020; Baltruszewicz et al. 2021; Kikstra et al. 2021b). This also recognises
9 that mitigation policies are politically, economically and socially more feasible, as well as more
10 effective, when there is a two-way alignment between climate action and well-being (OECD 2019a).
11 There is *medium evidence and high agreement* that well-designed demand for services scenarios are
12 consistent with adequate levels of well-being for everyone (Rao and Baer 2012; Grubler et al. 2018;
13 Rao et al. 2019b; Millward-Hopkins et al. 2020; Kikstra et al. 2021b), with high and/or improved quality
14 of life (Max-Neef 1995; Vogel et al. 2021) and improved levels of happiness (Easterlin et al. 2010) and
15 sustainable human development (Gadrey and Jany-Catrice 2006; Arrow et al. 2013; Dasgupta and
16 Dasgupta 2017). While demand for services is high as development levels increase, and related
17 emissions are growing in many countries (Yumashev et al. 2020; Bamisile et al. 2021), there is also
18 evidence that provisioning systems delink services provided from emissions (Conte Grand 2016; Patra
19 et al. 2017; Kavitha et al. 2020). Various mitigation strategies, often classified into Avoid-Shift-
20 Improve (ASI) options, effectively reduce primary energy demand and/or material input (Haas et al.
21 2015; Haberl et al. 2017; Samadi et al. 2017; Hausknost et al. 2018; Haberl et al. 2019; Van den Berg
22 et al. 2019; Ivanova et al. 2020). Users' participation in decisions about how services are provided, not
23 just their technological feasibility, is an important determinant of their effectiveness and sustainability
24 (Whittle et al. 2019; Vanegas Cantarero 2020).

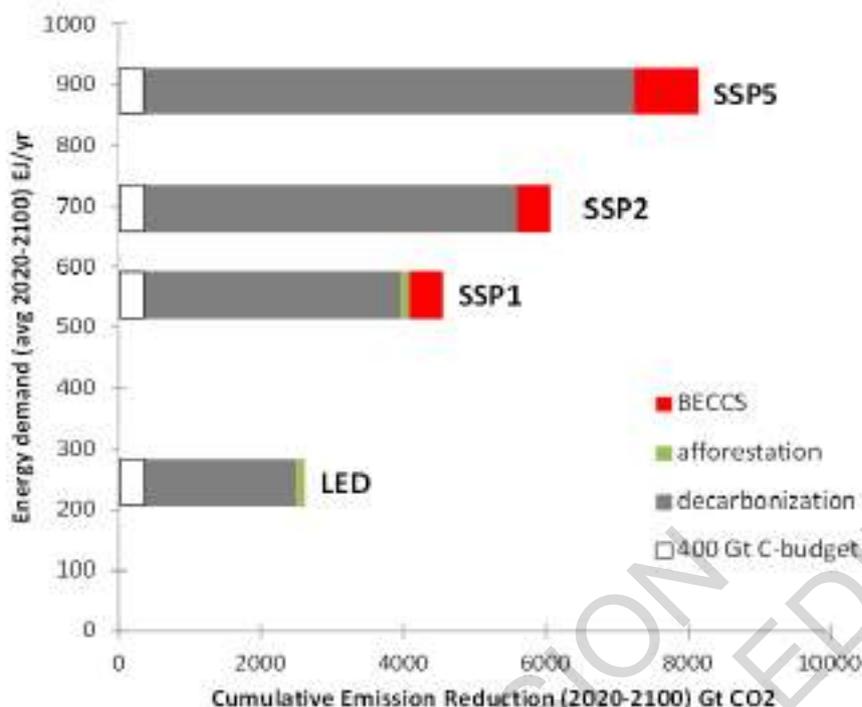

25
26 Sector-specific mitigation approaches (Chapters 6-11) emphasise the potential of mitigation via
27 improvements in energy- and materials- efficient manufacturing (Gutowski et al. 2013; Gramkow and
28 Anger-Kraavi 2019; Olatunji et al. 2019; Wang et al. 2019), new product design (Fishedick et al.
29 2014), energy-efficient buildings (Lucon et al. 2014), shifts in diet (Bajželj et al. 2014; Smith et al.
30 2014), and transport infrastructure design shifts (Sims et al. 2014), compact urban forms (Seto et al.
31 2014). In this chapter, service-related mitigation strategies are categorized as Avoid, Shift, or Improve
32 (ASI) options to show how mitigation potentials, and social groups who can deliver them, are much
33 broader than usually considered in traditional sector-specific presentations. ASI originally arose from
34 the need to assess the staging and combinations of interrelated mitigation options in the provision of
35 transportation services (Hidalgo and Huizenga 2013). In the context of transportation services, ASI
36 seeks to mitigate emissions through *avoiding* as much transport service demand as possible (e.g.,
37 telework to eliminate commutes, mixed-use urban zoning to shorten commute distances), *shifting*
38 remaining demand to more efficient modes (e.g., bus rapid transit replacing passenger vehicles), and
39 *improving* the carbon intensity of modes utilised (e.g., electric buses powered by renewables) (Creutzig
40 et al. 2016a). This chapter summarises ASI options and potentials across sectors and generalises the
41 definitions. 'Avoid' refers to all mitigation options that reduce unnecessary (in the sense of being not
42 required to deliver the desired service output) energy consumption by redesigning service provisioning
43 systems; 'shift' refers to the switch to already existing competitive efficient technologies and service
44 provisioning systems; and 'improve' refers to improvements in efficiency in existing technologies. The
45 Avoid-Shift-Improve framing operates in three domains: 'Socio-cultural', where social norms, culture,
46 and individual choices play an important role – a category especially but not only relevant for avoid
47 options; 'Infrastructure', which provides the cost and benefit landscape for realising options and is
48 particularly relevant for shift options; and 'Technologies', especially important for the improve options.
49 Avoid, Shift, and Improve choices will be made by individuals and households, instigated by salient
50 and respected role models and novel social norms, but require support by adequate infrastructures

1 designed by urban planners and building and transport professionals, corresponding investments, and a
2 political culture supportive of mitigation action. This is particularly true for many Avoid and Shift
3 decisions that are difficult because they encounter psychological barriers of breaking routines, habits
4 and imagining new lifestyles and the social costs of not conforming to society (Kaiser 2006). Simpler
5 Improve decisions like energy efficiency investments on the other hand can be triggered and sustained
6 by traditional policy instruments complemented by behavioural nudges.

7
8 A key concern about climate change mitigation policies is that they may reduce quality of life. Based
9 on growing literature, in this chapter we adopt the concept of Decent Living Standards (DLS, explained
10 further in relation to other individual and collective well-being measures and concepts in the Social
11 Sciences Primer) as a universal set of service requirements essential for achieving basic human well-
12 being. DLS includes the dimensions of nutrition, shelter, living condition, clothing, health care,
13 education, and mobility (Frye et al. 2018; Rao and Min 2018b). DLS provides a fair, direct way to
14 understand the basic low-carbon energy needs of society and specifies the underlying material and
15 energy requirements. This chapter also comprehensively assesses related well-being metrics that result
16 from demand-side action observing overall positive effects (5.3). Similarly, ambitious low-emissions
17 demand-side scenarios suggest that well-being could be maintained or improved while reducing global
18 final energy demand, and some current literature estimates that it is possible to meet Decent Living
19 Standards for all within the 2-degree warming window (Grubler et al. 2018; Burke 2020; Keyßer and
20 Lenzen 2021) (5.4). A key concern here is how to blend new technologies with social change to integrate
21 Improving ways of living, Shifting modalities and Avoiding certain kinds of emissions altogether (5.6).
22 Social practice theory emphasizes that material stocks and social relations are key in forming and
23 maintaining habits (Reckwitz 2002; Haberl et al. 2021). This chapter reflects these insights by assessing
24 the role of infrastructures and social norms in GHG emission intensive or low-carbon lifestyles (5.4).

25 A core operational principle for sustainable development is equitable access to services to provide well-
26 being for all, while minimising resource inputs and environmental and social externalities/trade-offs,
27 underpinning the Sustainable Development Goals (SDGs) (Princen 2003; Lamb and Steinberger 2017;
28 Dasgupta and Dasgupta 2017). Sustainable development is not possible without changes in
29 consumption patterns within the widely recognised constraints of planetary boundaries, resource
30 availability, and the need to provide decent living standards for all (Langhelle 2000; Toth and Szigeti
31 2016; O'Neill et al. 2018). Inversely, reduced poverty and higher social equity offer opportunities for
32 delinking demand for services from emissions, e.g., via more long-term decision making after having
33 escaped poverty traps and by reduced demand for non-well-being enhancing status consumption (Nabi
34 et al. 2020; Ortega-Ruiz et al. 2020; Parker and Bhatti 2020; Teame and Habte 2020) (5.3).

35
36 Throughout this chapter we discuss how people can realise various opportunities to reduce GHG
37 emission-intensive consumption (5.2 and 5.3), and act in various roles (5.4), within an enabling
38 environment created by policy instruments and infrastructure that builds on social dynamics (5.6).

14
15 **Box 5.1 Bibliometric foundation of demand-side climate change mitigation**

16 A bibliometric overview of the literature found 99,065 academic peer-reviewed papers identified with
17 34 distinct search queries addressing relevant content of this chapter (Creutzig et al. 2021a). The
18 literature is growing rapidly (15% yr⁻¹) and the literature body assessed in the AR6 period (2014-2020)
19 is twice as large as all literature published before.

20
21 A large part of the literature is highly repetitive and/or includes no concepts or little quantitative or
22 qualitative data of relevance to this chapter. For example, a systematic review on economic growth and
23 decoupling identified more than 11,500 papers treating this topic, but only 834 of those, i.e. 7%,
24 included relevant data (Wiedenhofer et al. 2020). In another systematic review, assessing quantitative
25 estimates of consumption-based solutions (Ivanova et al. 2020), only 0.8% of papers were considered
26 after consistency criteria were enforced. Altogether, we relied on systematic reviews wherever possible.
27 Other important papers were not captured by systematic reviews, but included in this chapter through
28 expert judgement. Based on topical modelling and relevance coding of resulting topics, the full literature
29 body can be mapped into two dimensions, where spatial relationships indicate topical distance (Box
30 5.1, Figure 1). The interpretation of topic demonstrates that the literature organises in four clusters of
31 high relevance for demand-side solutions (housing, mobility, food, and policy), whereas other clusters

1 (nature, energy supply) are relatively less relevant.

2
3 **Box 5.1, Figure 1 Map of the literature on demand, services and social aspects of climate change**
4 **mitigation.**

5 Dots show document positions obtained by reducing the 60-dimensional topic scores to two dimensions
6 aiming to preserve similarity in overall topic score. The two axes therefore have no direct interpretation
7 but represent a reduced version of similarities between documents across 60 topics. Documents are
8 coloured by query category. Topic labels of the 24 most relevant topics are placed in the centre of each of
9 the large clusters of documents associated with each topic. % value in caption indicates the proportion of
10 studies in each “relevance” bracket.

13

14 Section 5.2 provides evidence on the links among mitigation and well-being, services, equity, trust, and
15 governance. Section 5.3 quantifies the demand-side opportunity space for mitigation, relying on the
16 Avoid, Shift and Improve framework. Section 5.4 assesses the relevant contribution of different parts
17 of society to climate change mitigation. Section 5.5 evaluates the overall dynamics of social transition
18 processes while Section 5.6 summarises insights on governance and policy packages for demand-side
19 mitigation and well-being. A Social Science Primer defines and discusses key terms and social science
20 concepts used in the context of climate change mitigation.

START BOX 5.2 HERE**Box 5.2 COVID-19, service provisioning and climate change mitigation**

There is now *high evidence and high agreement* that the COVID-19 pandemic has increased the political feasibility of large-scale government actions to support the services for provision of public goods, including climate change policies. Many behavioural changes due to COVID-19 reinforce sufficiency and emphasis on solidarity, economies built around care, livelihood protection, collective action, and basic service provision, linked to reduced emissions.

COVID-19 led to direct and indirect health, economic, and confinement-induced hardships and suffering, mostly for the poor, and reset habits and everyday behaviours of the well-off too, enabling a reflection on the basic needs for a good life. Although COVID-19 and climate change pose different kinds of threats and therefore elicit different policies, there are several lessons from COVID-19 for advancing climate change mitigation (Klenert et al. 2020; Manzanedo and Manning 2020; Stark 2020). Both crises are global in scale, requiring holistic societal response; governments can act rapidly, and delay in action is costly (Bouman et al. 2020a; Klenert et al. 2020). The pandemic highlighted the role of individuals in collective action and many people felt morally compelled and responsible to act for others (Budd and Ison, 2020). COVID-19 also taught the effectiveness of rapid collective action (physical distancing, wearing masks, etc.) as contributions to the public good. The messaging about social distancing, wearing masks and handwashing during the pandemic called attention to the importance of effective public information (e.g. also about reducing personal carbon footprints), recognising that rapid pro-social responses are driven by personal and socio-cultural norms (Sovacool et al. 2020a; Bouman et al. 2020a). In contrast, low trust in public authorities impairs the effectiveness of policies and polarizes society (Bavel et al. 2020; Hornsey 2020).

During the shutdown, emissions declined relatively most in aviation, and absolutely most in car transport (Le Quéré et al. 2020, Sarkis et al. 2020), and there were disproportionately strong reductions in GHG emissions from coal (Bertram et al. 2021)(Chapter 2). At their peak, CO₂ emissions in individual countries decreased by 17% in average (Le Quéré et al. 2020). Global energy demand was projected to drop by 5% in 2020, energy-related CO₂ emissions by 7%, and energy investment by 18% (IEA 2020a). Covid-19 shock and recovery scenarios project final energy demand reductions of 1–36 EJ yr⁻¹ by 2025 and cumulative CO₂ emission reductions of 14–45 GtCO₂ by 2030 (Kikstra et al. 2021a). Plastics use and waste generation increased during the pandemic (Klemeš et al. 2020; Prata et al. 2020). Responses to COVID-19 had important connections with energy demand and GHG emissions due to quarantine and travel restrictions (Sovacool et al. 2020a). Reductions in mobility and economic activity reduced energy use in sectors such as industry and transport, but increased energy use in the residential sector (Diffenbaugh et al. 2020). COVID-19 induced behavioural changes that may translate into new habits, some beneficial and some harmful for climate change mitigation. New digitally enabled service accessibility patterns (videoconferencing, telecommuting) played an important role in sustaining various service needs while avoiding demand for individual mobility. However, public transit lost customers to cars, personalised two wheelers, walking and cycling, while suburban and rural living gained popularity, possibly with long-term consequences. Reduced air travel, pressures for more localised food and manufacturing supply chains (Hobbs 2020; Nandi et al. 2020; Quayson et al. 2020), and governments' revealed willingness to make large-scale interventions in the economy also reflect sudden shifts in service provisions and GHG emissions, some likely to be lasting (Aldaco et al. 2020; Bilal et al. 2020; Boyer 2020; Norouzi et al. 2020; Prideaux et al. 2020; Hepburn et al. 2020; Sovacool et al. 2020a). If changes in some preference behaviours, e.g. for larger homes and work environments to enable home working and online education, lead to sprawling suburbs or gentrification with linked

1 environmental consequences, this could translate into long-term implications for climate change
2 (Beunoyer et al. 2020; Diffenbaugh et al. 2020). Recovering from the pandemic by adopting low
3 energy demand practices – embedded in new travel, work, consumption and production behaviour and
4 patterns– could reduce carbon prices for a 1.5°C consistent pathway by 19%, reduce energy supply
5 investments until 2030 by 1.8 trillion USD, and lessen pressure on the upscaling of low-carbon energy
6 technologies (Kikstra et al. 2021a).

7
8 COVID-19 drove hundreds of millions of people below poverty thresholds, reversing decades of
9 poverty reduction accomplishments (Krieger 2020; Mahler et al. 2020; Patel et al. 2020; Sumner et al.
10 2020) and raising the spectre of intersecting health and climate crises that are devastating for the most
11 vulnerable (Flyvbjerg 2020; Phillips et al. 2020). Like those of climate change, pandemic impacts fall
12 heavily on disadvantaged groups, exacerbate the uneven distribution of future benefits, amplify existing
13 inequities, and introduce new ones (Devine-Wright et al. 2020; Beunoyer et al. 2020). Addressing such
14 inequities is a positive step towards the social trust that leads to improved climate policies as well as
15 individual actions. Increased support for care workers and social infrastructures within a solidarity
16 economy is consistent with lower-emission economic transformation (Shelley 2017; Di Chiro 2019;
17 Pichler et al. 2019; Smetschka et al. 2019).

18
19 Fiscally, the pandemic may have slowed the transition to a sustainable energy world: governments
20 redistributed public funding to combat the disease, adopted austerity and reduced capacity, i.e. among
21 nearly 300 policies implemented to counteract the pandemic, the vast majority are related to rescue,
22 including worker and business compensation, and only 4% of these focus on green policies with
23 potential to reduce GHG emissions in the long-term; some rescue policies also assist emissions-
24 intensive business (Leach et al. 2021; Hepburn et al. 2020). However, climate investments can double
25 as the basis of the COVID-19 recovery (Stark 2020), with policies focused on both economic multipliers
26 and climate impacts such as clean physical infrastructure, natural capital investment, clean R&D and
27 education and training (Hepburn et al. 2020). This requires attention to investment priorities, including
28 often-underprioritized social investment, given how inequality intersects with and is a recognised core
29 driver of environmental damage and climate change (Millward-Hopkins et al. 2020).

30
31 **END BOX 5.2 HERE**

32 33 **5.2 Services, well-being and equity in demand-side mitigation**

34 As outlined in section 5.1, mitigation, equity and well-being go hand in hand to motivate actions.
35 Global, regional, and national actions/policies that advance inclusive well-being and build social trust
36 strengthen governance. There is *high evidence and high agreement* that demand-side measures cut
37 across all sectors, and can bring multiple benefits (Mundaca et al. 2019; Wachsmuth and Duscha 2019;
38 Geels 2020; Niamir et al. 2020b; Garvey et al. 2021; Roy et al. 2021). Since effective demand requires
39 affordability, one of the necessary conditions for acceleration of mitigation through demand side
40 measures is wide and equitable participation from all sectors of society. Low-cost low-emissions
41 technologies, supported by institutions and government policies, can help meet service demand and
42 advance both climate and well-being goals (Steffen et al. 2018a; Khosla et al. 2019). This section
43 introduces metrics of well-being and their relationship to GHG emissions, and clarifies the concept of
44 service provisioning.

45 **5.2.1 Metrics of well-being and their relationship to GHG emissions**

46 There is *high evidence and agreement* in the literature that human well-being and related metrics
47 provide a societal perspective which is inclusive, compatible with sustainable development, and

1 generates multiple ways to mitigate emissions. Development targeted to basic needs and well-being for
2 all entails less carbon-intensity than GDP-focused growth (Rao et al. 2014; Lamb and Rao 2015).

3
4 Current socioeconomic systems are based on high-carbon economic growth and resource use (Steffen
5 et al. 2018b). Several systematic reviews confirm that economic growth is tightly coupled with
6 increasing CO₂ emissions (Ayres and Warr 2005; Tiba and Omri 2017; Mardani et al. 2019;
7 Wiedenhofer et al. 2020) although the level of emissions depends on inequality (Baležentis et al. 2020;
8 Liu et al. 2020b), and on geographic and infrastructural constraints that force consumers to use fossil
9 fuels (Pottier et al. 2021). Different patterns emerge in the causality of the energy-growth nexus; (i)
10 energy consumption causes economic growth; (ii) growth causes energy consumption; (iii)
11 bidirectional causality; and (iv) no significant causality (Ozturk 2010). In a systematic review, Mardani
12 et al. (Mardani et al. 2019) found that in most cases energy use and economic growth have a
13 bidirectional causal effect, indicating that as economic growth increases, further CO₂ emissions are
14 stimulated at higher levels; in turn, measures designed to lower GHG emissions may reduce economic
15 growth. However, energy substitution and efficiency gains may offer opportunities to break the
16 bidirectional dependency (Komiyama 2014; Brockway et al. 2017; Shuai et al. 2019). Worldwide trends
17 reveal that at best only relative decoupling (resource use grows at a slower pace than GDP) was the
18 norm during the twentieth century (Jackson 2009; Krausmann et al. 2009; Ward et al. 2016; Jackson
19 2017), while absolute decoupling (when material use declines as GDP grows) is rare, observed only
20 during recessions or periods of low or no economic growth (Heun and Brockway 2019; Hickel and
21 Kallis 2019; Vadén et al. 2020; Wiedenhofer et al. 2020). Recent trends in OECD countries demonstrate
22 the potential for absolute decoupling of economic growth not only from territorial but also from
23 consumption-based emissions (Le Quéré et al. 2019), albeit at scales insufficient for mitigation
24 pathways (Vadén et al. 2020) (Chapter 2).

25
26 Energy demand and demand for GHG intensive products increased from 2010 until 2020 across all
27 sectors and categories. 2019 witnessed a reduction in energy demand growth rate to below 1% and 2020
28 an overall decline in energy demand, with repercussions into energy supply disproportionately affecting
29 coal via merit order effects (Bertram et al. 2021) (Cross-Chapter Box 1 in Chapter 1). There was a slight
30 but significant shift from high carbon beef consumption to medium carbon intensive poultry
31 consumption. Final energy use in buildings grew from 118 EJ in 2010 to around 128 EJ in 2019
32 (increased about 8%). The highest increase was observed in non-residential buildings, with a 13%
33 increase against 8% in residential energy demand (IEA 2019a). While electricity accounted for one-
34 third of building energy use in 2019, fossil fuel use also increased at a marginal annual average growth
35 rate of 0.7% since 2010 (IEA 2020a). Energy-related CO₂ emissions from buildings have risen in recent
36 years after flattening between 2013 and 2016. Direct and indirect emissions from electricity and
37 commercial heat used in buildings rose to 10 GtCO₂ in 2019, the highest level ever recorded. Several
38 factors have contributed to this rise, including growing energy demand for heating and cooling with
39 rising air-conditioner ownership and extreme weather events. A critical issue remains for how
40 comfortable people feel with temperatures they will be exposed to in the future and this depends on
41 factors such as physical, psychological and behavioral (Singh et al. 2018; Jacobs et al. 2019). Literature
42 now shows *high evidence and high agreement* around the observation that policies and infrastructure
43 interventions that lead to change in human preferences are more valuable for climate change mitigation.
44 In economics, welfare evaluations are predominantly based on the preference approach. Preferences are
45 typically assumed to be fixed, so that only changes in relative prices will reduce emissions. However,
46 as decarbonisation is a societal transition, individuals' preferences do shift and this can contribute to
47 climate change mitigation (Gough 2015). Even if preferences are assumed to change in response to
48 policy, it is nevertheless possible to evaluate policy, and demand-side solutions, by approaches to well-
49 being/welfare that are based on deeper concepts of preferences across disciplines (Fleurbaey and
50 Tadenuma 2014; Dietrich and List 2016; Mattauch and Hepburn 2016; Roy and Pal 2009; Komiyama

1 2014). In cases of past societal transitions, such as smoking reduction, there is evidence that societies
2 guided the processes of shifting preferences, and values changed along with changing relative prices
3 (Nyborg and Rege 2003; Stuber et al. 2008; Brownell and Warner 2009). Further evidence on changing
4 preferences in consumption choices pertinent to decarbonisation includes (Grinblatt et al. 2008;
5 Weinberger and Goetzke 2010) for mobility; (Erb et al. 2016; Muller et al. 2017; Costa and Johnson
6 2019) for diets; (Baranzini et al. 2017) for solar panel uptake. If individuals' preferences and values
7 change during a transition to the low-carbon economy, then this overturns conclusions on what count
8 as adequate or even optimal policy responses to climate change mitigation in economics (Jacobsen et
9 al. 2012; Schumacher 2015; Dasgupta et al. 2016; Daube and Ulph 2016; Ulph and Ulph 2021). In
10 particular, if policy instruments, such as awareness campaigns, infrastructure development or education,
11 can change people's preferences, then policies or infrastructure provision – socially constrained by
12 deliberative decision making -- which change both relative prices and preferences, are more valuable
13 for mitigation than previously thought (Mattauch et al. 2016, 2018; Creutzig et al. 2016b). The
14 provisioning context of human needs is participatory, so transformative mitigation potential arises from
15 social as well as technological change (Lamb and Steinberger 2017). Many dimensions of well-being
16 and 'basic needs' are social not individual in character (Schneider 2016), so extending well-being and
17 DLS analysis to emissions also involves understanding individual situations in social contexts. This
18 includes building supports for collective strategies to reduce emissions (Chan et al. 2019), going beyond
19 individual consumer choice. Climate policies that affect collective behaviour fairly are the most
20 acceptable policies across political ideologies (Clayton 2018); thus collective preferences for mitigation
21 are synergistic with evolving policies and norms in governance contexts that reduce risk, ensure social
22 justice and build trust (Atkinson et al. 2017; Cramton et al. 2017; Milkoreit 2017; Tvinnereim et al.
23 2017; Smith and Reid 2018; Carattini et al. 2019).

24
25 Because of data limitations, which can make cross-country comparisons difficult, health-based
26 indicators and in particular life expectancy (Lamb et al. 2014) have sometimes been proposed as quick
27 and practical ways to compare local or national situations, climate impacts, and policy effects (Decancq
28 et al. 2009; Sager 2017; Burstein et al. 2019). A number of different well-being metrics are valuable in
29 emphasising the constituents of what is needed for a decent life in different dimensions (Porter et al.
30 2017; Smith and Reid 2018; Lamb and Steinberger 2017). The SDGs overlap in many ways with such
31 indicators, and the data needed to assess progress in meeting the SDGs is also useful for quantifying
32 well-being (Gough 2017). For the purposes of this chapter, indicators directly relating GHG emissions
33 to well-being for all are particularly relevant.

34
35 Well-being can be categorised either as "hedonic" or "eudaimonic". Hedonic well-being is related to a
36 subjective state of human motivation, balancing pleasure over pain, and has gained influence in
37 psychology assessing 'subjective well-being' such as happiness and minimising pain, assuming that the
38 individual is motivated to enhance personal freedom, self-preservation and enhancement (Sirgy 2012;
39 Ganglmair-Wooliscroft and Wooliscroft 2019; Brand-Correa and Steinberger 2017; Lamb and
40 Steinberger 2017). Eudaimonic well-being focuses on the individual in the broader context, associating
41 happiness with virtue (Sirgy 2012) allowing for social institutions and political systems and considering
42 their ability to enable individuals to flourish. Eudaimonic analysis supports numerous development
43 approaches (Fanning and O'Neill 2019) such as the capabilities (Sen 1985), human needs (Doyal and
44 Gough 1991; Max-Neef et al. 1991) and models of psychosocial well-being (Ryan and Deci 2001).
45 Measures of well-being differ somewhat in developed and developing countries (Sulemana et al. 2016;
46 Ng and Diener 2019); for example, food insecurity, associated everywhere with lower subjective well-
47 being, is more strongly associated with poor subjective well-being in more-developed countries
48 (Frongillo et al. 2019); in wealthier countries, the relationship between living in rural areas is less
49 strongly associated with negative well-being than in less-developed countries (Requena 2016); and
50 income inequality is negatively associated with subjective well-being in developed countries, but

1 positively so in less-developed countries (Ngamaba et al. 2018). This chapter connects demand side
2 climate mitigation options to multiple dimensions of well-being going beyond single dimensional
3 metric of GDP which is at the core of IAMs. Many demand side mitigation solutions generate positive
4 and negative impacts on wider dimensions of human well-being which are not always quantifiable
5 (*medium evidence, medium agreement*).

6 7 **5.2.1.1 Services for well-being**

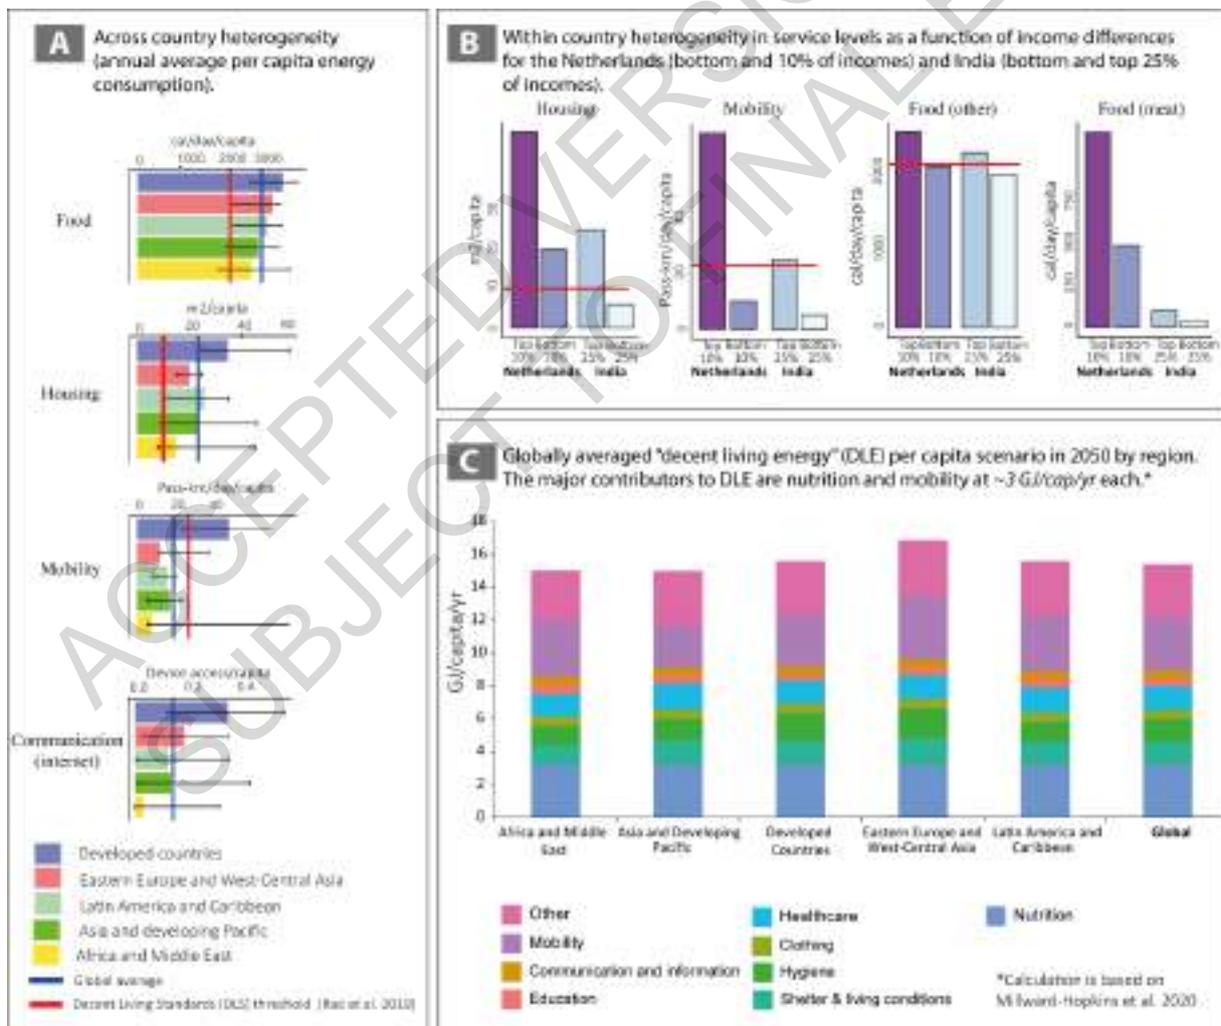

8 Well-being needs are met through services. Provision of services associated with low-energy demand
9 is a key component of current and future efforts to reduce carbon emissions. Services can be provided
10 in various culturally-appropriate ways, with diverse climate implications. There is *high evidence and*
11 *high agreement* in the literature that many granular service provision systems can make ‘demand’ more
12 flexible, provide new options for mitigation, support access to basic needs, and enhance human well-
13 being. Energy services offer an important lens to analyse the relationship between energy systems and
14 human well-being (Jackson and Papathanasopoulou 2008; Druckman and Jackson 2010; Mattioli 2016;
15 Walker et al. 2016; Fell 2017; Brand-Correa et al. 2018; King et al. 2019; Pagliano and Erba 2019;
16 Whiting et al. 2020). Direct and indirect services provided by energy, rather than energy itself, deliver
17 well-being benefits (Kalt et al. 2019). For example, illumination and transport are intermediary services
18 in relation to education, healthcare, meal preparation, sanitation, etc. which are basic human needs.
19 Sustainable consumption and production revolve around ‘doing more and better with the same’ and
20 thereby increasing well-being from economic activities ‘by reducing resource use, degradation and
21 pollution along the whole lifecycle, while increasing quality of life’ (UNEP 2010). Although energy is
22 required for delivering human development by supporting access to basic needs (Lamb and Rao 2015;
23 Lamb and Steinberger 2017), a reduction in primary energy use and/or shift to low-carbon energy, if
24 associated with the maintenance or improvement of services, can not only ensure better environmental
25 quality but also directly enhance well-being (Roy et al. 2012) the correlation between human
26 development and emissions are not necessarily coupled in the long term, which implies prioritize human
27 well-being and the environment over economic growth (Steinberger et al. 2020). At the interpersonal
28 and community level, cultural specificities, infrastructure, norms, and relational behaviours differ. (Box
29 5.3). For example, demand for space heating and cooling depends on building materials and designs,
30 urban planning, vegetation, clothing and social norms as well as geography, incomes, and outside
31 temperatures (Campbell et al. 2018; Ivanova et al. 2018; IEA 2019b; Dreyfus et al. 2020; Brand-Correa
32 et al. 2018). In personal mobility, different variable needs satisfiers (e.g., street space allocated to cars,
33 busses or bicycles) can help satisfy human needs, such as accessibility to jobs, health care, and
34 education. Social interactions and normative values play a crucial role in determining energy demand.
35 Hence, demand-side and service-oriented mitigation strategies are most effective if geographically and
36 culturally differentiated (Niamir et al. 2020a).

37
38 Decent Living Standards (DLS) serves as a socio-economic benchmark as it views human welfare not
39 in relation to consumption but rather in terms of services which together help meet human needs (e.g.
40 nutrition, shelter, health, etc.), recognising that these service needs may be met in many different ways
41 (with different emissions implications) depending on local contexts, cultures, geography, available
42 technologies, social preferences, and other factors. Therefore, one key way of thinking about providing
43 well-being for all with low carbon emissions centres around prioritising ways of providing services for
44 DLS in a low-carbon way (including choices of needs satisfiers, and how these are provided or made
45 accessible). They may be supplied to individuals or groups / communities, both through formal markets
46 and/or informally, e.g. by collaborative work, in coordinated ways that are locally-appropriate, designed
47 and implemented in accordance with overlapping local needs.

48 The most pressing DLS service shortfalls, as shown in Figure 5.2, lie in the areas of nutrition, mobility,
49 and communication. Gaps in regions such as Africa and the Middle East are accompanied by current
50 levels of service provision in the highly industrialised countries at much higher than DLS levels for the

1 same three service categories. The lowest population quartile by income worldwide faces glaring
 2 shortfalls in housing, mobility, and nutrition. Meeting these service needs using low-emissions energy
 3 sources is a top priority. Reducing GHG emissions associated with high levels of consumption and
 4 material throughput by those far above DLS levels has potential to address both emissions and
 5 inequality in energy and emission footprints (Otto et al. 2019). This, in turn, has further potential
 6 benefits; under the conditions of ‘fair’ income reallocation public services, this can reduce national
 7 carbon footprint by up to 30% while allowing the consumption of those at the bottom to increase
 8 (Millward-Hopkins and Oswald 2021). The challenge then is to address the upper limits of
 9 consumption. When consumption supports the satisfaction of basic needs any decrease causes
 10 deficiencies in human-need satisfaction, contrary, in the case of consumption that exceeds the limits of
 11 basic needs. A deprivation causes a subjective discomfort (Brand-Correa et al. 2020) therefore,
 12 establishing minimum and maximum standards of consumption or sustainable consumption corridors
 13 (Wiedmann et al. 2020) has been suggested to collectively not surpassing the environmental limits
 14 depending on the context. In some countries, carbon intensive ways of satisfying human needs have
 15 been locked-in, e.g. via car-dependent infrastructures (Druckman and Jackson 2010; Jackson and
 16 Papatanasopoulou 2008; King et al. 2019; Mattioli 2016), and both infrastructure reconfiguration and
 17 adaptation are required to organise need satisfaction in low-carbon ways (see also Section 10.2 in
 18 Chapter 10).

 10 **dimensions for final energy consumption at 149 EJ (15.3 GJ capita⁻¹yr⁻¹) in 2050 (Millward-Hopkins et al.**
 11 **2020), requiring advanced technologies in all sectors and radical demand-side changes. Values are shown**
 12 **for 5 world regions based on WG III AR6 Regional breakdown. Here we use passenger km/day/capita as**
 13 **metric for mobility only as a reference, however, transport and social inclusion research suggest the aim**
 14 **is to maximize accessibility and not travel levels or travelled distance.**
 15

16 There is *high evidence and high agreement* in the literature that vital dimensions of human well-being
 17 correlate with consumption, but only up to a threshold. High potential for mitigation lies in using low-
 18 carbon energy for new basic needs satisfaction while cutting emissions of those whose basic needs are
 19 already met (Grubler et al. 2018; Rao and Min 2018b; Millward-Hopkins et al. 2020; Rao et al. 2019b;
 20 Keyßer and Lenzen 2021). Decent Living Standards indicators serve as tools to clarify this socio-
 21 economic benchmark and identify well-being for all compatible mitigation potential. Energy services
 22 provisioning opens up avenues of efficiency and possibilities for decoupling energy services demand
 23 from primary energy supply, while needs satisfaction leads to the analysis of the factors influencing the
 24 energy demand associated with the achievement of well-being (Brand-Correa and Steinberger 2017;
 25 Tanikawa et al. 2021). Vital dimensions of well-being correlate with consumption, but only up to a
 26 threshold, decent living energy thresholds range ~13–18.4 GJ⁻¹cap⁻¹yr of final energy consumption but
 27 the current consumption ranges from under 5 GJ⁻¹cap⁻¹yr to over 200 GJ⁻¹cap⁻¹yr (Millward-Hopkins et
 28 al. 2020), thus a mitigation strategy that protects minimum levels of essential-goods service delivery
 29 for DLS, but critically views consumption beyond the point of diminishing returns of needs satisfaction,
 30 is able to sustain well-being while generating emissions reductions (Goldemberg et al. 1988; Jackson
 31 and Marks 1999; Druckman and Jackson 2010; Girod and De Haan 2010; Vita et al. 2019a;
 32 Baltruszewicz et al. 2021). Such relational dynamics are relevant both within and between countries,
 33 due to variances in income levels, lifestyle choice (see also 5.4.4), geography, resource assets and local
 34 contexts. Provisioning for human needs is recognised as participatory and interrelational; transformative
 35 mitigation potential can be found in social as well as technological change (Mazur and Rosa 1974;
 36 Goldemberg et al. 1985; Hayward and Roy 2019; Lamb and Steinberger 2017; O’Neill et al. 2018; Vita
 37 et al. 2019a). More equitable societies which provide DLS for all can devote attention and resources to
 38 mitigation (Dubash 2013; Rafaty 2018; Richards 2003; Oswald et al. 2021). For further exploration of
 39 these concepts, see the Chapter 5 Supplementary Material I.
 40

41 **5.2.2 Inequity in access to basic energy use and services**

42 **5.2.2.1 Variations in access to needs-satisfiers for Decent Living Standards**

43 There is very *high evidence and very high agreement* that globally, there are differences in the amount
 44 of energy that societies require to provide the basic needs for everyone. At present nearly one-third of
 45 the world’s population are ‘energy-poor’ facing challenges in both access and affordability, i.e., more
 46 than 2.6 billion people have little or no access to energy for clean cooking. About 1.2 billion lack energy
 47 for cleaning, sanitation and water supply, lighting, and basic livelihood tasks (Sovacool and Drupady
 48 2016; Rao and Pachauri 2017). The current per capita energy requirement to provide a decent standard
 49

FOOTNOTE ² The countries and areas classification in this figure deviate from the standard classification scheme adopted by WGIII as set out in Annex II, section 1.

1 of living range from ~5 to 200 GJ cap⁻¹yr⁻¹ (Steckel et al. 2013; Lamb and Steinberger 2017; Rao et al.
2 2019b; Millward-Hopkins et al. 2020), which shows the level of inequality that exists; this depends on
3 the context such as geography, culture, infrastructure or how services are provided (Brand-Correa et al.
4 2018) (Box 5.3). However, through efficient technologies and radical demand-side transformations, the
5 final energy requirements for providing DLS by 2050 is estimated at 15.3 GJ cap⁻¹yr⁻¹ (Millward-
6 Hopkins et al. 2020). Recent DLS estimates for Brazil, South Africa, and India are in the range between
7 15 and 25 GJ cap⁻¹yr⁻¹ (Rao et al. 2019b). The most gravely energy-poor are often those living in informal
8 settlements, particularly women who live in sub-Saharan Africa and developing Asia, whose socially-
9 determined responsibilities for food, water, and care are highly labour-intensive and made more intense
10 by climate change (Guruswamy 2016; Wester et al. 2019). For example, in Brazil, India and South
11 Africa, where inequality is extreme (Alvaredo et al. 2018) mobility (51-60%), food production and
12 preparation (21-27%) and housing (5-12%) dominate total energy needs (Rao et al. 2019b). Minimum
13 requirements of energy use consistent with enabling well-being for all is between 20 and 50 GJ cap⁻¹
14 yr⁻¹ depending on context (Rao et al. 2019b). Inequality in access to and availability of services for
15 human well-being varies in extreme degree across countries and income groups. In developing countries
16 the bottom 50% receive about 10% of the energy used in land transport and less than 5% in air transport,
17 while the top 10% use ~45% of the energy for land transport and around 75% for air transport (Oswald
18 et al. 2020). Within-country analysis shows that particular groups in China— women born in the rural
19 West with disadvantaged family backgrounds— face unequal opportunities for energy consumption
20 (Shi 2019). Figure 5.3 shows the wide variation across world regions in people’s access to some of the
21 basic material prerequisites for meeting DLS, and variations in energy consumption, providing a
22 starting point for comparative global analysis.

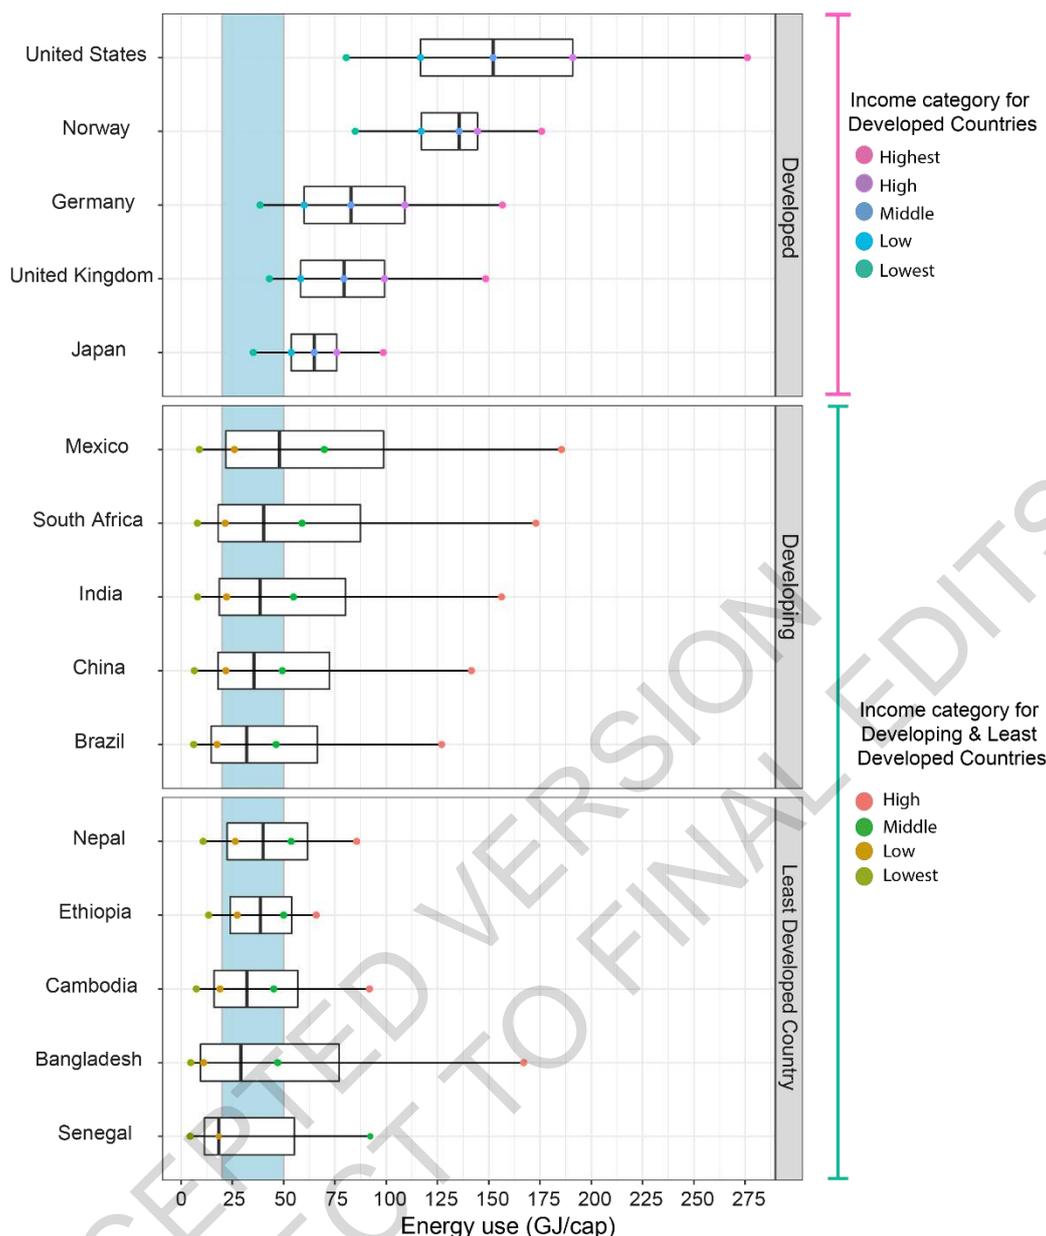

Figure 5.3 Energy use per capita of three groups of countries ranked by socioeconomic development and displayed for each country based on four or five different income groups (according the data availability) as well as geographical representation. The final energy use for decent living standards (20-50 GJ cap⁻¹) is indicated in the blue column (Rao et al. 2019b) as a reference for global range, rather than dependent on each country .

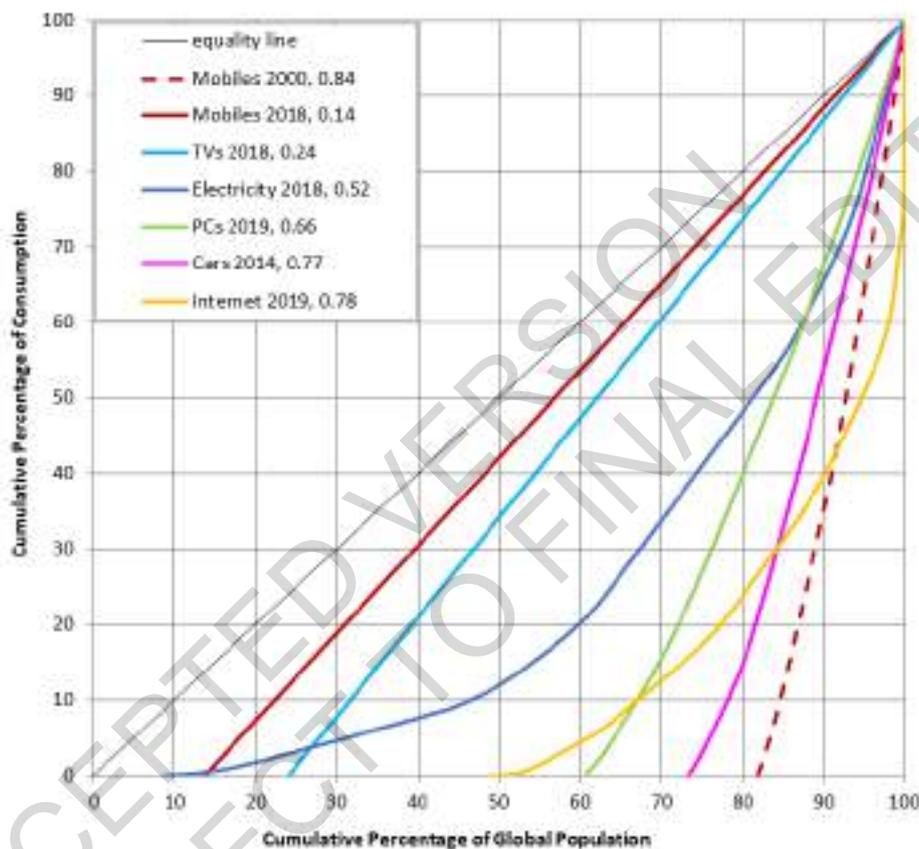

Data based on (Oswald et al. 2020).

START BOX 5.3 HERE

Box 5.3 Inequities in access to and levels of end-use technologies and infrastructure services

Acceleration in mitigation action needs to be understood from societal perspective. Technologies, access and service equity factors sometimes change rapidly. Access to technologies, infrastructures and products, and the services they provide, are essential for raising global living standards and improving human well-being (Alkire and Santos 2014; Rao and Min 2018b). Yet access to and levels of service delivery are distributed extremely inequitably as of now. How fast such inequities can be reduced by granular end-use technologies is illustrated by the cellphone (households with mobiles), comparing the

1 situation between 2014 and 2018. In this eighteen-year period, cellphones changed from a very
 2 inequitably-distributed technology to one with almost universal access, bringing accessibility benefits
 3 especially to populations with very low disposable income and to those whose physical mobility is
 4 limited (Porter 2016). Every human has the right to dignified decent life, to live in good health and to
 5 participate in society. This is a daunting challenge, requiring that in the next decade governments build
 6 out infrastructure to provide billions of people with access to a number of services and basic amenities
 7 in comfortable homes, nutritious food, and transit options (Rao and Min 2018b). For long, this challenge
 8 was thought to also be an impediment to developing countries’ participation in global climate mitigation
 9 efforts. However, recent research shows that this need not be the case (Millward-Hopkins et al. 2020;
 10 Rao et al. 2019b).

Box 5.3, Figure 1 International inequality in access and use of goods and services.
 Upper panel: International Lorenz curves and Gini coefficients accounting for the share of population living in households without access (origin of the curves on the y-axis), multiple ownership not considered. Lower panel: Gini, number of people without access, access rates and coverage in terms of share of global population and number of countries included. *Reduced samples lead to underestimation of inequality. A sample, for example, of around 80% of world population (taking the same 43 countries as

1 **for mobiles and cars) led to a lower Gini of around 0.48 (-0.04) for electricity. The reduced sample was**
2 **kept for mobiles in 2018 to allow for comparability with 2000.**

3 Source: (Zimm 2019)

4
5 Several of the United Nations Sustainable Development Goals (SDGs) (UN 2015) deal with providing
6 access to technologies and service infrastructures to the share of population so far excluded, showing
7 that the UN 2030 Agenda has adopted a multidimensional perspective on poverty. Multidimensional
8 poverty indices, such as the Social Progress Indicator (SPI) and the Individual Deprivation Measure, go
9 beyond income and focus on tracking the delivery of access to basic services by the poorest population
10 groups, both in developing countries (Fulton et al. 2009; Alkire and Robles 2017; Alkire and Santos
11 2014; Rao and Min 2018b), and in developed countries (Townsend 1979; Aaberge and Brandolini 2015;
12 Eurostat 2018). At the same time, the SDGs, primarily SDG 10 on reducing inequalities within and
13 among countries, promote a more equitable world, both in terms of inter- as well as intra-national
14 equality.

15 Access to various end-use technologies and infrastructure services features directly in the SDG targets
16 and among the indicators used to track their progress (UNESCO 2017; UN 2015): Basic services in
17 households (SDG 1.4.1), Improved water source (SDG 6.1.1); Improved sanitation (SDG 6.1.2);
18 Electricity (SDG 7.1.1); Internet - fixed broadband subscriptions (SDG 17.6.2); Internet - proportion of
19 population (SDG 17.8.1). Transport (public transit, cars, mopeds or bicycles) and media technologies
20 (mobile phones, TVs, radios, PCs, Internet) can be seen as proxies for access to mobility and
21 communication, crucial for participation in society and the economy (Smith et al. 2015). In addition,
22 SDG 10 is a more conventional income-based inequality goal, referring to income inequality (SDG
23 10.1), social, economic and political inclusion of all (SDG 10.2.), and equal opportunities and reduced
24 inequalities of outcome (SDG 10.3).

25 **END BOX 5.3 HERE**

27 **5.2.2.2 Variations in energy use**

28 There is *high evidence and high agreement* in the literature that through equitable distribution, well-
29 being for all can be assured at the lowest-possible energy consumption levels (Steinberger and Roberts
30 2010; Oswald et al. 2020) by reducing emissions related to consumption as much as possible, while
31 assuring DLS for everyone (Anneck 2002; de Zoysa 2011; Ehrlich and Ehrlich 2013; Spangenberg
32 2014; Toroitich and Kerber 2014; Dario Kenner 2015; Smil 2017; Toth and Szigeti 2016; Otto et al.
33 2019; Baltruszewicz et al. 2021). For example, at similar levels of human development, per capita
34 energy demand in the US was 63% higher than in Germany (Arto et al. 2016); those patterns are
35 explained by context in terms of various climate, cultural and historical factors influencing consumption
36 Context matter even in within country analysis ,e.g. electricity consumption in US show that efficiency
37 innovations do exert positive influence on savings of residential energy consumption, but the
38 relationship is mixed; on the contrary, affluence (household income and home size) and context
39 (geographical location) drives significantly resource utilization (Adua and Clark 2019), affluence is
40 central to any future prospect in terms of environmental conditions (Wiedmann et al. 2020). In China,
41 inequality of energy consumption and expenditure varies highly depending on the energy type, end-use
42 demand and climatic region (Wu et al. 2017).

43 Consumption is energy and materials-intensive and expands along with income. About half of the
44 energy used in the world is consumed by the richest 10% of people, most of whom live in developed
45 countries, especially when one includes the energy embodied in the goods they purchase from other
46 countries and the structure of consumption as a function of income level (Wolfram et al. 2016; Arto et
47 al. 2016; Santillán Vera et al. 2021). International trade plays a central role being responsible for shifting
48 burdens in most cases from low-income developing countries producers to high income developed
49 countries as consumers (Wiedmann et al. 2020). China is the largest importing market for EU and
50 United States, which accounts for near half and 40% of their imports in energy use respectively (Wu et

1 al. 2019). Wealthy countries have exported or outsourced their climate and energy crisis to low and
2 middle-income countries (Baker 2018) exacerbated by intensive international trade (Steinberger et al.
3 2012; Scherer et al. 2018). Therefore, issues of total energy consumption are inseparably related to the
4 energy inequity among the countries and regions of the world.

5
6 Within the energy use induced by global consumer products, household consumption is the biggest
7 contributor, contributing to around three quarters of the global total (Wu et al. 2019). A more granular
8 analysis of household energy consumption reveals that the lowest two quintiles in countries with
9 average annual income below 15,000 USD cap⁻¹ consume less energy than the international energy
10 requirements for DLS (20-50 GJ cap⁻¹); 77% of people consume less than 30 GJ cap⁻¹yr⁻¹ and 38%
11 consume less than 10 GJ cap⁻¹yr⁻¹ (Oswald et al. 2020). Many energy-intensive goods have high price
12 elasticity (>1.0), implying that growing incomes lead to over-proportional growth of energy footprints
13 in these consumption categories. Highly unequally distributed energy consumption is concentrated in
14 the transport sector, ranging from vehicle purchase to fuels, and most unequally in package holidays
15 and aviation (Gössling 2019; Oswald et al. 2020).

16
17 Socio-economic dynamics and outcomes affect whether provisioning of goods and services is achieved
18 at low energy demand levels (Figure 5.4). Specifically, multivariate regression shows that public service
19 quality, income equality, democracy, and electricity access enable higher need satisfaction at lower
20 energy demand, whereas extractivism and economic growth beyond moderate levels of affluence are
21 reduce need satisfaction at higher energy demand (Vogel et al. 2021). Altogether this demonstrates that
22 at a given level of energy provided, there is large scope to improve service levels for well-being by
23 modifying social economic context without increasing energy supply (Figure 5.4).

24

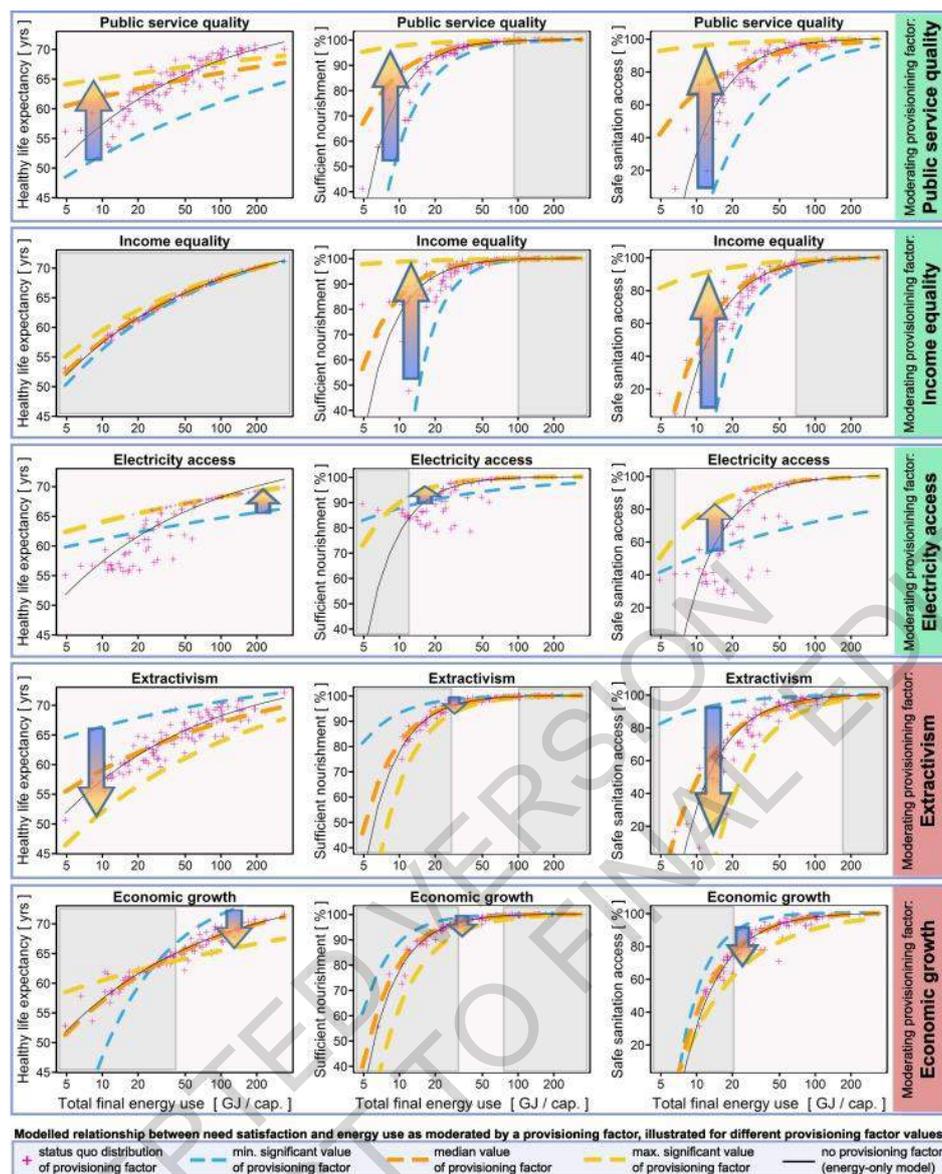

Figure 5.4 Improving services for well-being is possible, often at huge margin, at a given (relatively low) level of energy use

Source:(Vogel et al. 2021)

5.2.2.3 Variations in consumption-based emissions

The carbon footprint of a nation is equal to the direct emissions occurring due to households' transport, heating and cooking, as well as the impact embodied in the production of all consumed goods and services (Wiedmann and Minx 2008; Davis and Caldeira 2010; Hübler 2017; Vita et al. 2019a). There are large differences in carbon footprints between the poor and the rich. As a result of energy use inequality, the lowest global emitters (the poorest 10% in developing countries) in 2013 emitted about 0.1t CO₂ cap⁻¹, whereas the highest global emitters (the top 1% in the richest countries) emitted about 200-300 tCO₂ cap⁻¹ (World Bank 2019), . The poorest 50% of the world's population are responsible for only about 10% of total lifetime consumption emissions, in contrast about ~50% of the world's GHG emissions can be attributed to consumption by the world's richest 10%, with the average carbon footprint of the richest being 175 times higher than that of the poorest 10% (Chancel and Piketty 2015) consuming the global carbon budget by nearly 30% during the period 1990-2015 (Karthi et al. 2020; Gore 2020). While the mitigation efforts often focus on the poorest, the lifestyle and consumption patterns of the affluent people often influence the growing middle class (Otto et al. 2019), e.g. Across

1 EU countries, only 5% of households are living within the 1.5% climate limits and the top 1% emit
2 more than 22 times the target on average, being the transport in both land and air a characteristic of the
3 highest emitters (Ivanova and Wood 2020).

4
5 In low-income nations-which can exhibit per-capita carbon footprints 30 times lower than wealthy
6 nations (Hertwich and Peters 2009) emissions are predominantly domestic and driven by provision of
7 essential services (shelter, low-meat diets, clothing). Per capita carbon footprints average 1.6 tonnes per
8 year for the lowest income category, then quickly increase to 4.9 and 9.8 tonne for the two middle-
9 income categories and finally to an average of 17.9 tonnes for the highest income category. Global CO₂
10 emissions remain concentrated: the top 10% of emitters contribute about 35-45% of the total, while the
11 bottom 50% contribute just 13-15% of global emissions (Hubacek et al. 2017; Chancel and Piketty
12 2015). In wealthy nations, services such as private road transport, frequent air travel, private jet
13 ownership, meat-intensive diets, entertainment and leisure add significant emissions, while a
14 considerable fraction of the carbon footprint is imported from abroad, embedded in goods and services
15 (Hubacek et al. 2017).

16
17 High income households consume and demand energy at an order of magnitude greater than what is
18 necessary for DLS (Oswald et al. 2020). Energy-intensive goods, such as package holidays, have a
19 higher income elasticity of demand than less energy-intensive goods like food, water supply and
20 housing maintenance, which results in high-income individuals having much higher energy footprints
21 (Oswald et al. 2020). Evidence highlights highly unequal GHG emission in aviation: only 2-4% of
22 global population flew internationally in 2018, with 1% of world population emitting 50% of CO₂ from
23 commercial aviation (Gössling and Humpe 2020). Some individuals may add more than 1,600 t CO₂ yr⁻¹
24 individually by air travel (Gössling 2019).

25
26 The food sector dominates in all income groups, comprising 28% of households' carbon footprint, with
27 cattle and rice the major contributors (Scherer et al. 2018), food also accounts for 48% and 70% of
28 household impacts on land and water resources, being the meat, dairy, and processed food rising fast
29 together with income (Ivanova et al. 2016). Roughly 20-40% of food produced worldwide is lost to
30 waste before it reaches the market, or is wasted by households, the energy embodied in wasted food
31 was estimated at ~36 EJyr⁻¹, and during the period 2010-2016 global food loss and waste equalled 8-
32 10% of total GHG emissions (Godfray and Garnett 2014; Springmann et al. 2018; Mbow et al. 2019).
33 Global agri-food supply chains are crucial in the variation of per capita food consumption-related-GHG
34 footprints, mainly in the case of red meat and dairy (Kim et al. 2020) since highest per capita food-
35 consumption-related GHG emissions do not correlate perfectly with the income status of countries.
36 Thus, it is also crucial to focus on high-emitting individuals and groups within countries, rather than
37 only those who live in high-emitting countries, since the top 10% of emitters live on all continents and
38 one third of them are from the developing world (Chakravarty et al. 2009; Pan et al. 2019).

39
40 The environmental impact of increasing equity across income groups can be either positive or negative
41 (Hubacek et al. 2017; Scherer et al. 2018; Rao and Min 2018a; Millward-Hopkins et al. 2020).
42 Projections for achieving equitable levels of service provision globally predict large increases in global
43 GHG emissions and demand for key resources (Blomsma and Brennan 2017), especially in passenger
44 transport, which is predicted to increase nearly three-fold between 2015 and 2050, from 44 trillion to
45 122 trillion passenger-kilometres (OECD 2019a), and associated infrastructure needs, increasing freight
46 (Murray et al. 2017), increasing demand for cooling (IEA 2018), and shifts to carbon-intensive high-
47 meat diets (FAO 2018).

48
49 Increasing incomes for all to attain DLS raises emissions and energy footprints, but only slightly
50 (Jorgenson et al. 2016; Chakravarty et al. 2009; Scherer et al. 2018; Millward-Hopkins et al. 2020;

1 Oswald et al. 2020, 2021). The amount of energy needed for a high global level of human development
2 is dropping (Steinberger and Roberts 2010) and could by 2050 be reduced to 1950 levels (Millward-
3 Hopkins et al. 2020) requiring a massive deployment of technologies across the different sectors as well
4 as demand-side reduction consumption. The consumption share of the bottom half of the world's
5 population represents less than 20% of all energy footprints, which is less than what the top 5% of
6 people consume (Oswald et al. 2020).

7
8 Income inequality itself also raises carbon emissions (Hao et al. 2016; Sinha 2016; Uzar and Eyuboglu
9 2019; Baloch et al. 2020; Wiedmann et al. 2020; Oswald et al. 2020; Vogel et al. 2021). Wide inequality
10 can increase status-based consumption patterns, where individuals spend more to emulate the standards
11 of the high-income group (the Veblenian effect); inequality also diminishes environmental efforts by
12 reducing social cohesion and cooperation (Jorgenson et al. 2017) and finally, inequality also operates
13 by inducing an increase in working hours that leads to higher economic growth and, consequently,
14 higher emissions and ecological footprint, so working time reduction is key for policy to both reduce
15 emissions and protect employment (Fitzgerald et al. 2015, 2018).

16 **5.2.3 Equity, trust, and participation in demand-side mitigation**

17 There is *high evidence and high agreement* in literature that socio-economic equity builds not only well-
18 being for all, but also trust and effective participatory governance, which in turn strengthen demand-
19 side climate mitigation. Equity, participation, social trust, well-being, governance and mitigation are
20 parts of a continuous interactive and self-reinforcing process (Figure 5.5). Section SM5.1 in the
21 Supplemental Material for this chapter contains more detail on these links, drawing from social science
22 literature.

23
24
25 Economic growth in equitable societies is associated with lower emissions than in inequitable societies
26 (McGee and Greiner 2018), and income inequality is associated with higher global emissions (Ravallion
27 et al. 1997; Rao and Min 2018c; Diffenbaugh and Burke 2019; Fremstad and Paul 2019; Liu and Hao
28 2020; McGee and Greiner 2018). Relatively slight increases in energy consumption and carbon
29 emissions produce great increases in human development and well-being in less-developed countries,
30 and the amount of energy needed for a high global level of human development is dropping (Steinberger
31 and Roberts 2010). Equitable & democratic societies which provide high quality public services to their
32 population have high well-being outcomes at lower energy use than those which do not, whereas those
33 which prioritize economic growth beyond moderate incomes and extractive sectors display a reversed
34 effect (Vogel et al. 2021).

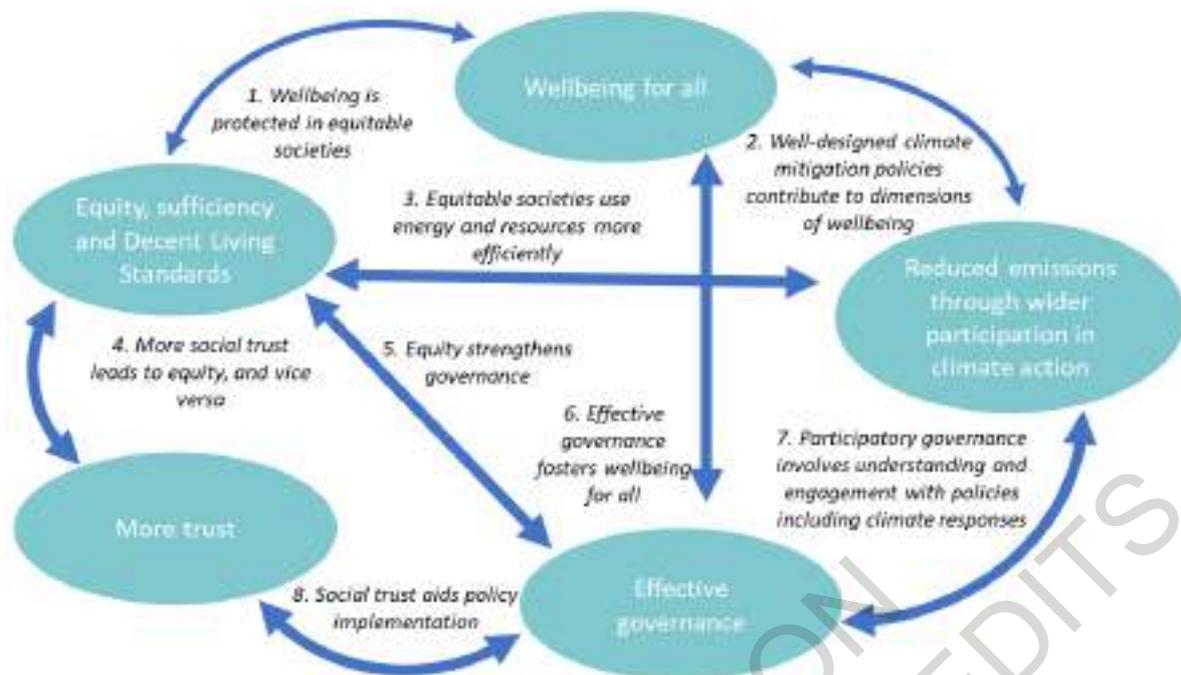

Figure 5.5 Well-being, equity, trust, governance and climate mitigation: positive feedbacks. Well-being for all, increasingly seen as the main goal of sustainable economies, reinforces emissions reductions through a network of positive feedbacks linking effective governance, social trust, equity, participation and sufficiency. This diagram depicts relationships noted in this chapter text and explained further in the Social Science Primer (supplementary material I in this Chapter). The width of the arrows corresponds to the level of confidence and degree of evidence from recent social sciences literature.

Well-designed climate mitigation policies ameliorate constituents of well-being (Creutzig et al. 2021b). The study shows that among all demand-side option effects on well-being 79% are positive, 18% are neutral (or not relevant/specify), and only 3% are negative (*high confidence*) (Creutzig et al. 2021b) (Figure 5.6). Figure 5.6 illustrates active mobility (cycling and walking), efficient buildings and prosumer choices of renewable technologies have the most encompassing beneficial effects on wellbeing with no negative outcome detected. Urban and industry strategies are highly positive overall for wellbeing, but they will also reshape supply-side businesses with transient intermediate negative effects. Shared mobility, like all others, has overall highly beneficial effects on wellbeing, but also displays a few negative consequences, depending on implementation, such as a minor decrease in personal security for patrons of ridesourcing.

Well-being improvements are most notable in health quality, air, and energy (*high confidence*). These categories are also most substantiated in the literature, often under the framing of co-benefits. In many cases, co-benefits outweigh the mitigation benefits of specific GHG emission reduction strategies. Food (*medium confidence*), mobility (*high confidence*), and water (*medium confidence*) are further categories where wellbeing is improved. Mobility has entries with highest well-being rankings for teleworking, compact cities, and urban system approaches. Effects on well-being in water and sanitation mostly comes from buildings and urban solutions. Social dimensions, such as personal security, social cohesion, and especially political stability are less predominantly represented. An exception is economic stability, suggesting that demand-side options generate stable opportunities to participate in economic activities (*high confidence*). Although the relation between demand-side mitigation strategies and the social aspects of human wellbeing is important, this has been less reflected in the literature so far, and hence the assessment finds more neutral/unknown interactions (Figure 5.6).

1 Policies designed to foster higher well-being for all via climate mitigation include reducing emissions
2 through wider participation in climate action, building more effective governance for improved
3 mitigation, and including social trust, greater equity, and informal-sector support as integral parts of
4 climate policies. Public participation facilitates social learning and people’s support of and engagement
5 with climate change priorities; improved governance is closely tied to effective climate policies
6 (Phuong et al. 2017). Better education, health care, valuing of social diversity, and reduced poverty –
7 characteristics of more equal societies—all lead to resilience, innovation, and readiness to adopt
8 progressive and locally-appropriate mitigation policies, whether high-tech or low-tech, centralised or
9 decentralised (Tanner et al. 2009; Lorenz 2013; Chu 2015; Cloutier et al. 2015; Mitchell 2015; Martin
10 and Shaheen 2016; Vandeweerd et al. 2016; Turnheim et al. 2018). Moreover, these factors are the ones
11 identified as enablers of high need satisfaction at lower energy use (Vogel et al. 2021).

12
13 There is less policy lock-in in more equitable societies (Seto et al. 2016). International communication,
14 networking, and global connections among citizens are more prevalent in more equitable societies, and
15 these help spread promising mitigation approaches (Scheffran et al. 2012). Climate-related injustices
16 are addressed where equity is prioritised (Klinsky and Winkler 2014). Thus, there is high confidence in
17 the literature that addressing inequities in income, wealth, and DLS not only raises overall well-being
18 and furthers the SDGs but also improves the effectiveness of climate change mitigation policies. For
19 example, job creation, retraining for new jobs, local production of livelihood necessities, social
20 provisioning, and other positive steps toward climate mitigation and adaptation are all associated with
21 more equitable and resilient societies (Okvat and Zautra 2011; Bentley 2014; Klinsky et al. 2016; Roy
22 et al. 2018a). At all scales of governance, the popularity and sustainability of climate policies requires
23 attention to the fairness of their health and economic implications for all, and participatory engagement
24 across social groups – a responsible development framing (Cazorla and Toman 2001; Dulal et al. 2009;
25 Chuku 2010; Shonkoff et al. 2011; Navroz 2019; Hofstad and Vedeld 2020; Muttitt and Kartha 2020;
26 Waller et al. 2020; Roy and Schaffartzik 2020; Temper et al. 2020). Far from being secondary or even
27 a distraction from climate mitigation priorities, an equity focus is intertwined with mitigation goals
28 (Klinsky et al. 2016). Demand-side climate mitigation options have pervasive ancillary, equity-
29 enhancing benefits, e.g. for health, local livelihoods, and community forest resources (Figure 5.6)
30 (Chhatre and Agrawal 2009; Garg 2011; Shaw et al. 2014; Serrao-Neumann et al. 2015; Klausbruckner
31 et al. 2016; Salas and Jha 2019). Limiting climate change risks is fundamental to collective well-being
32 (Max-Neef et al. 1989; Yamin et al. 2005; Nelson et al. 2013; Pecl et al. 2017; Tschakert et al. 2017;
33 Gough 2015, 2017). Section 5.6 discusses well-designed climate policies more fully, with examples.
34 Rapid changes in social norms which are underway and which underlie socially-acceptable climate
35 policy initiatives are discussed in section 5.4.

36
37 The distinction between necessities and luxuries helps to frame a growing stream of social sciences
38 literature with climate policy relevance (Arrow et al. 2004; Ramakrishnan and Creutzig 2021). Given
39 growing public support worldwide for strong sustainability, sufficiency, and sustainable consumption,
40 changing demand patterns and reduced demand are accompanying environmental and social benefits
41 (Jackson 2008; Fedrigo et al. 2010; Schroeder 2013; Figge et al. 2014; Spangenberg and Germany 2016;
42 Spengler 2016; Mont et al. 2020; Burke 2020). Beyond a threshold, increased material consumption is
43 not closely correlated with improvements in human progress (Kahneman and Deaton 2010; Vita et al.
44 2019b, 2020; Frank 1999; Steinberger and Roberts 2010; Oishi et al. 2018; Xie et al. 2018; Wang et al.
45 2019; Roy et al. 2012). Policies focusing on the “super-rich,” also called the “polluter elite,” are gaining
46 attention for moral or norms-based as well as emissions-control reasons (Kenner 2019; Pascale et al.
47 2020; Stratford 2020; Otto et al. 2019) (see Section 5.2.2.3). Conspicuous consumption by the wealthy
48 is the cause of a large proportion of emissions in all countries, related to expenditures on such things as
49 air travel, tourism, large private vehicles and large homes (Brand and Boardman 2008; Brand and

1 Preston 2010; Gore 2015; Sahakian 2018; Osuoka and Haruna 2019; Lynch et al. 2019; Roy and Pal
2 2009; Hubacek et al. 2017; Jorgenson et al. 2017; Gössling 2019; Kenner 2019; Roy et al. 2012).
3 Since no country now meets its citizens' basic needs at a level of resource use that is globally
4 sustainable, while high levels of life satisfaction for those just escaping extreme poverty require even
5 more resources, the need for transformative shifts in governance and policies is large (O'Neill et al.
6 2018; Vogel et al. 2021).

5

1 **Inequitable societies use energy and resources less efficiently.** Higher income inequality is
2 associated with higher carbon emissions, at least in developed countries (Grunewald et al. 2011; Golley
3 and Meng 2012; Chancel et al. 2015; Grunewald et al. 2017; Jorgenson et al. 2017; Sager 2017; Klasen
4 2018; Liu et al. 2019); reducing inequality in high-income countries helps to reduce emissions (Klasen
5 2018). There is high agreement in the literature that alienation or distrust weakens collective governance
6 and fragments political approaches towards climate action (Smit and Pilifosova 2001; Adger et al. 2003;
7 Hammar and Jagers 2007; Van Vossole 2012; Bulkeley and Newell 2015; Smith and Howe 2015; ISSC
8 et al. 2016; Smith and Mayer 2018; Fairbrother et al. 2019; Kulin and Johansson Sevä 2019; Liao et al.
9 2019; Alvarado et al. 2018; Hayward and Roy 2019).

10
11 Populism and politics of fear are less prevalent under conditions of more income equality (Chevigny
12 2003; Bryson and Rauwolf 2016; O'Connor 2017; Fraune and Knodt 2018; Myrick and Evans Comfort
13 2019). Ideology and other social factors also play a role in populist climate scepticism, but many of
14 these also relate to resentment of elites and desire for engagement (Swyngedouw 2011; Lockwood
15 2018; Huber et al. 2020). “Climate populism” movements are driven by an impetus for justice (Beeson
16 2019; Hilson 2019). When people feel powerless and/or that climate change is too big a problem to
17 solve because others are not acting, they may take less action themselves (Williams and Jaftha 2020).
18 However, systems for benefit-sharing can build trust and address large-scale “commons dilemmas”, in
19 the context of strong civil society (Barnett 2003; Mearns and Norton 2009; Inderberg et al. 2015;
20 Sovacool et al. 2015; Hunsberger et al. 2017; Soliev and Theesfeld 2020). Leadership is also important
21 in fostering environmentally-responsible group behaviours (Liu and Hao 2020).

22 In some less-developed countries, higher income inequality may in fact be associated with lower per
23 capita emissions, but this is because people who are excluded by poverty from access to fossil fuels
24 must rely on biomass (Klasen 2018). Such energy poverty – the fact that millions of people do not have
25 access to energy sources to help meet human needs – implies the opposite of development (Guruswamy
26 2010, 2020). In developing countries, livelihood improvements do not necessarily cause increases in
27 emissions (Peters et al. 2012; Reusser et al. 2013; Creutzig et al. 2015a; Chhatre and Agrawal 2009;
28 Baltruszewicz et al. 2021) and poverty alleviation causes negligible emissions (Chakravarty et al. 2009).
29 Greater equity is an important step towards sustainable service provisioning (Godfray et al. 2018;
30 Dorling 2019; Timko 2019).

31
32 As discussed in Section 5.6, policies to assist the low-carbon energy transition can be designed to
33 include additional benefits for income equality, besides contributing to greater energy access for the
34 poor (Burke and Stephens 2017; Frank 2017; Healy and Barry 2017; Sen 2017; Chapman et al. 2018;
35 La Viña et al. 2018; Chapman and Fraser 2019; Piggot et al. 2019; Sunderland et al. 2020). Global and
36 intergenerational climate inequities impact people’s well-being, which affects their consumption
37 patterns and political actions (Gori-Maia 2013; Clayton et al. 2015; Pizzigati 2018; Albrecht et al. 2007;
38 Fritze et al. 2008) (see Box 5.4).

39
40 **Consumption reductions, both voluntary and policy-induced, can have positive and double-**
41 **dividend effects on efficiency as well as reductions in energy and materials use (Mulder et al.**
42 **2006; Harriss and Shui 2010; Grinde et al. 2018; Spangenberg and Lorek 2019; Figge et al. 2014;**
43 **Vita et al. 2020).** Less waste, better emissions control and more effective carbon policies lead to better
44 governance and stronger democracies. Systems-dynamics models linking strong emissions-reducing
45 policies and strong social equity policies show that a low-carbon transition in conjunction with social
46 sustainability is possible, even without economic growth (Kallis et al. 2012; Jackson and Victor 2016;
47 Stuart et al. 2017; S. D’alessandro et al. 2019; Huang et al. 2019; Victor 2019; Chapman and Fraser
48 2019; Gabriel and Bond 2019). Such degrowth pathways may be crucial in combining technical
49 feasibility of mitigation with social development goals (Hickel et al. 2021; Keyßer and Lenzen 2021).

1 Multi-level or polycentric governance can enhance well-being and improve climate governance and
2 social resilience, due to varying adaptive, flexible policy interventions at different times and scales
3 (Kern and Bulkeley 2009; Lidskog and Elander 2009; Amundsen et al. 2010; Keskitalo 2010; Lee and
4 Koski 2015; Jokinen et al. 2016; Lepeley 2017; Marquardt 2017; Di Gregorio et al. 2019). Institutional
5 transformation may also result from socio-ecological stresses that accompany climate change, leading
6 to more effective governance structures (David Tàbara et al. 2018; Patterson and Huitema 2019; Barnes
7 et al. 2020). An appropriate, context-specific mix of options facilitated by policies can deliver both
8 higher well-being and reduced disparity in access to basic needs for services concurrently with climate
9 mitigation (Thomas and Twyman 2005; Klinsky and Winkler 2014; Lamb et al. 2014; Mearns and
10 Norton 2009; Lamb and Steinberger 2017). Hence, nurturing equitable human well-being through
11 provision of decent living standards for all goes hand in hand with climate change mitigation (ISSC et
12 al. 2016; OECD 2019a). There is *high confidence* in the literature that addressing inequities in income,
13 wealth, and DLS not only raises overall well-being and furthers the SDGs but also improves the
14 effectiveness of climate change mitigation policies.
15

16 **Participatory governance involves understanding and engagement with policies, including**
17 **climate policies.** Greater public participation in climate policy processes and governance, by increasing
18 the diversity of ideas and stakeholders, builds resilience and allows broader societal transformation
19 towards systemic change even in complex, dynamic and contested contexts (Dombrowski 2010; Wise
20 et al. 2014; Haque et al. 2015; Jodoin et al. 2015; Mitchell 2015; Kaiser 2020; Alegria 2021). This
21 sometimes involves complex policy discussions that can lead to governance innovations, also
22 influencing social norms (Martinez 2020). A specific example are citizen assemblies, deliberating
23 public policy challenges, such as climate change (Devaney et al. 2020). Activist climate movements are
24 changing policies as well as normative values (see Section 5.4 and the Social Science Primer).
25 Environmental justice and climate justice activists worldwide have called attention to the links between
26 economic and environmental inequities, collected and publicised data about them, and demanded
27 stronger mitigation (Goodman 2009; Schlosberg and Collins 2014; Jafry et al. 2019; Cheon
28 2020). Youth climate activists, and Indigenous leaders, are also exerting growing political influence
29 towards mitigation (Helferty and Clarke 2009; White 2011; Powless 2012; Petheram et al. 2015;
30 Curnow and Gross 2016; Grady-Benson and Sarathy 2016; Claeys and Delgado Pugley 2017; UN 2015;
31 O'Brien et al. 2018; Rowlands and Gomez Peña 2019; Bergmann and Ossewaarde 2020; Han and Ahn
32 2020; Nkrumah 2021). Indigenous resurgence (activism fuelled by ongoing colonial social /
33 environmental injustices, land claims, and deep spiritual/cultural commitment to environmental
34 protection) not only strengthens climate leadership in many countries, but also changes broad social
35 norms by raising knowledge of Indigenous governance systems which supported sustainable lifeways
36 over thousands of years (Wildcat 2014; Chanza and De Wit 2016; Whyte 2018, 2017; Temper et al.
37 2020). Related trends include recognition of the value of traditional ecological knowledge, Indigenous
38 governance principles, decentralisation, and appropriate technologies (Lange et al. 2007; Goldthau
39 2014; Whyte 2017).
40

41 **Social trust aids policy implementation.** More equal societies display higher trust, which is a key
42 requirement for successful implementation of climate policies (Rothstein and Teorell 2008; Carattini et
43 al. 2015; Klenert et al. 2018; Patterson et al. 2018). Inter-personal trust among citizens often promotes
44 pro-environment behaviour by influencing perceptions (Harring and Jagers 2013), enhancing
45 cooperation, and reducing free-riding and opportunistic behaviour (Gür 2020). Individual support for
46 carbon taxes and energy innovations falls when collective community support is lacking (Bolsen et al.
47 2014; Simon 2020; Smith and Mayer 2018). Social trust has a positive influence on civic engagement
48 among local communities, NGOs, and self-help groups for local clean cooking fuel installation (Nayak
49 et al. 2015).
50

1 Section 5.6 includes examples of climate mitigation policies and policy packages which address the
2 interrelationships shown in Figure 5.5. Improving well-being for all through climate mitigation includes
3 emissions-reduction goals in policy packages that ensure equitable outcomes, prioritize social trust-
4 building, support wide public participation in climate action including within the informal sector, and
5 facilitate institutional change for effective multi-level governance, as integral components of climate
6 strategies. This strategic approach, and its feasibility of success, rely on complex contextual factors
7 that may differ widely, especially between Global North and Global South (Atteridge et al. 2012;
8 Patterson et al. 2018; Jewell and Cherp 2020; Singh et al. 2020, 2021).

10 **START BOX 5.4 HERE**

12 **Box 5.4 Gender, race, intersectionality and climate mitigation**

13 There is *high evidence* and *high agreement* that empowering women benefits both mitigation and
14 adaptation, because women prioritise climate change in their voting, purchasing, community leadership,
15 and work both professionally and at home (*high evidence, high agreement*). Increasing voice and agency
16 for those marginalised in intersectional ways by Indigeneity, race, ethnicity, dis/ability, and other
17 factors has positive effects for climate policy (*high evidence, high agreement*).

18
19 Climate change affects people differently along all measures of difference and identity, which have
20 intersectional impacts linked to economic vulnerability and marginalisation (Morello Frosch et al. 2009;
21 Dankelman 2010; Habtezion 2013; Godfrey and Torres 2016; Walsh 2016; Flatø et al. 2017; Goodrich
22 et al. 2019; Perkins 2019; Gür 2020). Worldwide, racialized and Indigenous people bear the brunt of
23 environmental and climate injustices through geographic location in extraction and energy “sacrifice
24 zones”, areas most impacted by extreme weather events, and/or through inequitable energy access
25 (Aubrey 2019; Gonzalez 2020; Lacey-Barnacle et al. 2020; Porter et al. 2020; Temper et al. 2020; Jafry
26 et al. 2019) Disparities in climate change vulnerability not only reflect pre-existing inequalities, they
27 also reinforce them. For example, inequities in income and in the ownership and control of household
28 assets, familial responsibilities due to male out-migration, declining food and water access, and
29 increased disaster exposure can undermine women's ability to achieve economic independence, enhance
30 human capital, and maintain physical and mental health and well-being (Chandra et al. 2017; Eastin
31 2018; Das et al. 2019). Studies during the COVID crisis have found that, in general, women’s economic
32 and productive lives have been affected disproportionately to men’s (Alon et al. 2020; ILO 2020).
33 Women have less access to social protections and their capacity to absorb economic shocks is very low,
34 so they face a “triple burden” during crises -- including those resulting from climate change -- and this
35 is heightened for women in the less-developed countries and for those who are intersectionally
36 vulnerable (Coates et al. 2020; McLaren et al. 2020; Wenham et al. 2020; Azong and Kelso 2021; Erwin
37 et al. 2021; Maobe and Atela 2021; Nicoson 2021; Sultana 2021; Versey 2021). Because men currently
38 hold the majority of energy-sector jobs, energy transition will impact them economically and
39 psychologically; benefits, burdens and opportunities on both the demand and supply sides of the
40 mitigation transition have a range of equity implications (Pearl-Martinez and Stephens 2017; Standal et
41 al. 2020; Mang-Benza 2021). Mitigating gendered climate impacts requires addressing inequitable
42 power relations throughout society (Wester and Lama 2019).

43
44 Women’s well-being and gender-responsive climate policy have been emphasized in international
45 agreements including the Paris accord (UNFCCC 2015), CEDAW General Recommendation 37
46 (Vijayarasa 2021), and the 2016 Decision 21/CP.22 on Gender and Climate Change (UNFCCC 2016;
47 Larson et al. 2018). Increasing the participation of women and marginalised social groups, and
48 addressing their special needs, helps to meet a range of SDGs, improve disaster and crisis response,
49 increase social trust, and improve climate mitigation policy development and implementation (Alber

1 2009; Whyte 2014; Elnakat and Gomez 2015; Salehi et al. 2015; Buckingham and Kulcur 2017; Cohen
2 2017; Kronsell 2017; Lee and Zusman 2019).

3
4 Women have a key role in the changing energy economy due to their demand and end use of energy
5 resources in socially-gendered productive roles in food production and processing, health, care,
6 education, clothing purchases and maintenance, commerce, and other work both within and beyond the
7 home (Räty and Carlsson-Kanyama 2009; Oparaocha and Dutta 2011; Bob and Babugura 2014;
8 Macgregor 2014; Perez et al. 2015; Bradshaw 2018; Clancy and Feenstra 2019; Clancy et al. 2019;
9 Fortnam et al. 2019; Rao et al. 2019a; Quandt 2019; Horen Greenford et al. 2020; Johnson 2020).
10 Women's work and decision-making are central in the food chain and agricultural output in most
11 developing countries, and in household management everywhere. Emissions from cooking fuels can
12 cause serious health damages, and unsustainable extraction of biofuels can also hurt mitigation (Bailis
13 et al. 2015), so considering health, biodiversity and climate tradeoffs and co-benefits is important
14 (Rosenthal et al. 2018; Aberilla et al. 2020; Mazorra et al. 2020). Policies on energy use and
15 consumption are often focused on technical issues related to energy supply, thereby overlooking
16 'demand-side' factors such as household decision-making, unpaid work, livelihoods and care
17 (Himmelweit 2002; Perch 2011; Fumo 2014; Hans et al. 2019; Huyer and Partey 2020). Such gender-
18 blindness represents the manifestation of wider issues related to political ideology, culture and tradition
19 (Carr and Thompson 2014; Thoyre 2020; Perez et al. 2015; Fortnam et al. 2019).

20
21 Women, and all those who are economically and/or politically marginalised, often have less access to
22 energy and use less, not just because they may be poorer but case studies show because their
23 consumption choices are more ecologically-inclined and their energy use is more efficient (Lee et al.
24 2013; Permana et al. 2015; Li et al. 2019). Women's carbon footprints are about 6-28% lower than
25 men's (with high variation across countries), mostly based on their lower meat consumption and lower
26 vehicle use (Isenhour and Ardenfors 2009; Räty and Carlsson-Kanyama 2010; Barnett et al. 2012;
27 Medina and Toledo-Bruno 2016; Ahmad et al. 2017; Fernström Nåtby and Rönnerfalk 2018; Räty and
28 Carlsson-Kanyama 2009; Li et al. 2019). Gender-based income redistribution in the form of pay equity
29 for women could reduce emissions if the redistribution is revenue-neutral (Terry 2009; Dengler and
30 Strunk 2018). Also, advances in female education and reproductive health, especially voluntary family
31 planning, can contribute greatly to reducing world population growth (Abel et al. 2016; Dodson et al.
32 2020).

33
34 Carbon emissions are lower per capita in countries where women have more political 'voice',
35 controlling for GDP per capita and a range of other factors (Ergas and York 2012). While most people
36 recognize that climate change is happening (Lewis et al. 2018; Ballew et al. 2019), climate denialism
37 is more prevalent among men (McCright and Dunlap 2011; Anshelm and Hultman 2014; Jylhä et al.
38 2016; Nagel 2015), while women are more likely to be environmental activists, and to support stronger
39 environmental and climate policies (Stein 2004; McCright and Xiao 2014, Whyte 2014). Racialised
40 groups are more likely to be concerned about climate change and to take political action to support
41 climate mitigation policies (Leiserowitz and Akerlof 2010; Schuldt and Pearson 2016; Pearson et al.
42 2017; Ballew et al. 2020; Godfrey and Torres 2016; Johnson 2020). This underscores the important
43 synergies between equity and mitigation. The contributions of women, racialised people, and
44 Indigenous people who are socially positioned as those first and most affected by climate change – and
45 therefore experts on appropriate climate responses – are substantial (Dankelman and Jansen 2010;
46 Wickramasinghe 2015; Black 2016; Vinyeta et al. 2016; Pearse 2017). Equitable power, participation,
47 and agency in climate policy-making is hence an effective contribution for improving governance and
48 decision making on climate change mitigation (Reckien et al. 2017; Collins 2019). Indigenous
49 knowledge is an important source of guidance for biodiversity conservation, impact assessment,
50 governance, disaster preparedness and resilience (Salick and Ross 2009; Green and Raygorodetsky

1 2010; Speranza et al. 2010; Mekuriaw Bizuneh 2013; Mekuriaw 2017), and women are often the local
2 educators, passing on and utilising traditional and Indigenous knowledge (Ketlhoilwe 2013; Onyige
3 2017; Azong et al. 2018).

4
5 Higher female political participation, controlled for other factors, leads to higher stringency in climate
6 policies, and results in lower GHG emissions (Cook et al. 2019). Gender equity also is correlated with
7 lower per capita CO₂-eq emissions (Ergas and York 2012). In societies where women have more
8 economic equity, their votes push political decision-making in the direction of
9 environmental/sustainable development policies, less high-emission militarisation, and more emphasis
10 on equity and social policies e.g. via wealth and capital gains taxes (Resurrección 2013; UNEP 2013;
11 Glemarec et al. 2016; Bryan et al. 2018; Crawford 2019; Ergas and York 2012). Changing social norms
12 on race and climate are linked and policy-relevant (Benegal 2018; Elias et al. 2018; Slocum 2018; Gach
13 2019; Wallace-Wells 2019; Temple 2020; Drolet 2021). For all these reasons, climate policies are
14 strengthened by including more differently-situated knowledge and diverse perspectives, such as
15 feminist expertise in the study of power (Bell et al. 2020a; Lieu et al. 2020); clarifying equity goals (e.g.
16 distinguishing among ‘reach, ‘benefit’, and ‘empowerment’; obtaining disaggregated data and using
17 clear empirical equity measures; and confronting deeply-engrained inequities in society (Lau et al.
18 2021). Inclusivity in climate governance spans mitigation-adaptation, supply-demand and formal-
19 informal sector boundaries in its positive effects (Morello Frosch et al. 2009; Dankelman 2010; Bryan
20 and Behrman 2013; Habtezion 2013; Godfrey and Torres 2016; Walsh 2016; Flatø et al. 2017; Wilson
21 et al. 2018; Goodrich et al. 2019; Perkins 2019; Bell et al. 2020b; Gür 2020).

22
23 **END BOX 5.4 HERE**

24 25 **5.3 Mapping the opportunity space**

26 Reducing global energy demand and resource inputs while improving well-being for all requires an
27 identification of options, services and pathways that do not compromise essentials of a decent living.
28 To identify such a solution space, this section summarises socio-cultural, technological and
29 infrastructural interventions through the avoid/shift/improve (ASI) concept. ASI (see Section 5.1)
30 provides a categorisation of options aimed at continuously eliminating wastes in the current systems of
31 service provision (see Section 5.3.1.1). It also concisely presents demand side options to reduce GHG
32 emissions by individual choices which can be leveraged by supporting policies, technologies and
33 infrastructure. Two key concepts for evaluating the efficiency of service provision systems are: resource
34 cascades and exergy. These concepts provide powerful analytical lenses through which to identify and
35 substantially reduce energy and resource waste in service provision systems both for decent living
36 standards (see Section 5.3.2) and higher well-being levels. They typically focus on end-use conversion
37 and service delivery improvements as the most influential opportunities for system-wide waste
38 reductions. Review of the state of modelling low energy and resource demand pathways in long-term
39 climate mitigation scenarios (recognising the importance of such scenarios for illuminating technology
40 and policy pathways for more efficient service provision) and summary of the mitigation potentials
41 estimated from relevant scenarios to date are in Section 5.3.3. Finally, it reviews the role of three
42 megatrends that are transforming delivery of the services in innovative ways – digitalisation, the sharing
43 economy, and the circular economy (see Section 5.3.4). The review of megatrends makes an assessment
44 highlighting the potential risks of rebound effects, and even accelerated consumption; it also scopes for
45 proactive and vigilant policies to harness their potential for future energy and resource demand
46 reductions, and, conversely, avoiding undesirable outcomes.

1 5.3.1 Efficient service provision

2 This section organises demand reductions under the ASI framework. It presents service-oriented
3 demand-side solutions consistent with decent living standards (Table 5.1) (Creutzig et al. 2018). The
4 sharing economy, digitalisation, and the circular economy all can contribute to ASI strategies, with the
5 circular economy tentatively more on the supply side, and the sharing economy and digitalisation
6 tentatively more on the demand side (see Section 5.3.4). These new service delivery models go beyond
7 sectoral boundaries (IPCC sector chapter boundaries explained in Chapter 12) and take advantage of
8 technological innovations, design concepts, and innovative forms of cooperation cutting across sectors
9 to contribute to systemic changes worldwide. Some of these changes can be realised in the short term,
10 such as energy access, while others may take a longer period, such as radical and systemic eco-
11 innovations like shared electric autonomous vehicles. It is important to understand benefits and
12 distributional impacts of these systemic changes.

13 5.3.1.1 Integration of service provision solutions with A-S-I framework

15 Assessment of service-related mitigation options within the ASI framework is aided by decomposition
16 of emissions intensities into explanatory contributing factors, which depend on the type of service
17 delivered. Table 5.1 shows ASI options in selected sectors and services. It summarises resource, energy,
18 and emissions intensities commonly used by type of service (Cuenot et al. 2010; Lucon et al. 2014;
19 Fishedick et al. 2014). Also relevant: the concepts of service provision adequacy (Arrow et al. 2004;
20 Samadi et al. 2017), establishing the extents to which consumption levels exceed (e.g., high-calorie
21 diets contributing to health issues (Roy et al. 2012); excessive food waste) or fall short of (e.g.,
22 malnourishment) service level sufficiency (e.g., recommended calories) (Millward-Hopkins et al.
23 2020); and service level efficiency (e.g., effect of occupancy on the energy intensity of public transit
24 passenger-km travelled (Schäfer and Yeh 2020). Service-oriented solutions in this chapter are discussed
25 in the context of Table 5.1. Implementation of these solutions requires combinations of institutional,
26 infrastructural, behavioural, socio-cultural, and business changes that are mentioned in Section 5.2 and
27 discussed in Section 5.4.

28 **Table 5.1 Avoid-Shift-Improve options in selected sectors and services. Many options, such as urban form**
29 **and infrastructures are systemic, and influence several sectors simultaneously. Linkages to concepts**
30 **presented in sectoral chapters are indicated in parentheses in the first column.**

31 Source: adapted from Creutzig et al. 2018

Service	Emission decomposition factors	Avoid	Shift	Improve
Mobility [passenger-km] (Ch 8,10, 11,16)	kg CO ₂ = (passenger km)*(MJ pkm ⁻¹)* ¹ *(kg CO ₂ MJ ⁻¹)	Innovative mobility to reduce passenger-km: Integrate transport & land use planning Smart logistics Tele-working Compact cities Fewer long-haul flights Local holidays	Increased options for mobility MJ pkm⁻¹: Modal shifts, from car to cycling, walking, or public transit from air travel to high speed rail	Innovation in equipment design MJ pkm⁻¹ and CO₂-eq MJ⁻¹: Lightweight vehicles Hydrogen vehicles Electric vehicles Eco-driving
Shelter [Square meters] (Ch 8,9, 11)	kg CO ₂ = (square meters)*(tons material m ⁻²)*(kg CO ₂ ton material ⁻¹)	Innovative dwellings to reduce square meters: Smaller decent dwellings	Material efficient housing tons material m⁻²: Less material-intensive dwelling designs	Low emission dwelling design kgCO₂ ton⁻¹ material: Use wood as material

		Shared common spaces Multigenerational housing	Shift from single-family to multi-family dwellings	Use low-carbon production processes for building materials (e.g., cement and steel)
Thermal comfort [indoor temperature] (Ch 9,16)	kg CO ₂ = (Δ°C m ³ to warm or cool) (MJ m ⁻³)*(kg CO ₂ MJ ⁻¹)	Choice of healthy indoor temperature Δ°C m³: Reduce m ² as above Change temperature set-points Change dressing code Change working times	Design options to reduce MJ Δ°C⁻¹ m³: Architectural design (shading, natural ventilation, etc.)	New technologies to reduce MJ Δ°C⁻¹ m³ and kgCO₂/MJ: Solar thermal devices Improved insulation Heat pumps District heating
Goods [units] (Ch 11,12)	kg CO ₂ = product units * (kg material product ⁻¹)*(kg CO ₂ kg material ⁻¹)	More service per product: Reduce consumption quantities Long lasting fabric, appliances Sharing economy	Innovative product design kg material product⁻¹: Materials efficient product designs	Choice of new materials kg CO₂ kg material⁻¹: Use of low carbon materials New manufacturing processes and equipment use
Nutrition [Calories consumed] (Ch 6,12)	kg CO ₂ -eq = (calories consumed)*(calories produced calories consumed ⁻¹)*(kg CO ₂ -eq calorie produced ⁻¹)	Reduce calories produced/calories consumed and optimize calories consumed: Keep calories in line with daily needs and health guidelines Reduce waste in supply chain and after purchase	Add more variety in food plate to reduce kg CO₂-eq cal⁻¹ produced Dietary shifts from ruminant meat and dairy to other protein sources while maintaining nutritional quality	Reduce kg CO₂-eq cal⁻¹ produced: Improved agricultural practices Energy efficient food processing
Lighting [lumens] (Ch 9, 16)	kg CO ₂ = lumens*(kWh lumen ⁻¹)*(kg CO ₂ kWh ⁻¹)	Minimize artificial lumen demand: Occupancy sensors Lighting controls	Design options to increase natural lumen supply: Architectural designs with maximal daylighting	Demand innovation lighting technologies kWh lumens⁻¹ and power supply kg CO₂ kWh⁻¹: LED lamps

1
2 Opportunities for avoiding waste associated with the provision of services, or avoiding overprovision
3 of or excess demand for services themselves, exist across multiple service categories. Avoid options
4 are relevant in all end-use sectors, namely, teleworking and avoiding long-haul flights, adjusting
5 dwelling size to household size, avoiding short life span product, and food waste. Cities and built
6 environments can play an additional role. For example, more compact designs and higher accessibility
7 reduce travel demand and translate into lower average floor space and corresponding heating/cooling
8 and lighting demand, and thus between 5% to 20% of GHG emissions of end-use sectors (Creutzig et
9 al. 2021b). Avoidance of food loss and wastage – which equalled 8–10% of total anthropogenic GHG
10 emissions from 2010-2016 (Mbow et al. 2019), while millions suffer from hunger and malnutrition – is
11 a prime example (see Chapter 12). A key challenge in meeting global nutrition services is therefore to
12 avoid food loss and waste while simultaneously raising nutrition levels to equitable standards globally.
13 Literature results indicate that in developed economies consumers are the largest source of food waste,

1 and that behavioural changes such as meal planning, use of leftovers, and avoidance of over-preparation
2 can be important service-oriented solutions (Gunders et al. 2017; Schanes et al. 2018), while
3 improvements to expiration labels by regulators would reduce unnecessary disposal of unexpired items
4 (Wilson et al. 2017) and improved preservation in supply chains would reduce spoilage (Duncan and
5 Gulbahar 2019). ~931 million tons of food waste was generated in 2019 globally, 61% of which came
6 from households, 26% from food service and 13% from retail.

7
8 Demand side mitigations are achieved through changing *Socio-cultural factors*, *Infrastructure use* and
9 *Technology adoption* by various social actors in urban and other settlements, food choice and waste
10 management (*high confidence*) (Figure 5.7). In all sectors, end-use strategies can help reduce the
11 majority of emissions, ranging from 28.7% (4.13 GtCO₂-eq) emission reductions in the industry sector,
12 to 44.2% (7.96 GtCO₂-eq) in the food sectors, to 66.75% (4.671 GtCO₂-eq) emission reductions in the
13 land transport sector, and 66% (5.763 GtCO₂-eq) in the buildings sector. These numbers are median
14 estimates and represent benchmark accounting. Estimates are approximations, as they are simple
15 products of individual assessments for each of the three *SIT* options. If interactions were taken into
16 account, the full mitigation potentials may be higher or lower, independent of relevant barriers to
17 realizing the median potential estimates. See more in Supplementary Material II Chapter 5, Table SM2.

18
19 The technical mitigation potential of food loss and waste reductions globally has been estimated at 0.1-
20 5.8 GtCO₂-eq (*high confidence*) (Poore and Nemecek 2018; Smith, et al. 2019) (Figure 5.7, 7.4.5, Table
21 12.3). Coupling food waste reductions with dietary shifts can further reduce energy, land, and resource
22 demand in upstream food provision systems, leading to substantial GHG emissions benefits. The
23 estimated technical potential for GHG emissions reductions associated with shifts to sustainable healthy
24 diets is 0.5-8 GtCO₂-eq (Smith et al. 2013; Jarmul et al. 2020; Creutzig et al. 2021b) (Figure 5.7, Table
25 12.2) (*high confidence*). Current literature on health, diets, and emissions indicates that sustainable food
26 systems providing healthy diets for all are within reach but require significant cross-sectoral action,
27 including improved agricultural practices, dietary shifts among consumers, and food waste reductions
28 in production, distribution, retail, and consumption (Table 12.9) (Erb et al. 2016; Muller et al. 2017;
29 Willett and al. 2018; Graça et al. 2019).

30
31 Reduced food waste and dietary shifts have highly relevant repercussions in the land use sector that
32 underpin the high GHG emission reduction potential. Demand side measure lead to changes in
33 consumption of land-based resources and can save GHG emissions by reducing or improving
34 management of residues or making land areas available for other uses such as afforestation or bioenergy
35 production (Smith et al. 2013; Hoegh-Guldberg et al. 2019). Deforestation is the second largest source
36 of anthropogenic greenhouse gas emissions, caused mainly by expanding forestry and agriculture and
37 in many cases this agricultural expansion is driven by trade demand for food e. g. across the tropics,
38 cattle and oilseed products accounts for half of the resulted deforestation carbon-emissions, embodied
39 in international trade to China and Europe (Creutzig et al. 2019a; Pendrill et al. 2019). Benefits from
40 shifts in diets and resulting lowered land pressure are also reflected in reductions of land degradation
41 and improved.

42
43 Increased demand for biomass can increase the pressure on forest and conservation areas (Cowie et al.
44 2013) and poses an heightened risk for biodiversity, livelihoods, and intertemporal carbon balances
45 (Creutzig et al. 2021c; Lamb et al. 2016) requiring policy and regulations to ensure sustainable forest
46 management which depends on forest type, region, management, climate, and ownership. This suggests
47 that demand-side actions hold sustainability advantages over the intensive use of bioenergy and
48 BECCS, but also enable land use for bioenergy by saving agricultural land for food.

1 In the transport sector, ASI opportunities exist at multiple levels, comprehensively summarised in
2 Bongardt et al (2013), Roy et al (2021) and Sims et al (2014) (Chapter 10). Modelling based on a
3 plethora of bottom-up insights and options reveals that a balanced portfolio of ASI policies brings the
4 global transport sector emissions in line with global warming of not more than 1.5°C (Gota et al. 2019).
5 For example, telework may be a significant lever for avoiding road transport associated with daily
6 commutes, achievable through digitalisation, but its savings depend heavily on the modes, distances,
7 and types of office use avoided (Hook et al. 2020) and whether additional travel is induced due to greater
8 available time (Mokhtarian 2002) or vehicle use by other household members (Kim et al. 2015; de
9 Abreu e Silva and Melo 2018). More robustly, avoiding kilometres travelled through improved urban
10 planning and smart logistical systems can lead to fuel, and, hence, emissions savings (IEA 2016, 2017a;
11 Creutzig et al. 2015a; Wiedenhofer et al. 2018), or through avoiding long-haul flights (IEA 2021). For
12 example, reallocating road and parking space to exclusive public transit lanes, protected bike lanes and
13 pedestrian priority streets can reduce vehicle kilometres travelled in urban areas (ITF 2021). At the
14 vehicle level, light weighting strategies (Fischedick et al. 2014) and avoiding inputs of carbon-intensive
15 materials into vehicle manufacturing can also lead to significant emissions savings through improved
16 fuel economy (Das et al. 2016; Hertwich et al. 2019; IEA 2019b).

17
18 Figure 5.7 shows Socio-cultural factors can contribute up to 15% to land transport GHG emissions
19 reduction by 2050, with 5% as our central estimate. Active mobility, such as walking and cycling, has
20 2%-10% potential in GHG emissions reduction. Well-design teleworking and telecommuting policies
21 can at least reduce transport related GHG emissions by 1%. A systematic review demonstrates that 26
22 of 39 studies identified suggest that teleworking reduces energy use, induced mainly by distance
23 traveled, and only eight studies suggest that teleworking increases or has a neutral impact on energy use
24 (Hook et al. 2020). Infrastructure use (specifically urban planning and shared pooled mobility) has about
25 20-50% (on average) potential in the land transport GHG emissions reduction, especially via redirecting
26 the ongoing design of existing infrastructures in developing countries, and with 30% as our central
27 estimate (see also 5.3.4.2). Technology adoption, particularly banning ICEs and 100% EV targets and
28 efficient lightweight cars, can contribute to between 30 and 70% of GHG emissions reduction in land
29 transport in 2050, with 50% as our central estimate. For details see Supplementary Material II Chapter
30 5, Table SM2 and Chapter 10.

31
32 Socio-cultural factors such avoid long-haul flights and shifting to train wherever possible can contribute
33 between 10% and 40% to aviation GHG emissions reduction by 2050 (Figure 5.7). Maritime transport
34 (shipping) emits around 940 MtCO₂ annually and is responsible for about 2.5% of global GHG
35 emissions (IMO 2020). Technology measures and management measures, such as slow steaming,
36 weather routing, contra-rotating propellers, and propulsion efficiency devices can deliver more fuel
37 savings between 1% and 40% than the investment required (Bouman et al. 2017). For details see
38 Supplementary Material II Chapter 5, Table SM2.

39
40 In the buildings sector, avoidance strategies can occur at the end use or individual building operation
41 level. End use technologies/strategies such as the use of daylighting (Bodart and De Herde 2002) and
42 lighting sensors can avoid demand for lumens from artificial light, while passive houses, thermal mass,
43 and smart controllers can avoid demand for space conditioning services. Eliminating standby power
44 losses can avoid energy wasted for no useful service in many appliances/devices, which may reduce
45 household electricity use by up to 10% (Roy et al. 2012). At the building level, smaller dwellings can
46 reduce overall demand for lighting and space conditioning services, while smaller dwellings, shared
47 housing, and building lifespan extension can all reduce the overall demand for carbon-intensive building
48 materials such as concrete and steel (Material Economics 2018; Pauliuk et al. 2021; Hertwich et al.
49 2019; IEA 2019b). Emerging strategies for materials efficiency, such as 3D printing to optimise the

1 geometries and minimise the materials content of structural elements, may also play a key role if thermal
2 performance and circularity can be improved (Mahadevan et al. 2020; Adaloudis and Bonnin Roca
3 2021). Several scenarios estimate an ‘avoid’ potential in the building sector, which includes reducing
4 waste in superfluous floor space, heating and IT equipment, and energy use, of between 10 and 30%,
5 in one case even by 50% (Nadel, Steven and Ungar 2019). For details see Chapter 9.

6 Socio-cultural factors and behavioral and social practices in energy saving like adaptive heating and
7 cooling by changing temperature can contribute about 15% to Buildings GHG emissions reduction by
8 2050 (Figure 5.7). Infrastructure use such as compact city and urban planning interventions, living floor
9 space rationalization, and access to low carbon architectural design has about 20% potential in the
10 Buildings GHG emissions reduction. Technology adoption, particularly access to energy efficient
11 technologies, and choice for installation of renewable can contribute between 30% and 70% to GHG
12 emissions reeducation in Buildings sector. For details see Supplementary Material II Chapter 5, Table
13 SM2 and Chapter 8 and 9 .

14
15 Service efficiency strategies are emerging to avoid materials demand at the product level, including
16 dematerialisation strategies for various forms of packaging (Worrell and Van Sluisveld 2013) and the
17 concept of “products as services,” in which product systems are designed and maintained for long
18 lifespans to provide a marketable service (Oliva and Kallenberg 2003), thereby reducing the number of
19 products sold and tons of materials needed to provide the same service to consumers, consistent with
20 circular economy and materials efficiency principles (see Chapter 11). Successful examples of this
21 approach have been documented for carpets (Stubbs and Cocklin 2008), copiers (Roy 2000), kitchens
22 (Liedtke et al. 1998), vehicles (Ceschin and Vezzoli 2010; Williams 2006) and more (Roy 2000).

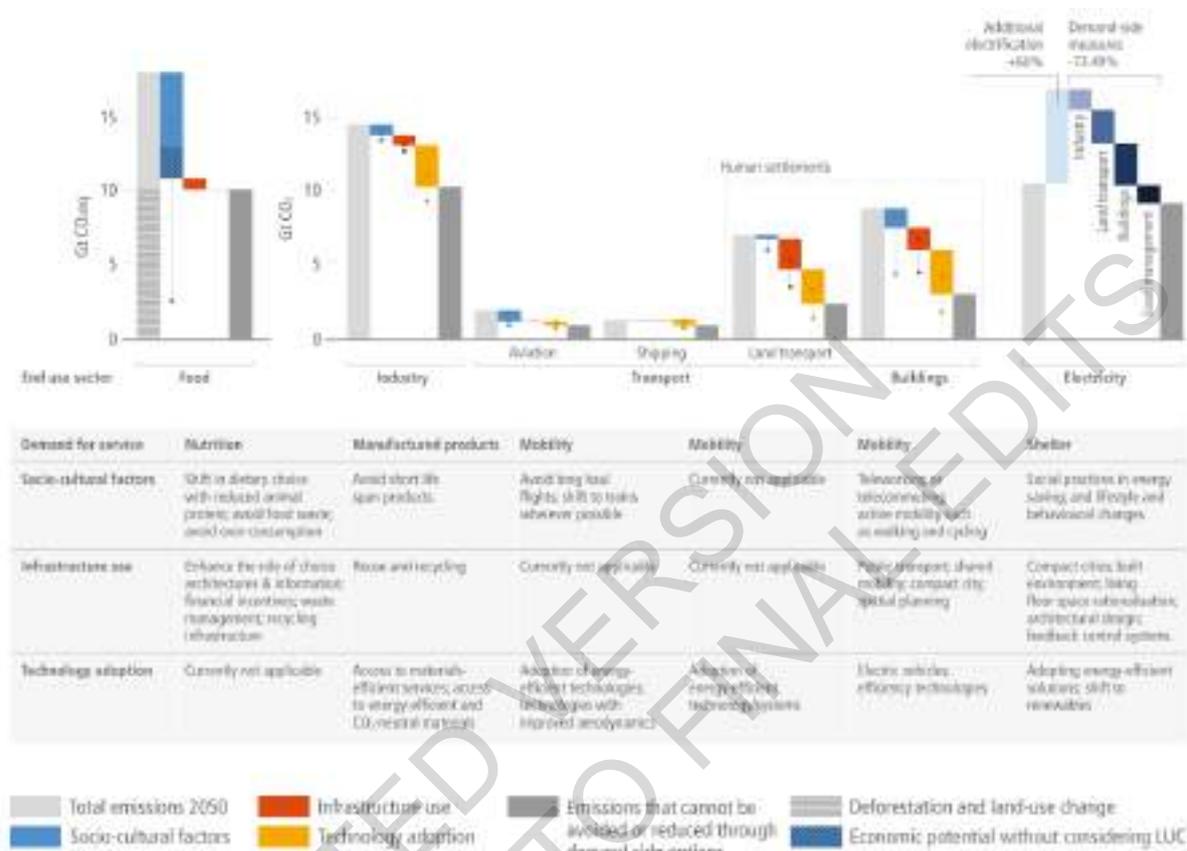

23
24 Shift strategies unique to the service-oriented perspective generally involve meeting service demands
25 at much lower life-cycle energy, emissions, and resource intensities (Roy and Pal 2009), through such
26 strategies as shifting from single-family to multi-family dwellings (reducing the materials intensity per
27 unit floor area (Ochsendorf et al. 2011)), shifting from passenger cars to rail or bus (reducing fuel,
28 vehicle manufacturing, and infrastructure requirements (Chester and Horvath 2009), shifting materials
29 to reduce resource and emissions intensities (e.g., low-carbon concrete blends (Scrivener and Gartner
30 2018)) and shifting from conventional to additive manufacturing processes to reduce materials
31 requirements and improve end-use product performance (Huang et al. 2016, 2017).

32
33 An important consideration in all ASI strategies is the potential for unintended rebound effects (Sorrell
34 et al. 2009; Brockway et al. 2021) as indicated in Figures 5.8, 5.12, and 5.13a, which must be carefully
35 avoided through various regulatory and behavioural measures (Santarius et al. 2016) and in many
36 developing country contexts rebound effects can help in accelerated provision of affordable access to
37 modern energy and a minimum level of per capita energy consumption (Saunders et al. 2021;
38 Chakravarty and Roy 2021). Extending the lifespan of energy inefficient products may lead to net
39 increases in emissions (Gutowski et al. 2011), whereas automated car sharing may reduce the number
40 of cars manufactured at the expense of increased demand for passenger kilometres due to lower travel
41 opportunity cost (Wadud et al. 2016) (see also 5.3.2).

42
43 Avoid short life span products in favour of products with longer lifespan as a *socio-cultural factor*;
44 *infrastructure use* such as increasing the re-usability and recyclability of product's components and
45 materials; and adopting the materials-efficient services and CO₂-neutral materials have about 29%
46 indicative potential by 2050. For details see Supplementary Material II Chapter 5, Table SM2 and
47 Chapter 11.

48
49 In summary, sector specific demand side mitigation options reflect important role of socio-cultural,
50 technological and infrastructural factors and interdependence among them (Figure 5.7). The assessment

1 in Figure 5.7 shows by 2050 high emission reduction potential can be realised with demand side actions
 2 alone which can be complementary to supply side interventions with considerable impact by reducing
 3 need for capacity addition on the electricity supply system. Integrated cross sectoral actions shown
 4 through sector coupling is also important for investment decision making and policy framing going
 5 beyond sector boundaries (*high evidence and high agreement*).

Figure 5.7 Demand-side mitigation options and indicative potentials

Mitigation response options related to demand for services have been categorised into three domains: ‘socio-cultural factors’, related to social norms, culture, and individual choices and behaviour; ‘infrastructure use’, related to the provision and use of supporting infrastructure that enables individual choices and behaviour; and ‘technology adoption’, which refers to the uptake of technologies by end users. Potentials in 2050 are estimated using the International Energy Agency’s 2020 World Energy Outlook STEPS (Stated Policy Scenarios) as a baseline. This scenario is based on a sector-by-sector assessment of specific policies in place, as well as those that have been announced by countries by mid-2020. This scenario was selected due to the detailed representation of options across sectors and sub-sectors. The heights of the coloured columns represent the potentials on which there is a high level of agreement in the literature, based on a range of case studies. The range shown by the dots connected by dotted lines represents the highest and lowest potentials reported in the literature which have low to medium levels of agreement. The demand side potential of socio-cultural factor in food has two parts. Economic potential of demand reduction through socio-cultural factors alone is 1.9 GtCO₂eq without considering LUC by diversion of agricultural land from food production to carbon sequestration purposes. If further changes in choice architectures and LUC due to this change in demand is considered indicative potential becomes 7 GtCO₂eq. The electricity panel presents separately the mitigation potential from changes in electricity demand associated with enhanced electrification in end use sectors. Electrification increases electricity demand, while it is avoided through demand-side mitigation strategies. Load management refers to demand side flexibility that can be achieved through incentive design like time of use pricing/monitoring by artificial intelligence, diversification of storage facilities etc. NZE (IEA Net Zero Emissions by 2050 Scenario) is used to compute the impact of end use sector electrification,

1 **while the impact of demand side response options is based on bottom-up assessments. Dark grey columns**
2 **show the emissions that cannot be avoided through demand-side mitigation options.**

3 **The table indicates which demand-side mitigation options are included. Options are categorised**
4 **according to: socio-cultural factors, infrastructure use, and technology adoption.**

5 (5.3, Supplementary Material 5.II)

6 7 8 **5.3.1.2 Household consumption options to reduce GHG emissions**

9 A systematic review of options to reduce the GHG emissions associated with household consumption
10 activities identified 6990 peer-reviewed journal papers, with 771 options that were aggregated into 61
11 consumption option categories ((Ivanova et al. 2020); Figure 5.8). In consistence with previous research
12 (Herendeen and Tanaka 1976; Pachauri and Spreng 2002; Pachauri 2007; Ivanova et al. 2016), a
13 hierarchical list of mitigation options emerges. Choosing low-carbon options, such as car-free living,
14 plant-based diets without or very little animal products, low-carbon sources of electricity and heating
15 at home as well as local holiday plans, can reduce an individual's carbon footprint by up to 9tCO₂-eq.
16 Realising these options requires substantial policy support to overcome infrastructural, institutional and
17 socio-cultural lock-in (see Sections 5.4 and 5.6).
18

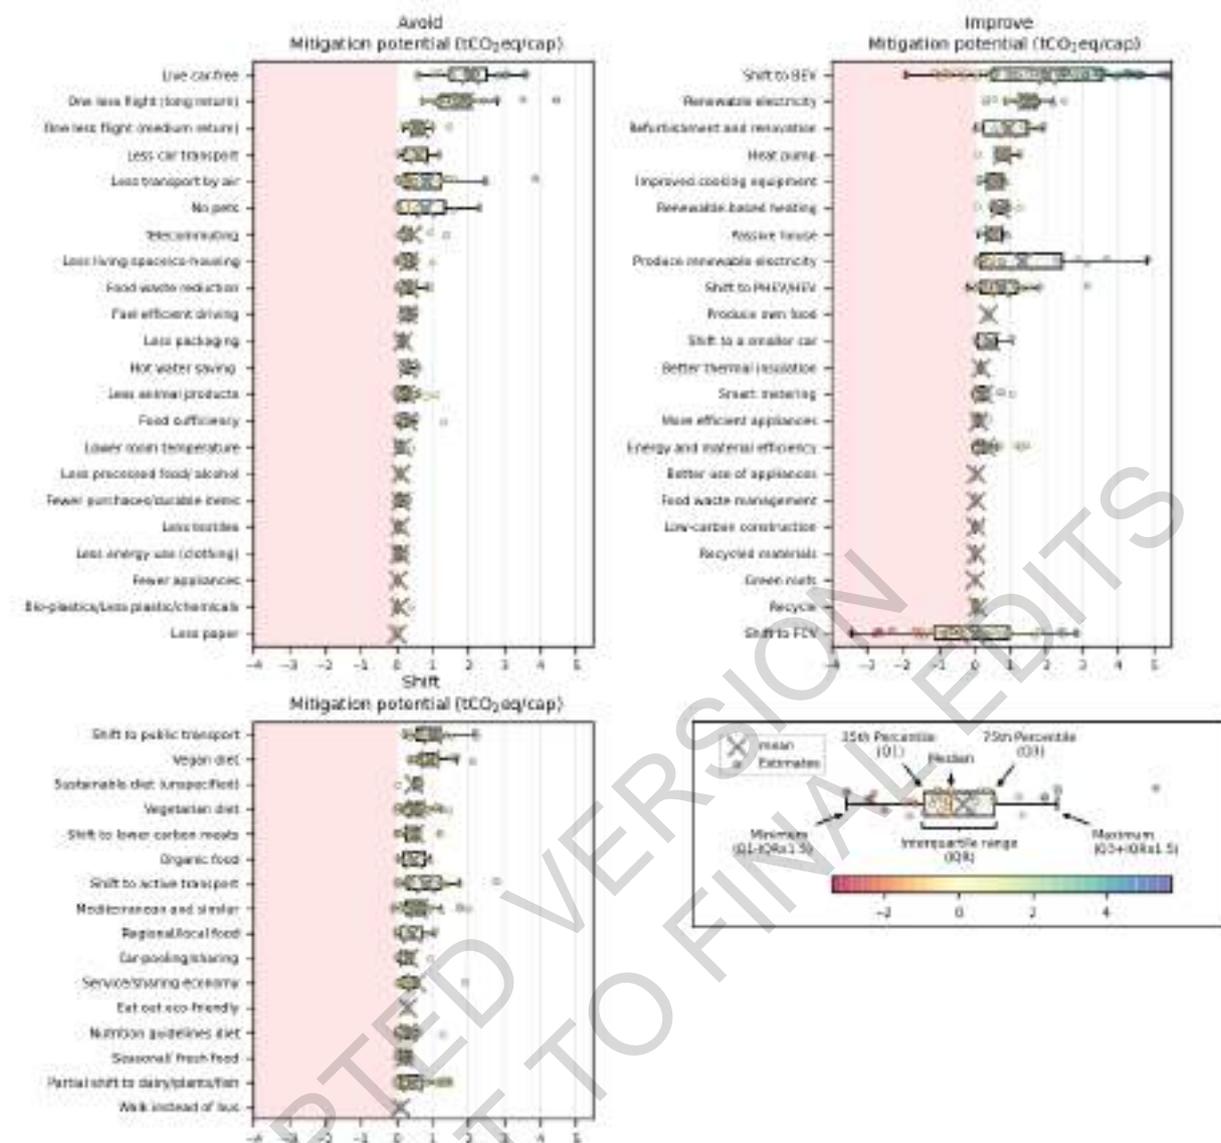

Figure 5.8 Synthesis of 60 demand side options ordered by the median GHG mitigation potential found across all estimates from the literature.

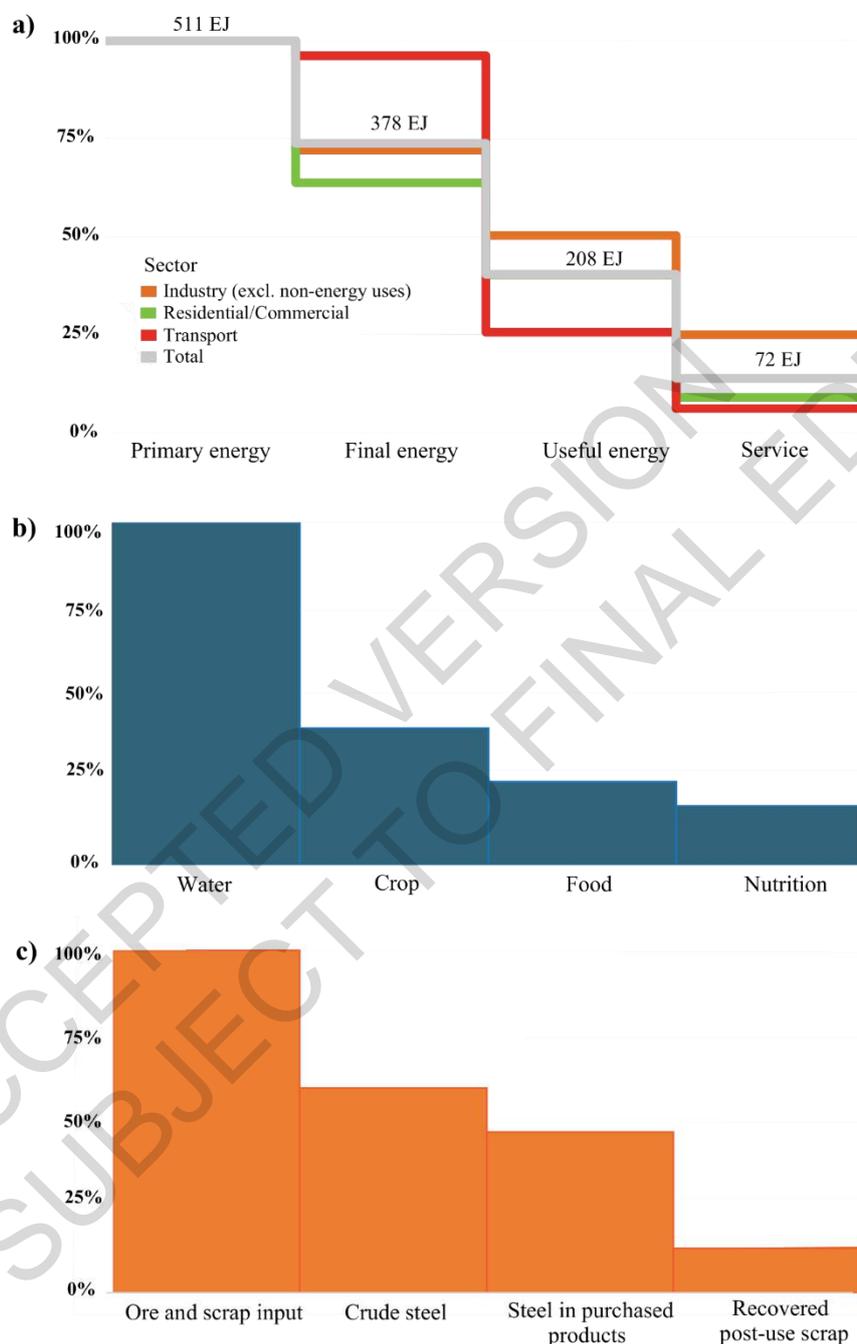

The x-s are averages. The boxes represent the 25th percentile, median and 75th percentiles of study results. The whiskers or dots show the minimum and maximum mitigation potentials of each option. Negative values (in the red area) represent the potentials for backfire due to rebound, i.e. a net-increase of GHG emissions due to adopting the option.

5.3.2 Technical tools to identify Avoid-Shift-Improve options

Service delivery systems to satisfy a variety of service needs (e.g., mobility, nutrition, thermal comfort, etc.) comprise a series of interlinked processes to convert primary resources (e.g. coal, minerals) into useable products (e.g. electricity, copper wires, lamps, light bulbs). It is useful to differentiate between conversion and processing steps “upstream” of end-users (mines, power plants, manufacturing facilities) and “downstream”, i.e. those associated with end-users, including service levels, and direct well-being benefits for people (Kalt et al. 2019). Illustrative examples of such resource processing systems steps and associated conversion losses drawn from the literature are shown in Figure 5.9. in the form of resource processing cascades for energy (direct energy conversion efficiencies (Nakićenović et al. 1993; De Stercke 2014)), water use in food production systems (water use efficiency and embodied water losses in food delivery and consumption (Lundqvist et al. 2008; Sadras et al. 2011)), and materials

1 (Ayres and Simonis 1994; Fischer-Kowalski et al. 2011) using the example of steel manufacturing, use
 2 and recycling at the global level (Allwood and Cullen 2012). Invariably, conversion losses along the
 3 entire service delivery systems are substantial, ranging from 83% (water) to 86% (energy) and 87%
 4 (steel) of primary resource inputs (TWI2050 2018). In other words, only between 14 to 17% of the
 5 harnessed primary resources remain at the level of ultimate service delivery.
 6

7
8

9 **Figure 5.9 Resource processing steps and efficiency cascades (in percent of primary resource inputs**
 10 **[vertical axis] remaining at respective step until ultimate service delivery) for illustrative global service**
 11 **delivery systems for energy (top panel, disaggregated into three sectorial service types and the aggregate**
 12 **total), food (middle panel, water use in agriculture and food processing, delivery and use), and materials**
 13 **(bottom panel, example steel). The aggregate efficiencies of service delivery chains is with 13-17% low.**
 14

Source: TWI2050 2018

1 Examples of conversion losses at the supply side of resource processing systems include for instance
2 for energy electricity generation (global output/input conversion efficiency of electric plants of 45% as
3 shown in energy balance statistics (IEA 2020b); for water embodied in food irrigation water use
4 efficiency (some 40% (Sadras et al. 2011)) and calorific conversion efficiency (food calories out/food
5 calories in) in meat production of 60% (Lundqvist et al. 2008), or for materials where globally only
6 47% or primary iron ore extracted and recovered steel scrap end up as steel in purchased products, (i.e.
7 a loss of 57%) (Allwood and Cullen 2012).

8
9 A substantial part of losses happen at the end-use point and in final service delivery (where losses
10 account for 47 to 60% of aggregate systems losses for steel and energy respectively, and for 23% in the
11 case of water embodied in food, i.e. food waste). The efficiency of service delivery (for a detailed
12 discussion cf. (Brand-Correa and Steinberger 2017)) has usually both a technological component
13 (efficiency of end-use devices such as cars, light bulbs) and a behavioural component (i.e. how
14 efficiently end-use devices are used, e.g. load factors, for a discussion of such behavioural efficiency
15 improvement options see e.g. (Dietz et al. 2009; Laitner et al. 2009; Ehrhardt-Martinez 2015; Kane and
16 Srinivas 2014; Lopes et al. 2017; Thaler 2015; Norton 2012). Using the example of mobility where
17 service levels are usually expressed by passenger-km, the service delivery efficiency is thus a function
18 of the fuel efficiency of the vehicle and its drivetrain (typically only about 20%-25% for internal
19 combustion engines, but close to 100% for electric motors) plus how many passengers the vehicle
20 actually transports (load factor, typically as low as 20%-25%, i.e. one passenger per vehicle that could
21 seat 4-5), i.e. an aggregate end-use efficiency of between 4-6% only. Aggregated energy end-use
22 efficiencies at the global level are estimated as low as 20% (De Stercke 2014), 13% for steel (recovered
23 post-use scrap, Allwood and Cullen, 2012), and some 70% for food (including distribution losses and
24 food wastes of some 30%, (Lundqvist et al. 2008).

25
26 To harness additional gains in efficiency by shifting the focus in service delivery systems to the end-
27 user can translate into large “upstream” resource reductions. For each unit of improvement at the end-
28 use point of the service delivery system (examples shown in Figure 5.9), primary resource inputs are
29 reduced between a factor of 6 to 7 units (water, steel, energy) (TWI2050 2018). For example, reducing
30 energy needs for final service delivery equivalent to 1 EJ, reduces primary energy needs by some 7 EJ.
31 There is thus *high evidence and high agreement* in the literature that the leverage effect for
32 improvements in end-use service delivery efficiency through behavioural, technological, and market
33 organisational innovations is very large, ranging from a factor 6-7 (resource cascades) to up to a factor
34 10 to 20 (exergy analysis) with the highest improvement potentials at the end-user and service
35 provisioning levels (for systemic reviews see (Nakićenović et al. 1996a; Grubler et al. 2012b; Sousa et
36 al. 2017). Also the literature shows *high agreement* that current conversion efficiencies are invariably
37 low, particularly for those components at the end-use and service delivery back end of service
38 provisioning systems. It also suggests that efficiencies might be actually even lower than those revealed
39 by direct input-output resource accounting as discussed above (Figure 5.9). Illustrative exergy
40 efficiencies of entire national or global service delivery systems range from 2.5% (USA, (Ayres 1989))
41 to 5% (OECD average, (Grubler et al. 2012b)) and 10% (global, Nakićenović et al., 1996) respectively.
42 Studies that adopt more restricted systems boundaries either leaving out upstream resource
43 processing/conversion or conversely end-use and service provision, show typical exergetic efficiencies
44 between 15% (city of Geneva, cf. (Grubler et al. 2012a)) to below 25% (Japan, Italy, and Brazil, albeit
45 with incomplete systems coverage that miss important conversion losses (Nakićenović et al. 1996b)).
46 These findings are confirmed by more recent exergy efficiency studies that also include longitudinal
47 time trend analysis (Cullen and Allwood 2010; Serrenho et al. 2014; Guevara et al. 2016; Brockway et
48 al. 2014, 2015). Figure 5.10 illustrates how energy demand reductions can be realized by improving the
49 resource efficiency cascades shown in Figure 5.9 above.

50

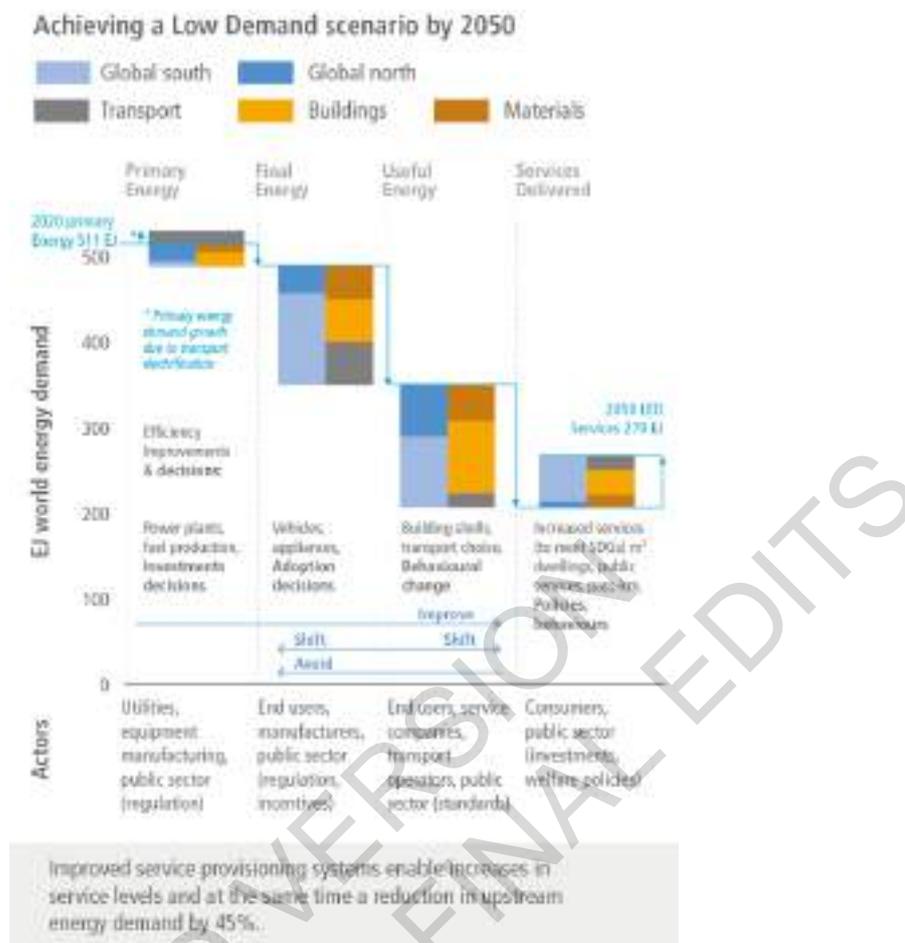

Figure 5.10 Realisable energy efficiency improvements by region and by end-use type between 2020 and 2050 in an illustrative Low Energy Demand scenario (in EJ). Efficiency improvements are decomposed by respective steps in the conversion chain from primary energy to final, and useful energy, and to service delivery and disaggregated by region (developed and developing countries) and end-use type (buildings, transport, materials). Improvements are dominated by improved efficiency in service delivery (153 EJ) and by more efficient end-use energy conversion (134 EJ). Improvements in service efficiency in transport shown here are conservative in this scenario but could be substantially higher with the full adoption of integrated urban shared mobility schemes. Increases in energy use due to increases in service levels and system effects of transport electrification (grey bars on top of first pair in the bar charts) that counterbalance some of the efficiency improvements are also shown. Examples of options for efficiency improvements and decision involved (grey text in the chart), the relative weight of generic demand-side strategies (improve, shift, avoid blue arrows), as well as prototype actors involved are also illustrated

Data: Figure 5.9 and Grubler et al. 2018.

5.3.3 Low demand scenarios

Long-term mitigation scenarios play a crucial role in climate policy design in the near term, by illuminating transition pathways, interactions between supply-side and demand-side interventions, their timing, and the scales of required investments needed to achieve mitigation goals (see Chapter 3). Historically, most long-term mitigation scenarios have taken technology-centric approaches with heavy reliance on supply-side solutions and the use of carbon dioxide removal, particularly in 1.5°C scenarios (Rogelj et al. 2018). Comparatively less attention has been paid to deep demand-side reductions incorporating socio-cultural change and the cascade effects (see Section 5.3.2) associated with ASI strategies, primarily due to limited past representation of such service-oriented interventions in long-term integrated assessment models (IAMs) and energy systems models (ESMs) (Napp et al. 2019; van

1 de Ven et al. 2018; Grubler et al. 2018). There is ample evidence of savings from sector- or issue-
2 specific bottom-up studies (see Section 5.3.1.2). However, these savings typically get lost in the
3 dominant narrative provided by IAMs and ESMs and in their aggregate-level evaluations of
4 combinations of ASI and efficiency strategies. As a result, their interaction effects do not typically get
5 equal focus alongside supply-side and carbon dioxide removal options (Van den Berg et al. 2019; Van
6 Vuuren et al. 2018; Samadi et al. 2017).

7
8 In response to 1.5°C ambitions, and a growing desire to identify participatory pathways with less
9 reliance on carbon dioxide removal with high uncertainty, some recent IAM and ESM mitigation
10 scenarios have explored the role of deep demand-side energy and resource use reduction potentials at
11 global and regional levels. Table 5.2 summarises long-term scenarios that aimed to: minimise service-
12 level energy and resource demand as a central mitigation tenet; specifically evaluate the role of
13 behavioural change and ASI strategies; and/or to achieve a carbon budget with limited/no carbon
14 dioxide removal. From assessment of this emerging body of literature, several general observations
15 arise and are presented below.

16
17 First, socio-cultural changes within transition pathways can offer Gigaton-scale CO₂ savings potential
18 at the global level, and therefore represent a substantial overlooked strategy in traditional mitigation
19 scenarios. Two lifestyle change scenarios conducted with the IMAGE IAM suggested that behaviour
20 and cultural changes such as heating and cooling set-point adjustments, shorter showers, reduced appliance
21 use, shifts to public transit, less meat intensive diets, and improved recycling can deliver an additional
22 1.7 Gt and 3 GtCO₂ savings in 2050, beyond the savings achieved in traditional technology-centric
23 mitigation scenarios for the 2°C and 1.5°C ambitions, respectively (van Sluisveld et al. 2016; Van
24 Vuuren et al. 2018). In its Sustainable Development Scenario, the IEA's behavioural change and
25 resource efficiency wedges deliver around 3 GtCO₂-eq reduction in 2050, combined savings roughly
26 equivalent to those of solar PV that same year (IEA 2019a). In Europe, a GCAM scenario evaluating
27 combined lifestyle changes such as teleworking, travel avoidance, dietary shifts, food waste reductions,
28 and recycling reduced cumulative EU-27 CO₂ emissions 2011-2050 by up to 16% compared to an SSP2
29 baseline (van de Ven et al. 2018). Also in Europe, a multi-regional input-output analysis suggested that
30 adoption of low-carbon consumption practices could reduce carbon footprints by 25%, or 1.4 Gt (Moran
31 et al. 2020). A global transport scenario suggests that transport sector emission can decline from
32 business as usual 18 GtCO₂-eq to 2 GtCO₂-eq if ASI strategies are deployed (Gota et al. 2019), a value
33 considerably below the estimates provided in IAM scenarios that have limited or no resolution in ASI
34 strategies (compare with Chapter 10).

35
36 The IEA's Net Zero Emissions by 2050 (NZE) scenario, in which behavioural changes lead to 1.7
37 GtCO₂ savings in 2030, expresses the substantial mitigation opportunity in terms of low-carbon
38 technology equivalencies: to achieve same emissions reductions, the global share of EVs in the NZE
39 would have to increase from 20% to 45% by 2030 or the number of installed heat pumps in homes in
40 the NZE would have to increase from 440 to 660 million in 2030 (IEA 2021).

41 In light of the limited number of mitigation scenarios that represent socio-behavioural changes
42 explicitly, there is *medium evidence* in the literature that such changes can reduce emissions at regional
43 and global levels, but *high agreement* within that literature that such changes hold up to gigaton-scale
44 CO₂ emissions reduction potentials.

45
46 Second, pursuant to the ASI principle, deep demand reductions require parallel pursuit of behavioural
47 change and advanced energy efficient technology deployment; neither is sufficient on its own. The LED
48 scenario (Figure 5.10) combines behavioural and technological change consistent with numerous ASI
49 strategies that leverage digitalisation, sharing, and circular economy megatrends to deliver decent living
50 standards while reducing global final energy demand in 2050 to 245 EJ (Grubler et al. 2018). This value

1 is 40% lower than final energy demand in 2018 (IEA 2019a), and a lower 2050 outcome than other
2 IAM/ESM scenarios with primarily technology-centric mitigation approaches (IEA 2017b; Teske et al.
3 2015). In the IEA's B2DS scenario, avoid/shift in the transport sector accounts for around 2 GtCO₂-eq
4 yr⁻¹ in 2060, whereas parallel vehicle efficiency improvements increase the overall mitigation wedge to
5 5.5 GtCO₂-eq yr⁻¹ in 2060 (IEA 2017b). Through a combination of behavioural change and energy
6 efficient technology adoption, the IEA's NZE requires only 340 EJ of global final energy demand with
7 universal energy access in 2050, which is among the lowest of IPCC net zero SR1.5 scenarios (IEA
8 2021).

9
10 Third, low demand scenarios can reduce both supply side capacity additions and the need for carbon
11 capture and removal technologies to reach emissions targets. Of the scenarios listed in Table 5.2 one
12 (LED-MESSAGE) reaches 2050 emissions targets with no carbon capture or removal technologies
13 (Grubler et al. 2018), whereas others report significant reductions in reliance on bioenergy with carbon
14 capture and storage (BECCS) compared to traditional technology-centric mitigation pathways (Liu et
15 al. 2018; Van Vuuren et al. 2018; Napp et al. 2019), with the IEA's NZE notably requiring the least
16 carbon dioxide removal (CDR) (1.8 Gt in 2050) and primary bioenergy (100 EJ in 2050) compared to
17 IPCC net zero SR1.5 scenarios (IEA 2021).

18
19 Fourth, the costs of reaching mitigation targets may be lower when incorporating ASI strategies for
20 deep energy and resource demand reductions. The TIAM-Grantham low demand scenarios displayed
21 reduction in mitigation costs (0.87–2.4% of GDP), while achieving even lower cumulative emissions
22 to 2100 (228 to ~475 GtCO₂) than its central demand scenario (741 to 1066 GtCO₂), which had a cost
23 range of (2.4–4.1% of GDP) (Napp et al. 2019). The GCAM behavioural change scenario concluded
24 that domestic emission savings would contribute to reduce the costs of achieving the internationally
25 agreed climate goal of the EU by 13.5% to 30% (van de Ven et al. 2018). The AIMS lifestyle case
26 indicated that mitigation costs, expressed as global GDP loss, would be 14% lower than the SSP2
27 reference scenario in 2100, for both 2°C and 1.5°C mitigation targets (Liu et al. 2018). These findings
28 mirror earlier AIM results, which indicated lower overall mitigation costs for scenarios focused on
29 energy service demand reductions (Fujimori et al. 2014). In the IEA's NZE, behavioural changes that
30 avoid energy and resource demand save USD4 trillion (cumulatively 2021-2050) compared to if those
31 emissions reductions were achieved through low-carbon electricity and hydrogen deployment (IEA
32 2021).

33
34 Based on the limited number of long-term mitigation scenarios that explicitly represent demand
35 reductions enabled by ASI strategies, there is *medium evidence* but with *high agreement* within that
36 literature that such scenarios can reduce dependence on supply-side capacity additions and carbon
37 capture and removal technologies with opportunity for lower overall mitigation costs.

38
39 If the limitations within most IAMs and ESMs regarding non-inclusion of granular ASI strategy analysis
40 can be addressed, it will expand and improve long-term mitigation scenarios (Van den Berg et al. 2019).
41 These include broader inclusion of mitigation costs for behavioural interventions (van Sluisveld et al.
42 2016), much greater incorporation of rebound effects (Krey et al. 2019), including from improved
43 efficiencies (Brockway et al. 2021) and avoided spending (van de Ven et al. 2018), improved
44 representation of materials cycle to assess resource cascades (Pauliuk et al. 2017), broader coverage of
45 behavioural change (Samadi et al. 2017; Saujot et al. 2020), improved consideration of how economic
46 development affects service demand (Semieniuk et al. 2021), explicit representation of intersectoral
47 linkages related to digitalisation, sharing economy, and circular economy strategies (see Section 5.3.4),
48 and institutional, political, social, entrepreneurial, and cultural factors (van Sluisveld et al. 2018).
49 Addressing the current significant modelling limitations will require increased investments in data
50 generation and collection, model development, and inter-model comparisons, with a particular focus

1 on socio-behavioural research that has been underrepresented in mitigation research funding to date
2 (Overland and Sovacool 2020).

3

4 Covid-19 interacts with demand-side scenarios (Box 5.2). Energy demand will mostly likely be reduced
5 between 2020 and 2030 compared to default pathway, and if recovery is steered towards low energy
6 demand, carbon prices for a 1.5 °C-consistent pathway will be by 19%, energy supply investments until
7 2030 by USD1.8 trillion reduced, and the pressure to rapidly upscale renewable energy technologies
8 will be softened (Kikstra et al. 2021a).

1 5.3.4 Transformative megatrends

2 The sharing economy, the circular economy, and digitalisation have all received much attention from
 3 the research, advocacy, business models and policy communities as potentially transformative trends
 4 for climate change mitigation (TWI2050 2019; IEA 2017a; Material Economics 2018). All are
 5 essentially emerging and contested concepts (Gallie 1955) that have the common goal of increasing
 6 convenience for users and rendering economic systems more resource-efficient, but which exhibit
 7 variability in the literature on their definitions and system boundaries. Historically, both sharing and
 8 circular economies have been commonplace in developing countries, where reuse, repair, and waste
 9 scavaging and recycling comprise the core of informal economies facilitated by human interventions
 10 (Wilson et al. 2006; Asim et al. 2012; Pacheco et al. 2012). Digitalisation is now propelling sharing and
 11 circular economy concepts in developed and developing countries alike (Roy et al. 2021), and the three
 12 megatrends are highly interrelated, as seen in Figure 5.11. For example, many sharing economy
 13 concepts rely on corporate or, to lesser degree, non-profit digital platforms that enable efficient
 14 information and opportunity sharing, thus making it part of the digitalisation trend. Parts of the sharing
 15 economy are also included in some circular economy approaches, as shared resource use renders
 16 utilisation of material more efficient. Digital approaches to material management also support the
 17 circular economy, such as through waste exchanges and industrial symbiosis. Digitalisation aims more
 18 broadly to deliver services in more efficient, timely, intelligent, and less resource-intensive ways (i.e.,
 19 by moving bits and not atoms), though the use of increasingly interconnected physical and digital
 20 systems in many facets of economies. With rising digitalisation also comes the risk of increased
 21 electricity use to power billions of devices and the internet infrastructure that connects them, as well as
 22 growing quantities of e-waste, presenting an important policy agenda for monitoring and balancing the
 23 carbon and resource costs and benefits of digitalisation (Malmödin and Lundén 2018; TWI2050 2019).
 24 Rebound effects and instigated consumption of digitalisation are risking to lead to a net increase in
 25 GHG emissions (Belkhir and Elmeligi 2018). The determinants and possible scales of mitigation
 26 potentials associated with each megatrend are discussed below.
 27

28
 29 **Figure 5.11 The growing nexus between digitalisation, the sharing economy, and the circular economy in**
 30 **service delivery systems. While these trends started mostly independently, rapid digitalisation is creating**
 31 **new synergistic opportunities with systemic potential to improve the quality of jobs, particularly in**

1 **developing economies. Widespread digitalisation may lead to net increases in electricity use, demand for**
2 **electronics manufacturing resources, and e-waste, all of which must be monitored and managed via**
3 **targeted policies**

5.3.4.1 *Digitalisation*

6 In the context of service provision, there are numerous opportunities for consumers to buy, subscribe
7 to, adopt, access, install or use digital goods and services (Wilson et al. 2020b). Digitalisation has
8 opened up new possibilities across all domains of consumer activity, from travel and retail to domestic
9 living and energy use. Digital platforms allow surplus resources to be identified, offered, shared,
10 transacted and exchanged (Frenken 2017). Real-time information flows on consumers' preferences and
11 needs mean service provision can be personalised, differentiated, automated, and optimised (TWI2050
12 2019). Rapid innovation cycles and software upgrades drive continual improvements in performance
13 and responsiveness to consumer behaviour. These characteristics of digitalisation enable new business
14 models and services that affect both service demand, from shared-ridehailing (ITF 2017a) to smart
15 heating (IEA 2017a), and how services are provisioned, from online farmers' markets (Richards and
16 Hamilton 2018) to peer-to-peer electricity trading to enable distributed power systems (Morstyn et al.
17 2018).

18 In many cases, digitalisation provides a 'radical functionality' that enables users to do or accomplish
19 something that they could not do before (Nagy et al. 2016). Indeed the consumer appeal of digital
20 innovations varies widely, from choice, convenience, flexibility and control to relational and social
21 benefits (Pettifor and Wilson 2020). Reviewing over 30 digital goods and services for mobility, food
22 buying and domestic living, Wilson et al. (2020b) also found shared elements of appeal across multiple
23 innovations including (i) making use of surplus, (ii) using not owning, (iii) being part of wider networks,
24 and (iv) exerting greater control over service provisioning systems. Digitalisation thus creates a strong
25 value proposition for certain consumer niches. Concurrent diffusion of many digital innovations
26 amplifies their disruptive potential (Schuelke-Leech 2018; Wilson et al. 2019b). Besides basic mobile
27 telephone service for communication, digital innovations have been primarily geared to population
28 groups with high purchasing power, and too little to the needs of poor and vulnerable people.

29
30 The long-term sustainability implications of digitalised services hinge on four factors: (1) the direct
31 energy demands of connected devices and the digital infrastructures (i.e. data centres and
32 communication networks) that provide necessary computing, storage, and communication services
33 (Chapter 9.4.6); (2) the systems-level energy and resource efficiencies that may be gained through the
34 provision of digital services (Wilson et al. 2020b); (3) the resource, material, and waste management
35 requirements of the billions of ICT devices that comprise the world's digital systems (Belkhir and
36 Elmeligi 2018; Malmodin and Lundén 2018) and (4) the magnitude of potential rebound effects or
37 induced energy demands that might unleash unintended and unsustainable demand growth, such as
38 autonomous vehicles inducing more frequent and longer journeys due to reduced travel costs (Wadud
39 et al. 2016). Estimating digitalisation's direct energy demand has historically been hampered by lack of
40 consistent global data on IT device stocks, their power consumption characteristics, and usage patterns,
41 for both consumer devices and the data centres and communication networks behind them. As a result,
42 quantitative estimates vary widely, with literature values suggesting that consumer devices, data
43 centres, and data networks account for anywhere from 6% to 12% of global electricity use (Gelenbe
44 and Caseau 2015; Cook et al. 2017; Malmodin and Lundén 2018). For example, within the literature on
45 data centres, top-down models that project energy use on the basis of increasing demand for internet
46 services tend to predict rapid global energy use growth, (Andrae and Edler 2015; Belkhir and Elmeligi
47 2018; Liu et al. 2020a), whereas bottom-up models that consider data center technology stocks and their
48 energy efficiency trends tend to predict slower but still positive growth (Hintemann and Hinterholzer
49 2019; Masanet et al. 2020; Shehabi et al. 2018; Malmodin 2020). Yet there is growing concern that

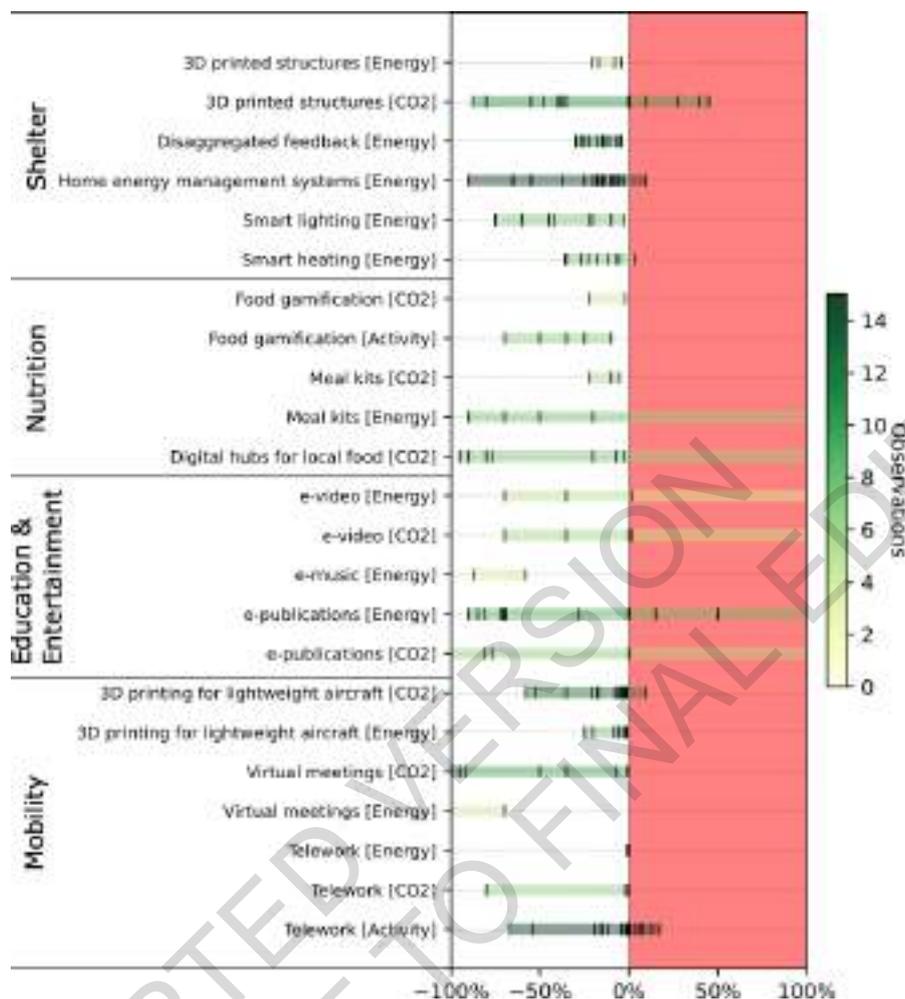

1 remaining energy efficiency improvements might be outpaced by rising demand for digital services,
2 particularly as data-intensive technologies such as artificial intelligence, smart and connected energy
3 systems, distributed manufacturing systems, and autonomous vehicles promise to increase demand for
4 data services even further in the future (TWI2050 2019; Masanet et al. 2020; Strubell et al. 2020).
5 Rapid digitalization is also contributing to an expanding e-waste problem, estimated to be the fastest
6 growing domestic waste stream globally (Forti V., Baldé C.P., Kuehr R. 2020).

7
8 As digitalisation proliferates, an important policy objective is therefore to invest in data collection and
9 monitoring systems and energy demand models of digitalised systems to guide technology and policy
10 investment decisions for addressing potential direct energy demand growth (IEA 2017a) and potentially
11 concomitant growth in e-waste.

12
13 However, the net systems-level energy and resource efficiencies gained through the provision of digital
14 services could play an important role in dealing with climate change and other environmental challenges
15 (Masanet and Matthews 2010; Melville 2010; Elliot 2011; Watson et al. 2012; Gholami et al. 2013;
16 Añón Higón et al. 2017). As shown in Figure 5.12, assessments of numerous digital service
17 opportunities for mobility, nutrition, shelter, and education and entertainment suggest that net emissions
18 benefits can be delivered at the systems level, although these effects are highly context-dependent.
19 Importantly, evidence of potential negative outcomes due to rebound effects, induced demand, or life-
20 cycle trade-offs can also be observed. For example, telework has been shown to reduce emissions where
21 long and/or energy-intensive commutes are avoided, but can lead to net emissions increases in cases
22 where greater non-work vehicle use occurs or only short, low-emissions commutes (e.g., via public
23 transit) are avoided (Viana Cerqueira et al. 2020; IEA 2020a; Hook et al. 2020). Similarly, substitution
24 of physical media by digital alternatives may lead to emissions increases where greater consumption is
25 fuelled, whereas a shift to 3D printed structures may require more emissions-intensive concrete
26 formulations or result in reduced thermal energy efficiency leading to life-cycle emissions increases
27 (Mahadevan et al. 2020; Yao et al. 2020).

28
29 Furthermore, digitalisation, automation and artificial intelligence, as general-purpose technologies, may
30 lead to a plethora of new products and applications that are likely to be efficient on their own but that
31 may also lead to undesirable changes or absolute increases in demand for products (Figure 5.12). For
32 example, last-mile delivery in logistics is both expensive and cumbersome. Battery-powered drones
33 enable a delivery of goods at similar life-cycle emissions to delivery vans (Stolaroff et al. 2018). At the
34 same time, drone delivery is cheaper in terms of time (immediate delivery) and monetary costs
35 (automation saves the highest cost component: personnel) (e.g. (Sudbury and Hutchinson 2016)). As a
36 result, demand for package delivery may increase rapidly. Similarly, automated vehicles reduce the
37 costs of time, parking, and personnel, and therefore may dramatically increase vehicle mileage (Wadud
38 et al. 2016; Cohen and Cavoli 2019). On-demand electric scooters offer mobility access preferable to
39 passenger cars, but can replace trips otherwise taken on public transit (de Bortoli and Christoforou
40 2020) and can come with significant additional energy requirements for night time system rebalancing
41 (Hollingsworth et al. 2019, ITF 2020). The energy requirements of cryptocurrencies is also a growing
42 concern, although considerable uncertainty exists surrounding the energy use of their underlying
43 blockchain infrastructure (Vranken 2017; de Vries 2018; Stoll et al. 2019). For example, while it is
44 clear that the energy requirements of global Bitcoin mining have grown significantly since 2017, recent
45 literature indicates a wide range of estimates for 2020 (47 TWh to 125 TWh) due to data gaps and
46 differences in modelling approaches (Lei et al. 2021). Initial estimates of the computational intensity
47 of artificial intelligence algorithms suggest that energy requirements may be enormous without
48 concerted effort to improve efficiencies, especially on the computational side (Strubell et al. 2020).

1 Efficiency gains enabled by digitalisation, in terms of reduced GHG emissions or energy use per service
 2 unit may be overcompensated by activity/scale effects.
 3

 11 **and scenarios at different scales, which are not directly comparable but useful for indicating the**
 12 **directionality and determinants of net emissions, energy, and activity effects.**

13 Sources: Erdmann and Hilty 2010; Gebler et al. 2014; Huang et al. 2016; Verhoef et al. 2018; Alhumayani et al.
 14 2020; Court and Sorrell 2020; Hook et al. 2020; IEA 2020a; Saade et al. 2020; Torres-Carrillo et al. 2020; Yao
 15 et al. 2020; Wilson et al. 2020c; Muñoz et al. 2021

16
17 Maximising the mitigation potential of digitalisation trends involves diligent monitoring and proactive
 18 management of both direct and indirect demand effects, to ensure that a proper balance is maintained.
 19 Direct energy demand can be managed through continued investments in and incentives for energy-
 20 efficient data centres, networks, and end-use devices (Masanet et al. 2011; Avgerinou et al. 2017; IEA
 21 2017a; Koronen et al. 2020). Shifts to low-carbon power are a particularly important strategy being
 22 undertaken by data centre and network operators (Cook et al. 2014; Huang et al. 2020), which might be
 23 adopted across the digital device spectrum as a proactive mitigation strategy where data demands
 24 outpace hardware efficiency gains, which may be approaching limits in the near future (Koomey et al.
 25 2011). Most recently, data centres are being investigated as a potential resource for demand response

1 and load balancing in renewable power grids (Zheng et al. 2020; Koronen et al. 2020), while a large
2 bandwidth for improving software efficiency has been suggested for overcoming slowing hardware
3 efficiency gains (Leiserson et al. 2020). Ensuring efficiency benefits of digital services while avoiding
4 potential rebound effects and demand surges will require early and proactive public policies to avoid
5 excess energy use (WBGU 2019; TWI2050 2019), which will also necessitate investments in data
6 collection and monitoring systems to ensure that net mitigation benefits are realised and that unintended
7 consequences can be identified early and properly managed (IEA 2017a).

8
9 Within a small but growing body of literature on the net effects of digitalisation, there is *medium*
10 *evidence* that digitalised consumer services can reduce overall emissions, energy use, and activity
11 levels, with *medium agreement* on the scale of potential savings with the important caveat that induced
12 demand and rebound effects must be managed carefully to avoid negative outcomes.

13 14 5.3.4.2 *The sharing economy*

15 Opportunities to increase service per product includes peer-to-peer based sharing of goods and services
16 such as housing, mobility, and tools. Hence, consumable products become durable goods delivering a
17 “product service”, which potentially could provide the same level of service with fewer products
18 (Fischedick, M. et al. 2014). The sharing economy is an old practice of sharing assets between many
19 without transferring ownership, which has been made new through focuses on sharing underutilised
20 products/assets in ways that promotes flexibility and convenience, often in a highly developed context
21 via gig economy/ online platforms. However, sharing economy offers the potential to shift from ‘asset-
22 heavy’ ownership to ‘asset-light’ access, especially in developing countries (Retamal 2019). General
23 conclusions on the sharing economy as a framework for climate change mitigation are challenging and
24 are better broken down to specific subsystems (Mi and Coffman 2019). See more in Supplementary
25 Material I Chapter 5, SM.5.4.3.

26 27 **Shared mobility**

28 Shared mobility is characterised by the sharing of an asset (e.g., a bicycle, e-scooter, vehicle), and the
29 use of technology (i.e. apps and the Internet) to connect users and providers. It succeeded by identifying
30 market inefficiencies and transferring control over transactions to consumers. Even though most shared
31 mobility providers operate privately, their services can be considered as part of a public transport system
32 in so far as it is accessible to most transport users and does not require private asset ownership. Shared
33 mobility reduces GHG emissions if it substitutes for more GHG intensive travel (usually private car
34 travel) (Martin and Shaheen 2011; Shaheen and Cohen 2019; Shaheen and Chan 2016; Santos et al.
35 2018; Axsen and Sovacool 2019), and especially if it changes consumer behaviour in the long run “by
36 shifting personal transportation choices from ownership to demand-fulfilment” (Mi and Coffman 2019).

37
38 Demand is an important driver for energy use and emissions because decreased cost of travel time by
39 sharing an asset (e.g. vehicle) could lead to an increase in emissions, but a high level of vehicle sharing
40 could reduce negative impacts associated with this (Brown and Dodder 2019). One example is the
41 megacity Kolkata, India, which has as many as twelve different modes of public transportation options
42 that co-exist and offer means of mobility to its 14 million citizens (see Box 5.7). Most public transport
43 modes are shared mobility options ranging from sharing between two people in a rickshaw or between
44 a few hundred in metro or sub-urban trains. Sharing also happens informally as daily commuters avail
45 shared taxis and neighbours borrow each other’s car or bicycle for urgent or day trips.

46
47 Shared mobility using private vehicle assets is categorised into four models (Santos et al. 2018): peer-
48 to-peer (P2P) platforms where individuals can rent the vehicle when not in use (Ballús-Armet et al.
49 2014); short term rental managed and owned by a provider (Enoch and Taylor 2006; Schaeffers et al.

1 2016; Bardhi and Eckhardt 2012); Uber-like ridehailing services (Wallsten 2015; Angrist et al. 2017);
2 and ride pooling using private vehicles shared by passengers to a common destination (Liyanage et al.
3 2019; Shaheen and Cohen 2019). The latest model – ride pooling – is promising in terms of congestion
4 and per capita CO₂ emissions reductions and is a common practice in developing countries, however is
5 challenging in terms of waiting and travel time, comfort, and convenience, relative to private cars
6 (Santos et al. 2018; Shaheen and Cohen 2019). The other three models often yield profits to private
7 parties, but remain mostly unrelated to reduction in CO₂ emissions (Santos et al. 2018). Shared travel
8 models, especially Uber-like models, are criticised because of the flexibilisation of labour, especially
9 in developing countries, in which unemployment rates and unregulated labour markets lie a foundation
10 of precarity that lead many workers to seek out wide-ranging means towards patching together a living
11 (Ettliger 2017; Wells et al. 2020). Despite the advantages of the shared mobility such as convenience
12 and affordability, consumers may also perceive risk formed by possible physical injury from strangers
13 or unexpected poor service quality (Hong et al. 2019).

14
15 From a mitigation perspective, the current state of shared mobility looks at best questionable (Fishman
16 et al. 2014; Ricci 2015; Zhang et al. 2019; Zhang and Mi 2018; Creutzig et al. 2019b; Martin 2016; Mi
17 and Coffman 2019). Transport entrepreneurs and government officials often conflate ‘smart’ and
18 “shared” vehicle with ‘sustainable’ mobility, a conflation not withstanding scrutiny (Noy and Givoni
19 2018). Surveys demonstrate that many users take free-floating car sharing instead of public transit,
20 rather than to replace their private car (Herrmann et al. 2014); while in the United States, ride hailing
21 and sharing data indicate that these services have increased road congestion and lowered transit
22 ridership, with an insignificant change in vehicle ownership, and may further lead to net increases in
23 energy use and CO₂ emissions due to deadheading (Diao et al. 2021; Ward et al. 2021). If substitution
24 effects and deadheading, which is the practice of allowing employees of a common carrier to use a
25 vehicle as a non-revenue passenger, are accounted for, flexible motor-cycle sharing in Djakarta is at
26 best neutral to overall GHG emissions (Suatmadi et al. 2019). Passenger surveys conducted in Denver
27 indicated that around 22% of all trips travelled with Uber and Lyft would have been travelled by transit,
28 12% would have walked or biked, and another 12% of induced demand or passengers that would not
29 have travelled at all (Henaio and Marshall 2019).

30
31 Positive effects can be realised directly in bike sharing due to its very low marginal transport emissions.
32 For example, in 2016, bike sharing in Shanghai reduced CO₂ emissions by 25ktCO₂ with additional
33 benefits to air quality (Zhang and Mi 2018). However, also bike-sharing can increase emissions from
34 motor vehicle usage when inventory management is not optimised during maintenance, collection, and
35 redistribution of dock-less bikes (Fishman et al. 2014; Zhang et al. 2019; Mi and Coffman 2019).

36
37 Shared mobility scenarios demonstrate that GHG emission reduction can be substantial when mobility
38 systems and digitalisation is regulated. Some studies model that ride pooling with electric cars (6 to 16
39 seats, which shifts the service to a more efficient transport mode (e.g., electric vehicle) and improves
40 its carbon intensity by cutting GHG emissions by one-third (International Transport Forum 2016), and
41 63-82% per mile compared to a privately owned hybrid vehicle in 2030, 87 to 94% lower than a
42 privately owned, gasoline-powered vehicle in 2014 (Greenblatt and Saxena 2015). This also realises
43 95% reduction in space required for public parking; total vehicle kilometres travelled would be 37%
44 lower than the present day, although each vehicle would travel ten times the total distance of current
45 vehicles (International Transport Forum 2016). Studies of Berlin and Lisbon demonstrate that sharing
46 strategies could reduce the number of cars by more than 90%, also saving valuable street space for
47 human-scale activity (Bischoff and Maciejewski 2016; Martinez and Viegas 2017; Creutzig et al.
48 2019b). The impacts will also depend on sharing levels – concurrent or sequential – and the future
49 modal split among public transit, automated electric vehicles fleets, and shared or pooled rides.

1 Evidence from attributional life-cycle assessments (LCAs) of ride-hailing, whether Uber-like or by taxi,
2 suggests that the key determinants of net emissions effects are average vehicle occupancy and vehicle
3 powertrain, with high-occupancy and electric drivetrain cars deliver the greatest emissions benefits,
4 even rivalling traditional metro/urban rail and bus options (Figure 5.13b). It is possible that shared
5 automated electric vehicles fleets could become widely used without many shared rides, and single or
6 even zero occupant vehicles will continue to dominate the majority of vehicle trips. It is also feasible
7 that shared rides could become more common, if automation makes route deviation more efficient, more
8 cost-effective, and more convenient, increasing total travel substantially (Wadud et al. 2016). Car
9 sharing with automated vehicles could even worsen congestion and emissions by generating additional
10 travel demand (Rubin et al. 2016). Travel time in autonomous vehicles can be used for other activities
11 but driving and travel costs are expected to decrease, which most likely will induce additional demand
12 for auto travel (Moeckel and Lewis 2017) and could even create incentives for further urban sprawl.
13 More generally, increased efficiency generated by big data and smart algorithms may generate rebound
14 effects in demand and potentially compromise the public benefits of their efficiency promise (Gossart
15 2015).

16
17 In many countries, shared mobility and ride pooling is often the norm. Here the challenge is to improve
18 service quality to keep users in shared mobility and public transport (see Box 5.7). A key barrier in
19 cities like Nairobi is the lack of public involvement of users and sustainability experts in designing
20 transport systems, leaving planning to transport engineers, and thus preventing inclusive shared
21 mobility system design (Klopp 2012).

22
23 Altogether, travel behaviour, business models, and especially public policy will be key components in
24 determining how pooling and shared automated electric vehicles impacts unfold (Shaheen and Cohen
25 2019). Urban-scale governance of smart mobility holds potential for prioritizing public transit and the
26 use of public spaces for human activities, managing the data as a digital sustainable commons (e.g., via
27 the installation of a Central Information Officer, as in Tel Aviv), and managing the social and
28 environmental risks of smart mobility to realise its benefits (Creutzig et al. 2019b). Pricing of energy
29 use and GHG emissions will be helpful to achieve these goals. The governance of shared mobility is
30 complicated, as it involves many actors, and is key to realise wider benefits of shared mobility
31 (Akyelken et al. 2018). New actors, networks and technologies enabling shared mobility are already
32 fundamentally challenging how transport is governed worldwide. This is not a debate about state versus
33 non-state actors but instead about the role the state takes within these new networks to steer, facilitate
34 and also reject different elements of the mobility system (Docherty et al. 2018).

35 36 **Shared accommodation**

37 In developing countries and in many student accommodations globally, shared accommodation allows
38 affordable housing for a large part of the population. For example, living arrangements are built
39 expressly around the practice of sharing toilets, bathrooms and kitchens. While the sharing of such
40 facilities does connote a lower level of service provision and quality of life, it provides access to a
41 consumer base with very low and unreliable incomes. Thus, sharing key facilities can help guarantee
42 the provision of affordable housing (Gulyani et al. 2018). In developed countries, large-scale
43 developments are targeting students and ‘young professionals’ by offering shared accommodation and
44 services. Historically shared accommodation has been part of the student life due to its flexible and
45 affordable characteristics. However, the expansion of housing supply through densification can use
46 shared facilities as an instrument to “commercialize small housing production, while housing
47 affordability and accessibility are threatened” (Uyttebrouck et al. 2020).

48

1 With respect to travel accommodations, several models are emerging in which accommodation is
2 offered to, or shared with, travellers by private people organised by business-driven or non-profit online
3 platforms. Accommodation sharing includes P2P, ICT-enabled, short-term renting, swapping,
4 borrowing or lending of existing privately-owned idling lodging facilities (Voytenko Palgan et al. 2017;
5 Möhlmann 2015).

6
7 With shared accommodation services via the platform economy, there may be risks of negative
8 sustainability effects, such as rebound effects caused by increased travel frequency (Tussyadiah and
9 Pesonen 2016). This is particularly a problem if apartments are removed from long-term rental markets,
10 thus indirectly inducing construction activities, with substantial GHG emissions on their own. However,
11 if a host shares their accommodation with a guest, the use of some resources, such as heating and
12 lighting, is shared, thereby leading to more efficient resource use per capita (Chenoweth 2009;
13 Voytenko Palgan et al. 2017). Given the nascence of shared accommodation via the platform economy,
14 quantifications of its systems-level energy and emissions impacts are lacking in the literature,
15 representing an important area for future study.

16 17 **Mitigation potentials of sharing economy strategies**

18 Sharing economy initiatives play a central role in enabling individuals to share underutilised products.
19 While the literature on the net effects of sharing economy strategies is still limited, available studies
20 have presented different mitigation potentials to date, as shown in Figure 5.13. For many sharing
21 economy strategies, there is a risk of negative rebound and induced demand effects, which may occur
22 by changing consuming patterns, e.g., if savings from sharing housing are used to finance air travel.
23 Thus, the mitigation potentials of sharing economy strategies will depend on stringent public policy and
24 consumer awareness that reigns in run-away consumption effects. Shared economy solutions generally
25 relate to the “Avoid” and “Shift” strategies (see Sections 5.1 and 5.3.2). On the one hand, they hold
26 potential for providing similar or improved services for well-being (mobility, shelter) at reduced energy
27 and resource input, with the proper policy signals and consumer responses. On the other hand, shared
28 economy strategies may increase emissions, e.g., shared mobility may shift activity away from public
29 transit and lead to lower vehicle occupancy, deadheading, and use of inefficient shared vehicles (Merlin
30 2019; Jones and Leibowicz 2019; Bonilla-Alicea et al. 2020; Ward et al. 2021). Similarly to
31 digitalisation, there is *medium evidence* that sharing economy can reduce overall emissions, energy use,
32 and activity levels, with *medium agreement* on the scale of potential savings if induced demand and
33 rebound effects can be carefully managed to avoid negative outcomes.
34

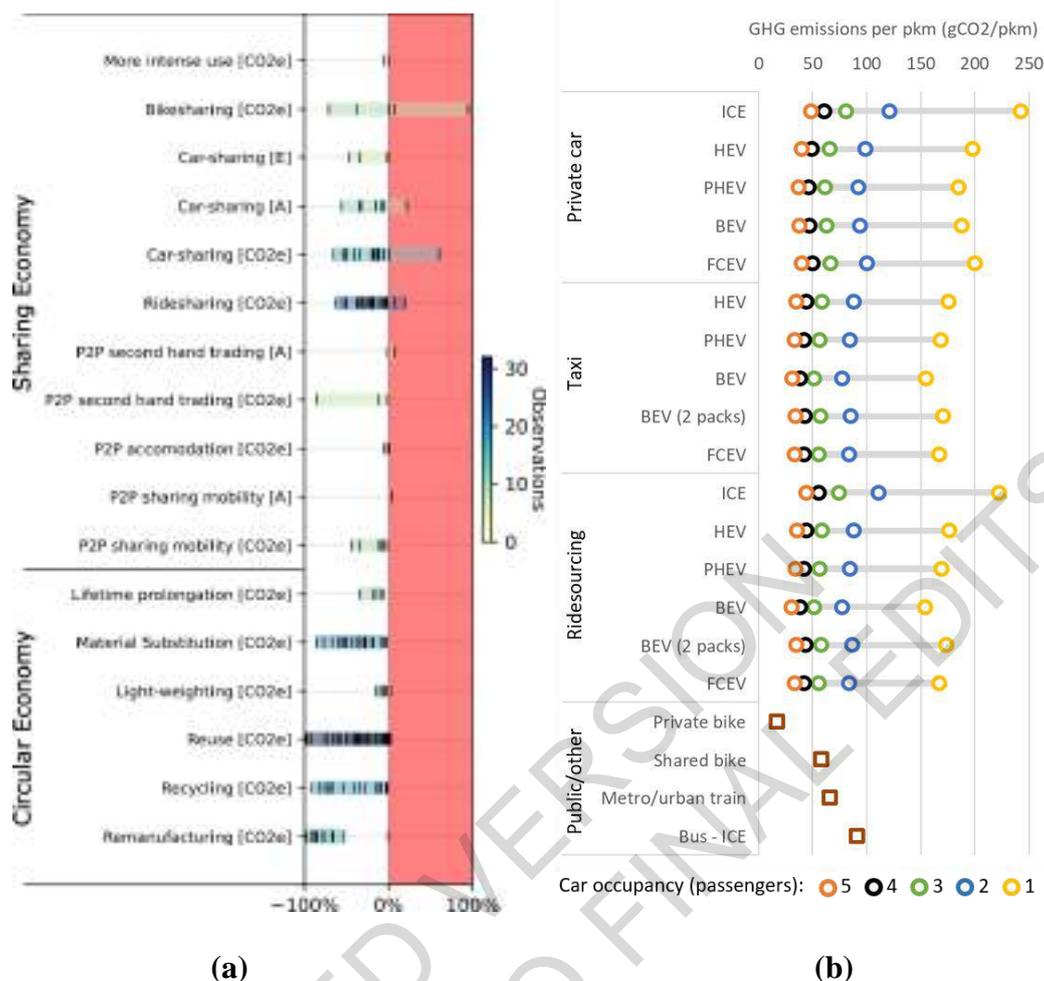

Figure 5.13

(a) Published estimates from 72 studies with 185 observations (indicated by vertical bars) of the relative mitigation potential of different shared and circular economy strategies, demonstrating limited observations for many emerging strategies, a wide variance in estimated benefits for most strategies, and within the sharing economy risk of increased emissions due to inefficient substitutions, induced demand, and rebound effects. Mitigation potentials are conditional on corresponding public policy and/or regulation. (b) Attributional LCA comparisons of ridesharing mobility options, which highlight the large effects of vehicle occupancy and vehicle technology on total CO₂ emissions per passenger-km and the preferability of high-occupancy and non-ICE configurations for emissions reductions compared to private cars. Also indicated are possible emissions increases associated with shared car mobility when it substitutes for non-motorised and public transit options.

BEV = battery electric vehicle; FCEV = fuel cell electric vehicle; HEV = hybrid electric vehicle; ICE = internal combustion engine; PHEV = plug-in hybrid electric vehicle.

The circular economy

While the demands for energy and materials will increase until 2060 following the traditional linear model of production and consumption, resulting in serious environmental consequences (OECD 2019b), the circular economy (CE) provides strategies for reducing societal needs for energy and primary materials to deliver the same level of service with lower environmental impacts. The CE framework embodies multiple schools of thought with roots in a number of related concepts (Blomsma and Brennan 2017; Murray et al. 2017), including cradle to cradle (McDonough and Braungart 2002), performance economy (Stahel 2016), biomimicry (Benyus 1997), green economy (Loiseau et al. 2016) and industrial ecology (Saavedra et al. 2018). As a result, there are also many definitions of CE: a systematic literature review identified 114 different definitions (Kirchherr et al. 2017). One of the most comprehensive models is suggested by the Netherlands Environmental Assessment Agency (Potting et al. 2018), which defines ten strategies for circularity: Refuse (R0), Rethink (R1), Reduce (R2), Reuse (R3), Repair (R4), Refurbish (R5), Remanufacture (R6), Repurpose (R7), Recycle (R8), and Recover energy (R9). Overall, the definition of CE is contested, with varying boundary conditions chosen. As illustrated in Figure 5.11, the CE overlaps with both the sharing economy and digitalisation megatrends.

In line with the principles of SDG12 (responsible consumption and production), the essence of building CE is to retain as much value as possible from products and components when they reach the end of their useful life in a given application (Linder and Williander 2017; Lewandowski 2016; Lieder and Rashid 2016; Stahel 2016). This requires an integrated approach during the design phase that, for example, extends product usage and ensures recyclability after use (de Coninck et al. 2018). While traditional “improve” strategies tend to focus on direct energy and carbon efficiency, service-oriented strategies focus on reducing life-cycle emissions through harnessing the leverage effect (Creutzig et al. 2018). The development of closed-loop models in service-oriented businesses can increase resource and energy efficiency, reducing emissions and contributing to climate change mitigation goals on national, regional, and global levels (Johannsdottir 2014; Korhonen et al. 2018). Key examples include remanufacturing of consumer products to extend lifespans while maintaining adequate service levels (Klausner et al. 1998), reuse of building components to reduce demand for primary materials and construction processes (Shanks et al. 2019), and improved recycling to reduce upstream resource pressures (IEA 2019b, 2017b).

Among the many schools of thought on the CE and climate change mitigation, two different trends can be distinguished from the literature to date. First, there are publications, many of them non peer-reviewed, that eulogize the perceived benefits of the CE, but in many cases stop short of providing a quantitative assessment. Promotion of CE from this perspective has been criticised as a greenwashing attempt by industry to avoid serious regulation (Isenhour 2019). Second, there are more methodologically rigorous publications, mostly originating in the industrial ecology field, but sometimes investigating only limited aspects of the CE (Bocken et al. 2017; Cullen 2017; Goldberg 2017). Conclusions on CE’s mitigation potential also differ with diverging definitions of the CE. A systematic review identified 3244 peer-reviewed articles addressing CE and climate change, but only 10% of those provide insights on how the CE can support mitigation, and most of them found only small potentials to reduce GHG emissions (Cantzler et al. 2020). Recycling is the CE category most investigated, while reuse and reduce strategies have seen comparatively less attention (Cantzler et al. 2020). However, mitigation potentials were also context- and material-specific, as illustrated by the ranges shown in Figure 5.13a.

There are three key concerns relating to the effectiveness of the CE concept. First, many proposals on the CE insufficiently reflect on thermodynamic constraints that limit the potential of recycling from

1 both mass conservation and material quality perspectives or ignore the considerable amount of energy
2 needed so reuse materials (Cullen 2017). Second, demand for materials and resources will likely
3 outpace efficiency gains in supply chains, becoming a key driver of GHG emissions and other
4 environmental problems, rendering the CE alone an insufficient strategy to reduce emissions
5 (Bengtsson et al. 2018). In fact, the empirical literature points out that only 6.5% of all processed
6 materials (4 Gt yr⁻¹) globally originate from recycled sources (Haas et al. 2015). The low degree of
7 circularity is explained by the high proportion of processed materials (44%) used to provide energy thus
8 not available for recycling; and the high rate of net additions to stocks of 17 Gt yr⁻¹. As long as long-
9 lived material stocks (e.g., in buildings and infrastructure) continue to grow, strategies targeting end-
10 of-pipe materials cannot keep pace with primary materials demand (Krausmann et al. 2017; Haas et al.
11 2020). Instead, a significant reduction of societal stock growth, and decisive eco-design is suggested
12 to advance the CE (Haas et al. 2015). Third, cost-effectiveness underlying CE activities may
13 concurrently also increase energy intensity and reduce labour intensity, causing systematically
14 undesirable effects. To a large extent, the distribution of costs and benefits of material and energy use
15 depends on institutions in order to include demand-side solutions. Thus, institutional conditions have
16 an essential role to play in setting rules differentiating profitable from nonprofitable activities in CE
17 (Moreau et al. 2017). Moreover, the prevalence CE practices such as reuse, refurbishment, and
18 recycling can differ substantially between developed and developing economies, leading to highly
19 context-specific mitigation potentials and policy approaches (McDowall et al. 2017).

20
21 One report estimates that the CE can contribute to more than 6 GtCO₂ emission reductions in 2030,
22 including strategies such as material substitution in buildings (Blok et al. 2016). Reform of the tax
23 system towards GHG emissions and the extraction of raw materials substituting taxes on labour is key
24 precondition to achieve such a potential. Otherwise rebound effects tends to take back a high share of
25 marginal CE efforts. A 50% reduction of GHG emissions in industrial processes, including the
26 production of goods in steel, cement, plastic, paper, and aluminium from 2010 until 2050 are impossible
27 to attain only with reuse and radical product innovation strategies, but will need to also rely on the
28 reduction of primary input (Allwood et al. 2010).

29
30 CE strategies generally correspond to the “Avoid” strategy for primary materials (see Sections 5.1 and
31 5.3.2). CE strategies in industrial settings improve well-being mostly indirectly, via the reduction of
32 environmental harm and climate impact. They can also save monetary resources of consumers by
33 reducing the need for consumption. It may seem counterintuitive, but reducing consumers' need for
34 consumption of a particular product/service (e.g. reducing energy consumption) may increase a
35 consumption of another one (e.g. travels) associated with some type of energy use, or lead to greater
36 consumption if additional secondary markets are created. Hence, carbon emissions could rise if the
37 rebound effect is not considered (Chitnis et al. 2013; Zink and Geyer 2017).

38
39 Looking at “Shift” strategy (see Sections 5.1 and 5.3.2), the role of individuals as consumers/users has
40 received less attention than other aspects of the CE (e.g. technological interventions as “Improve”
41 strategy and waste minimisation as “Avoid” strategy) within mainstream debates to date. One
42 explanation is CE has roots in the field of Industrial Ecology, which has historically emphasized
43 materials systems more than the end-user. By shifting this perspective from the supply-side to the
44 demand-side in the CE, users are, for the most part, discussed as social entities that now must form new
45 relations with businesses to meet their needs. That is, the demand-side approach largely replaces the
46 concept of a consumer with that of a user, who must either accept or reject new business models for
47 service provision, stimulated by the pushes and pulls of prices and performance (Hobson 2019).

48 Relevant contributions to climate change mitigation at Gigaton scale by the CE will remain out of scope
49 if decision makers and industry fail to reduce primary inputs (*high confidence*). Systemic

1 (consequential) analysis is required to avoid the risk that scaling effects negate efficiency gains; such
2 analysis is however rarely applied to date. For example, material substitution or refurbishment of
3 buildings brings risk of increasing emissions despite improving or avoiding current materials (Eberhardt
4 et al. 2019; Castro and Pasanen 2019) Besides, CE concepts that extend the lifetime of products and
5 increase the fraction of recycling are useful but are both thermodynamically limited and will remain
6 relatively small in scale as long as demand of primary materials continue to grow, and scale effects
7 dominate. In spite of presenting a large body of literature on CE in general, only a small but growing
8 body of literature exists on the net effects of its strategies from a quantitative perspective, with key
9 knowledge gaps remaining on specific CE strategies. There is *medium evidence* that CE can reduce
10 overall emissions, energy use, and activity levels, with *medium evidence* that sharing economy can
11 reduce overall emissions, energy use, and activity levels, with *medium agreement* on the scale of
12 potential savings.

15 **5.4 Transition toward high well-being and low-carbon demand societies**

16 Demand-side mitigation involves individuals (e.g. consumption choices), culture (e.g. social norms,
17 values), corporate (e.g. investments), institutions (e.g. political agency), and infrastructure change (*high*
18 *evidence, high agreement*). These five drivers of human behaviour either contribute to the status-quo of
19 a global high-carbon, consumption, and GDP growth oriented economy or help generate the desired
20 change to a low-carbon energy-services, well-being, and equity oriented economy (Jackson 2017;
21 Cassiers et al. 2018; Yuana et al. 2020)(Figure 5.14). Each driver has novel implications for the design
22 and implementation of demand-side mitigation policies. They show important synergies, making energy
23 demand mitigation a dynamic problem where the packaging and/or sequencing of different policies play
24 a role in their effectiveness, demonstrated in Sections 5.5 and 5.6. The Social Science Primer
25 (Supplementary Material I Chapter 5) describes theory and empirical insights about the interplay
26 between individual agency, the social and physical context of demand-side decisions in the form of
27 social roles and norms, infrastructure and technological constraints and affordances, and other formal
28 and informal institutions. Incremental interventions on all five fronts change social practices, effecting
29 simultaneously energy and well-being (Schot and Kanger 2018). Transformative change will require
30 coordinated use of all five drivers, as described in Figure 5.14 and Table 5. using novel insights about
31 behaviour change for policy design and implementation (*high evidence, high agreement*). In particular,
32 socio-economic factors, such as equity, public service quality, electricity access and democracy are
33 found to be highly significant in enabling need satisfaction at low energy use, whereas economic growth
34 beyond moderate incomes and extractive economic activities are observed to be prohibiting factors
35 (Vogel et al. 2021).

Demand side mitigation is about more than behavioural change. Reconfiguring the way services are provided while simultaneously changing social norms and preferences will help reduce emissions and access. Transformation happens through societal, technological and institutional changes.

Tilting the balance towards less resource intensive service provisioning

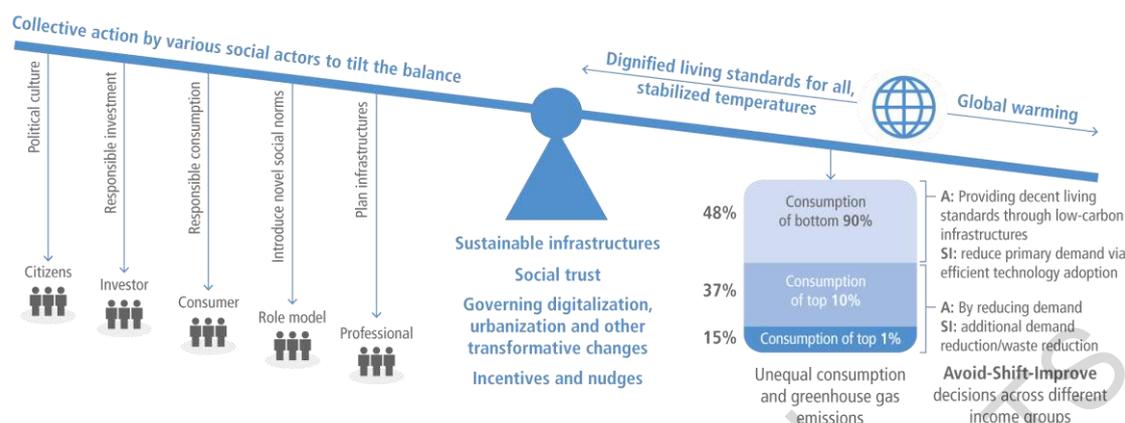

Figure 5.14 Role of people, demand-side action and consumption in reversing a planetary trajectory to a warming Earth towards effective climate change mitigation and dignified living standards for all

5.4.1 Behavioural Drivers

Behaviour change by individuals and households requires both *motivation* to change and *capacity* for change (option availability/knowledge; material/cognitive resources to initiate and maintain change) (Moser and Ekstrom 2010; Michie et al. 2011) and is best seen as part of more encompassing collective action. Motivation for change for collective good comes from economic, legal, social incentives, regard for deeper intrinsic value of concern for others over extrinsic values. Capacity for change varies; people in informal settlements or rural areas are incapacitated by socio-political realities and have limited access to new energy-service options.

Motivation and effort required for behaviour change increase from Improve to Shift to Avoid decisions. 'Improve' requires changes in personal purchase decisions, 'shift' involves changes in behavioural routines, 'avoid' also involves shifts in deeper values or mindsets. People set easy goals for themselves and more difficult ones for others (Attari et al. 2016) and underestimate the energy savings of behaviour changes that make a large difference (Attari et al. 2010). Most personal actions taken so far have small mitigation potential (recycling, ecodriving), and people refrain from options advocated more recently with high impact (less flying, living car free) (Dubois et al. 2019).

As individuals pursue a broad set of goals and use calculation-, emotion-, and rule-based processes when they make energy decisions, demand-side policies can use a broad range of behavioural tools that complement subsidies, taxes, and regulations (Chakravarty and Roy 2016; Mattauch et al. 2016; Niamir 2019) (*high evidence, high agreement*). The provision of targeted information, social advertisements, and influence of trusted in-group members and/role models or admired role models like celebrities can be used to create better climate change knowledge and awareness (Niamir et al. 2020c,b; Niamir 2019). Behavioural interventions like communicating changes in social norms can accelerate behaviour change by creating tipping points (Nyborg et al. 2016). When changes in energy-demand decisions (such as switching to a plant-based diet, Box 5.5) are motivated by the creation and activation of a social identity consistent with this and other behaviours, positive spillover can accelerate behaviour change (Truelove et al. 2014), both within a domain or across settings, e.g., from work to home (Maki and Rothman 2017).

START BOX 5.5 HERE**Box 5.5 Dietary shifts in UK society towards lower emission foods**

Meat eating is declining in the UK, alongside a shift from carbon-intensive red meat towards poultry. This is due to the interaction of behavioural, socio-cultural and organisational drivers (Vinnari and Vinnari 2014). Reduced meat consumption is primarily driven by issues of personal health and animal welfare, instead of climate or environment concerns (Latvala et al. 2012; Dibb and Fitzpatrick 2014; Hartmann and Siegrist 2017; Graça et al. 2019). Social movements have promoted shifts to a vegan diet (Morris et al. 2014; Laestadius et al. 2016) yet their impact on actual behaviour is the subject of debate (Taufik et al. 2019; Harguess et al. 2020; Sahakian et al. 2020). Companies have expanded new markets in non-meat products (MINTEL 2019). Both corporate food actors and new entrants offering more innovative ‘meat alternatives’ view consumer preferences as an economic opportunity, and are responding by increasing the availability of meat replacement products. No significant policy change has taken place in the UK to enable dietary shift (Wellesley and Froggatt 2015); however the Committee on Climate Change has recommended dietary shift in the Sixth Carbon Budget (Climate Change Committee 2020), involving reduced consumption of high-carbon meat and dairy products by 20% by 2030, with further reductions in later years in order to reach net zero by 2050. Agricultural policies serve to support meat production with large subsidies that lower production cost and effectively increase the meat intensity of diets at a population level (Simon 2003; Godfray et al. 2018). Deeper, population wide reductions in meat consumption are hampered by these lock-in mechanisms which continue to stabilise the existing meat production-consumption system. The extent to which policymakers are willing to actively stimulate reduced meat consumption thus remains an open question (Godfray et al. 2018). See more in Supplementary Material I Chapter 5, SM5.6.4.

END BOX 5.5 HERE

People’s general perceptions of climate risks, first covered in AR5, motivate behaviour change; more proximate and personal feelings of being at risk triggered by extreme weather and climate-linked natural disasters will increase concern and willingness to act (Bergquist et al. 2019), though the window of increased support is short (Sisco et al. 2017). 67% of individuals in 26 countries see climate change as a major threat to their country, an increase from 53% in 2013, though 29% also consider it a minor or no threat (Fagan and Huang 2019). Concern that the COVID-19 crisis may derail this momentum due to a finite pool of worry (Weber 2006) appears to be unwarranted: Americans’ positions on climate change in 2020 matched high levels of concern measured in 2019 (Leiserowitz et al. 2020). Younger, female, and more educated individuals perceive climate risks to be larger (Weber 2016; Fagan and Huang 2019). Moral values and political ideology influence climate risk perception and beliefs about the outcomes and effectiveness of climate action (Maibach et al. 2011). Motivation for demand-side solutions can be increased by focusing on personal health or financial risks and benefits that clearly matter to people (Petrovic et al. 2014). Consistent with climate change as a normally distant, non-threatening, statistical issue (Gifford 2011; Fox-Glassman and Weber 2016), personal experience with climate-linked flooding or other extreme weather events increases perceptions of risk and willingness to act (Weber 2013; Atreya and Ferreira 2015; Sisco et al. 2017) when plausible mediators and moderators are considered (Brügger et al. 2021), confirmed in all 24 countries studied by Broomell et al (2015)(Broomell et al. 2015). Discounting the future matters (Hershfield et al. 2014): across multiple countries, individuals more focused on future outcomes more likely engage in environmental actions (Milfont et al. 2012).

There is *medium evidence and high agreement* that demographics, values, goals, personal and social norms differentially determine ASI behaviours, in the Netherlands and Spain (Abrahamse and Steg

1 2009; Niamir 2019; Niamir et al. 2020b), the OECD (Ameli and Brandt 2015), and 11 European
2 countries (Mills and Schleich 2012; Roy et al. 2012). Education and income increase Shift and Improve
3 behaviour, whereas personal norms help to increase the more difficult Avoid behaviours (Mills and
4 Schleich 2012). Sociodemographic variables (household size and income) predict energy use, but
5 psychological variables (perceived behavioural control, perceived responsibility) predict *changes* in
6 energy use; younger households are more likely to adopt Improve decisions, whereas education
7 increases Avoid decisions (Ahmad et al. 2015). In India and developing countries, Avoid decisions are
8 made by individuals championing a cause, while Improve and Shift behaviour are increases by
9 awareness programmes and promotional materials highlighting environmental and financial benefits
10 (Roy et al. 2018a; Chakravarty and Roy 2016). Cleaner cookstove adoption (see Box 5.6), a widely
11 studied Improve solution in developing countries (Nepal et al. 2010; Pant et al. 2014), goes up with
12 income, education, and urban location. Female education and investments into reproductive health are
13 evident measures to reducing world population growth (Abel et al. 2016).

14 **START BOX 5.6 HERE**

15 **Box 5.6 Socio-behavioural aspects of deploying cookstoves**

16
17
18 Universal access to clean and modern cooking energy could cut premature death from household air
19 pollution by two-thirds, while reducing forest degradation and deforestation and contribute to the
20 reduction of up to 50% of CO₂ emissions from cooking (relative to baseline by 2030) (IEA 2017c; Hof
21 et al. 2019). However, in the absence of policy reform and substantial energy investments, 2.3 billion
22 people will have no access to clean cooking fuels such as biogas, LPG, natural gas or electricity in 2030
23 (IEA 2017c). Studies reveal that a combination of drivers influence adoption of new cookstove
24 appliances including affordability, behavioural and cultural aspects (lifestyles, social norms around
25 cooking and dietary practices), information provision, availability, aesthetic qualities of the technology,
26 perceived health benefits and infrastructure (spatial design of households and cooking areas). The
27 increasing efficiency *improvements* in electric cooking technologies, could enable households to *shift*
28 to electrical cooking at mass scale. The use of pressure cookers and rice cookers is now widespread in
29 South Asia and beginning to penetrate the African market as consumer attitudes are changing towards
30 household appliances with higher energy efficiencies (Batchelor et al. 2019). *Shifts* towards electric and
31 LPG stoves in Bhutan (Dendup and Arimura 2019), India (Pattanayak et al. 2019), Ecuador (Martínez
32 et al. 2017; Gould et al. 2018) and Ethiopia (Tesfamichael et al. 2021); and *improved* biomass stoves in
33 China (Smith et al. 1993). Significant subsidy, information (Dendup and Arimura 2019), social
34 marketing and availability of technology in the local markets are some of the key policy instruments
35 helping to adopt ICS (Pattanayak et al. 2019). There is no one-size-fits-all solution to household air
36 pollution – different levels of shift and improvement occur in different cultural contexts, indicating the
37 importance of socio-cultural and behavioural aspects in shifts in cooking practices. See more in
38 Supplementary Material Chapter 5, SM5.6.2.

39 **END BOX 5.6 HERE**

40
41 There is *high agreement* in the literature that the updating of educational systems from a
42 commercialised, individualised, entrepreneurial training model to an education cognizant of planetary
43 health and human well-being can accelerate climate change awareness and action (Mendoza and Roa
44 2014; Dombrowski et al. 2016) (also see Supplementary Material Chapter 5).

45
46 There is *high evidence and high agreement* that people's core values affect climate-related decisions
47 and climate policy support by shaping beliefs and identities (Dietz 2014; Steg 2016; Hayward and Roy
48 2019). People with altruistic and biospheric values are more likely to act on climate change and support

1 climate policies than those with hedonic or egoistic values (Taylor et al. 2014), because these values
2 are associated with higher awareness and concern about climate change, stronger belief that personal
3 actions can help mitigating climate change, and stronger feelings of responsibility for taking climate
4 action (Dietz 2014; Steg 2016). Research also suggest that egalitarian, individualistic, and hierarchical
5 worldviews (Wildavsky and Dake 1990) have their role, and that successful solutions require policy
6 makers of all three worldviews to come together and communicate with each other (Chuang et al. 2020).

7
8 Core values also influence which costs and benefits are considered (Hahnel et al. 2015; Gölz and Hahnel
9 2016; Steg 2016). Information provision and appeals are thus more effective when tailored to those
10 values (Bolderdijk et al. 2013; Boomsma and Steg 2014), as implemented by the energy-cultures
11 framework (Stephenson et al. 2015; Klanięcki et al. 2020). Awareness, personal norms, and perceived
12 behavioural control predict willingness to change energy-related behaviour above and beyond
13 traditional sociodemographic and economic predictors (Schwartz 1977; Ajzen 1985; Stern 2000), as do
14 perceptions of self-efficacy (Bostrom et al. 2019). However, such motivation for change is often not
15 enough, as actors also need capacity for change and help to overcome individual, institutional and
16 market barriers (Young et al. 2010; Carrington et al. 2014; Bray et al. 2011).

17
18 Table 5.4 describes common obstacles to demand-side energy behaviour change, from loss aversion to
19 present bias (for more detail see Supplementary Material Chapter 5). Choice architecture refers to
20 interventions (“nudges”) that shape the choice context and how choices are presented, with seemingly-
21 irrelevant details (e.g., option order or labels) often more important than option price (Thaler and
22 Sunstein 2009). There is *high evidence and high agreement* that choice architecture nudges shape
23 energy decisions by capturing deciders’ attention; engaging their desire to contribute to the social good;
24 facilitating accurate assessment of risks, costs, and benefits; and making complex information more
25 accessible (Yoeli et al. 2017; Zangheri et al. 2019). Climate-friendly choice architecture includes the
26 setting of proper defaults, the salient positioning of green options (in stores and online), forms of
27 framing, and communication of social norms (Johnson et al. 2012). Simplifying access to greener
28 options (and hence lowering effort) can promote ASI changes (Mani et al. 2013). Setting effective
29 “green” defaults may be the most effective policy to mainstream low-carbon energy choices (Sunstein
30 and Reisch 2014), adopted in many contexts (Jachimowicz et al. 2019) and deemed acceptable in many
31 countries (Sunstein et al. 2019). Table 5.3a lists how often different choice-architecture tools were used
32 in many countries over the past 10 years to change ASI behaviours, and how often each tool was used
33 to enhance an economic incentive. These tools have been tested mostly in developed countries.
34 Reduction in energy use (typically electricity consumption) is the most widely studied behaviour
35 (because metering is easily observable). All but one tool was applied to increase this Avoid behaviour,
36 with demand-side reductions from 0% to up to 20%, with most values below 3% (see also meta-analyses
37 by (Hummel and Maedche 2019; Nisa et al. 2019; van der Linden and Goldberg 2020; Stankuniene et
38 al. 2020; Khanna et al. 2021). Behavioural, economic, and legal instruments are most effective when
39 applied as an internally consistent ensemble where they can reinforce each other, a concept referred to
40 as “policy packaging” in transport policy research (Givoni 2014). A meta-analysis, combining evidence
41 of psychological and economic studies, demonstrates that feedback, monetary incentives and social
42 comparison operates synergistically and is together more effective than the sum of individual
43 interventions (Khanna et al. 2021). The same meta-analysis also shows that combined with monetary
44 incentives, nudges and choice architecture can reduce global GHG emissions from household energy
45 use by 5-6% (Khanna et al. 2021).

46
47 Choice architecture has been depicted as an anti-democratic attempt at manipulating the behaviour of
48 actors without their awareness or approval (Gumbert 2019). Such critiques ignore the fact that there is
49 no neutral way to present energy-use related decisions, as every presentation format and choice

1 environment influences choice, whether intentionally chosen or not. Educating households and policy
2 makers about the effectiveness of choice architecture and adding these behavioural tools to existing
3 market- and regulation-based tools in a transparent and consultative way can provide desired outcomes
4 with increased effectiveness, while avoiding charges of manipulation or deception. People consent to
5 choice architecture tools if their use is welfare-enhancing, policymakers are transparent about their
6 goals and processes, public deliberation and participation is encouraged, and the choice architect is
7 trusted (Sunstein et al. 2019).

1 Note: Papers in this review of behavioural interventions to reduce household energy demand were collected through a systemic literature search up to August 2021.
2 Studies are included in the reported counts if they are (1) experimental, (2) peer-reviewed or highly cited reports, (3) the intervention is behavioural, and (4) the targeted
3 behaviour is household energy demand. 559 papers are included in the review. Each paper was coded for: type of behavioural intervention, country of study, energy
4 demand behaviour targeted, whether the target is an avoid, shift, or improve behaviour, and whether the intervention includes an economic incentive. Some papers do
5 not report all elements. The energy demand behaviour column provides the count of papers that focus on each behaviour type (in parentheses after the behaviour). The
6 citations that follow are not exhaustive but exemplify papers in the category, selected for impact, range, and recency. The asterisk (*) indicates references that are meta-
7 analyses or systematic reviews. Papers within meta-analyses and systematic reviews that meet the inclusion criteria are counted individually in the total counts. The
8 full reference list is available at <https://osf.io/9463u/>.

Table 5.3b Summary of effects of behavioural interventions in Table 5.3a.

Behavioural Tool	Results (expressed in household energy savings, unless otherwise stated)	Results Summary
Set Proper Default	<p>Meta-analyses find a medium to strong effect of defaults on environmental behaviour. Jachimowicz et al. (2019) report a strong average effect of defaults on environmental behaviour (Cohen’s $d=0.75$, confidence interval 0.39 - 1.12), though not as high as for consumer decisions. They find that defaults, across domains, are more effective when they reflect an endorsement (recommendation by a trusted source) or endowment (reflecting the status quo). Nisa et al. (2019)* report a medium average effect size (Cohen’s $d = 0.35$; range 0.04 - 0.55).</p>	<p>A forest plot showing effect sizes for two studies. The x-axis is labeled 'Effect Size' and ranges from 0.0 to 1.5, with markers for 'small', 'medium', and 'large'. Jachimowicz 2019* has a point estimate of approximately 0.75 with a confidence interval from 0.39 to 1.12. Nisa 2019* has a point estimate of approximately 0.35 with a confidence interval from 0.04 to 0.55.</p>
Reach Out During Transitions	<p>The few interventions that focus on transitions and measure behaviour change (rather than energy savings) report mixed, moderate effect sizes. People were unwilling to change their behaviour if they are satisfied with current options (Mahapatra and Gustavsson 2008). Iweka et al. (2019) find that effective messages can prompt habit disruption.</p>	<p>A forest plot showing the percentage of energy savings. The x-axis is labeled '% Energy Savings' and ranges from 0 to 30%. A single horizontal line represents the 'Result Range' from approximately 5% to 15%.</p>
Timely Feedback & Reminders	<p>The average effects of meta-analyses of feedback interventions on household energy use reductions range from 1.8% to 7.7%, with large variations (Delmas et al. 2013; Buckley 2019; Nisa et al. 2019; Buckley 2020; Ahir and Chakraborty 2021; Khanna et al. 2021). The same is true for two literature reviews (Abrahamse et al. 2005; Bergquist et al. 2019). Most studies find a 4% - 10% average reduction during the intervention; some studies find a non-significant result (Dünnhoff and Duscha 2008) or a negative reduction (Winett et al. 1978).</p> <p>Real-time feedback is most effective, followed by personalized feedback (Buckley 2019, 2020). A review by Darby et al. (2006) finds direct feedback (from the meter or display monitor) is more effective than indirect feedback (via billing) (5 - 15% savings vs. 0 - 10% savings). Feedback effects (Cohen’s $d= .241$) are increased when combined with a monetary incentive (Cohen’s $d=.96$) and with a social comparison and a monetary incentive (Cohen’s $d=.714$) (Khanna et al. 2021)</p> <p>Sanguinetti et al. (2020) find that onboard feedback results in a 6.6% improvement in the fuel economy of cars (Cohen’s $d: .07, [.05,.08]$).</p>	<p>Four forest plots showing the percentage of energy savings for different studies. The x-axis is labeled '% Energy Savings' and ranges from 0 to 30%. Ahir 2021* has a point estimate of approximately 10% with a confidence interval from 5% to 15%. Buckley 2020* has a point estimate of approximately 5% with a confidence interval from 0% to 10%. Delmas 2013* has a point estimate of approximately 10% with a confidence interval from 0% to 20%. Khanna 2021* has a point estimate of approximately 5% with a confidence interval from 0% to 10%. Nisa 2019* has a point estimate of approximately 10% with a confidence interval from 0% to 20%.</p>

The effectiveness of feedback from in home displays (IHDs) is highly studied. Two reviews find them to have a 2 - 14% energy saving (Ehrhardt-Martinez and Donnelly 2010; Faruqui et al. 2010). A meta-analysis by McKerracher and Torriti (2013) finds a smaller range of results, with 3 - 5% energy savings.

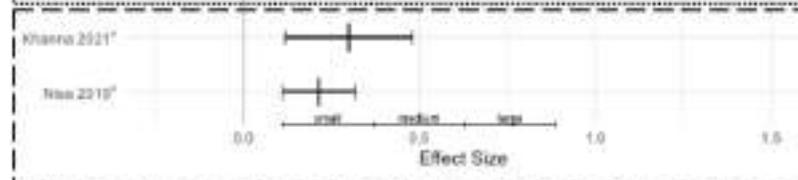

Make Information Intuitive & Easy to Access

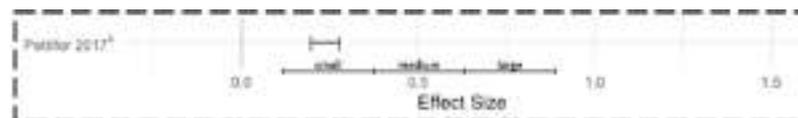

Meta-analyses of information interventions on household energy use find average energy savings between 1.8 - 7.4% and Cohen’s d effect sizes between .05 and .30 (Delmas et al. 2013; Buckley 2019, 2020; Nemati and Penn 2020; Ahir and Chakraborty 2021; Khanna et al. 2021); (Nisa et al. 2019)*. Study quality affects the measured effect—small sample sizes, shorter measurement windows, and self-selection are correlated with larger effects (Nisa et al. 2019; Nemati and Penn 2020). RCTs have a smaller effect size, 5.2% savings (95% CI [0.5%,9.5%]) (Nemati and Penn 2020).

Information combined with comparative feedback is more effective than information alone (d=.34 vs. .30, (Khanna et al. 2021); 8.5% vs. 7.4%, Delmas et al. 2013). Monetary incentives make information interventions more effective (Khanna et al. 2021).

Energy efficiency labeling has a heterogenous effect on investment in energy efficiency (Abrahamse et al. 2005; Andor and Fels 2018). Efficiency labels on houses lead to higher price mark ups (Jensen et al. 2016) and house prices (Brounen and Kok 2011). Energy star labels lead to significantly higher willingness to pay for refrigerators (Houde et al. 2013), but energy and water conservation varies by appliance from 0 - 23% (Kurz et al. 2005).

A meta-analysis of interventions to increase alternative fuel vehicle adoption find a small effect (d=.20 - .28) (Pettifor et al. 2017).

<p>Make Behaviour Observable & Provide Recognition</p>	<p>Making behaviour observable and recognition lead to 6-7% energy savings (Winett et al. 1978; Handgraaf et al. 2013; Nemati and Penn 2020) and a large effects size (Cohen’s $d = [.79,1.06]$; Nisa et al. 2019*). Community-wide interventions result in 17-27% energy savings (Iweka et al. 2019).</p> <p>Neighborhood social influence has a small ($d=.28$) effect on alternative fuel vehicle adoption (Pettifor et al. 2017).</p>	
<p>Communicate a Norm</p>	<p>The effect of social norm information on household energy savings ranges from 1.7-11.5% (Delmas et al. 2013; Buckley 2020) and Cohen’s d from .08-.32,(Abrahamse and Steg 2013; Bergquist et al. 2019; Khanna et al. 2021); (Nisa et al. 2019)*, with similar effects on choice of mode of transportation. Pettifor et al. (2017) report a small effect ($d=.20-.28$) on selecting a more energy efficient car.</p> <p>The Opower study (Allcott 2011), prototypical for the impact of social norms on household energy consumption, finds 2% reduction in long-term energy use and 11-20% energy reduction in the short run (Allcott 2011; Ayres et al. 2013; Costa and Kahn 2013; Allcott and Rogers 2014). Impact decays over time (Allcott and Rogers 2012). Norm interventions are less effective for low energy users (Schultz et al. 2007; Andor et al. 2017). Moral licensing and negative spillover can reduce the overall positive feedback of normative feedback (Tiefenbeck et al. 2013).</p>	
	<p>Interventions are more effective when the norm is implicitly inducted, in individualistic countries, and when people care about the norm (Nolan et al. 2008; Bergquist et al. 2019; Khanna et al. 2021). Descriptive norm interventions (social comparisons) are more effective when communicated online/email or through in-home displays compared to billing letters (Andor and Fels 2018), when the reference group is more specific (Shen et al. 2015). Dolan and Metcalfe (2013) find conservation increased from 4% to 11% when energy savings tips are added.</p>	

<p>Reframe Consequences in Terms People Care About</p>	<p>A meta-analysis by Khanna et al. (Khanna et al. 2021) finds a small and variable effect of motivational interventions that reframe consequences (Cohens's $d = [0, .423]$); Effect are larger when reframing is combined with monetary incentives and feedback ($d = .96$). Darby et al. (2006) report 10-20% savings for US pay-as-you-go systems. Providing lifecycle cost information increases likelihood of purchasing eco-innovative products (Kaenzig and Wüstenhagen 2010). Long term (10-year) operating cost information leads to higher WTP for energy efficiency compared to short term (1-year) cost information (Heinzle and Wüstenhagen 2012). Monetary information increases the success of energy reduction interventions (Newell and Siikamäki 2014; Andor and Fels 2018). Reframing interventions are more effective when combined with feedback ($d = .24-.96$) and with social comparisons and feedback ($d = .42$) (Khanna et al. 2021)</p>	<p>This forest plot shows the results for three studies. The top plot displays '% Energy Savings' on the x-axis (0, 10%, 20%, 30%). Darby 2006 shows a range from approximately 10% to 20%. The bottom plot displays 'Effect Size' on the x-axis (0.0, 0.3, 1.0, 1.5). Khanna 2021 shows a range from approximately 0.1 to 0.4, and Nisa 2019 shows a range from approximately 0.1 to 0.4. A legend indicates 'small', 'medium', and 'large' effect sizes.</p>
<p>Obtain a Commitment</p>	<p>Commitment and goal interventions result in significant energy reduction in half of studies (Abrahamse et al. 2005; Andor and Fels 2018); (Nisa et al. 2019)*. Nisa et al. (2019) report a moderate average effect (Cohen's $d = 0.34, [.11, .66]$). When results are significant, the energy savings are around 10% (Andor and Fels 2018). Self-set goals perform better than assigned goals (van Houwelingen and van Raaij 1989; McCalley and Midden 2002; Andor and Fels 2018) and reasonable goals perform better than unreasonably high or low goals (van Houwelingen and van Raaij 1989; Abrahamse et al. 2007; Harding and Hsiaw 2014). Interventions are more effective when the commitment is public (Pallak and Cummings 1976) and when combined with information and rewards (Slavin et al. 1981; Völlink and Meertens 1999).</p>	<p>This forest plot shows the results for three studies. The top plot displays '% Energy Savings' on the x-axis (0, 10%, 20%, 30%). Nisa 2019 (top) shows a point estimate at approximately 10%. Andor 2018 shows a point estimate at approximately 10%. The bottom plot displays 'Effect Size' on the x-axis (0.0, 0.5, 1.0, 1.5). Nisa 2019 (bottom) shows a range from approximately 0.1 to 0.4. A legend indicates 'small', 'medium', and 'large' effect sizes.</p>

1
 2 Note: The second column describes the effects of each of the eight behavioural tools. The third column plots the results of meta-analyses and reviews that focus on each tool.
 3 Effects are reported as described in the referenced paper, either as percentage of energy saved (dotted box) or by the effect size, measured as Cohen's D (dashed box).
 4 *Two responses to Nisa et al. (2019) challenge their conclusion that behavioural interventions have a small impact on household energy use (Stern 2020; van der Linden &
 5 Goldberg, 2020). We report the raw data collected and used in Nisa et al. (2019). Our data summary supports the arguments by Stern (2020) and van der Linden (2020) that
 6 interventions should be evaluated in combination, as well as individually, and that the results are highly sensitive to the chosen estimator.
 7 ^a Range reported as 95% confidence interval of results used in the meta-analysis or review.
 8 ^b Range reported as all results included in the meta-analysis or review.
 9 ^c No range reported.
 10 ^d Range indicates the reported results within a meta-analysis; this applies when multiple intervention types in a meta-analysis are classified as a single behavioural tool.
 11

5.4.2 Socio-cultural drivers of climate mitigation

Collective behaviours and social organisation is part of everyday life, and feeling part of active collective action renders mitigation measures efficient and pervasive (Climact 2018). Social and cultural processes play an important role in shaping what actions people take on climate mitigation, interacting with individual, structural, institutional and economic drivers (Barr and Prillwitz 2014). Just like infrastructures, social and cultural processes can ‘lock-in’ societies to carbon-intensive patterns of service delivery. They also offer potential levers to change normative ideas and social practices in order to achieve extensive emissions cuts (*high confidence*, see Table 5.4).

In terms of cultural processes, we can distinguish two levels of analysis: specific meanings associated with particular technologies or practices, and general narratives about climate change mitigation. Specific **meanings** (e.g. comfort, status, identity and agency) are associated with many technologies and everyday social practices that deliver energy services, from driving a car to using a cookstove (*high evidence, high agreement*, see Section 5.5). Meanings are symbolic and influence the willingness of individuals to use existing technologies or shift to new ones (Wilhite and Ling 1995; Wilhite 2009; Sorrell 2015). Symbolic motives are more important predictors of technology adoption than instrumental motives (Steg 2005; Noppers et al. 2014, 2015, 2016) (see mobility case study on app-cabs in Kolkata, Box 5.8). If an individual’s pro-environmental behavior is associated with personal meaning than it also increases subjective wellbeing (Zawadzki et al. 2020). Status consciousness is highly relevant in high GHG emission intensive consumption choices (cars, houses). However, inversely framing energy saving behaviour as high status is a promising strategy for emission reduction (Ramakrishnan and Creutzig 2021).

At a broader level, **narratives** about climate mitigation circulate within and across societies, as recognised in SR15, and are broader than the meanings associated with specific technologies (*high evidence, high agreement*). Narratives enable people to imagine and make sense of the future through processes of interpretation, understanding, communication and social interaction (Smith et al. 2017). Stories about climate change are relevant for mitigation in numerous ways. They can be utopian or dystopian (e.g. The great derangement by Amitav Ghosh) (Ghosh 2016), for example presenting apocalyptic stories and imagery to capture people’s attention and evoke emotional and behavioural response (O’Neill and Smith 2014). Reading climate stories has been shown to cause short-term influences on attitudes towards climate change, increasing the belief that climate change is human caused and increasing its issue priority (Schneider-Mayerson et al. 2020). Climate narratives can also be used to justify scepticism of science, drawing together coalitions of diverse actors into social movements that aim to prevent climate action (Lejano and Nero 2020). Narratives have been used by indigenous communities to imagine climate futures divergent from top-down narratives (Streeby 2018). Narratives are also used in integrated assessment and energy system models that construct climate stabilisation scenarios, for example in the choice of parameters, their interpretation and model structure (Ellenbeck and Lilliestam 2019). One important narrative choice of many models involves framing climate change as market failure (which leads to the result that carbon pricing is required). While such a choice can be justified, other model framings can be equally justified (Ellenbeck and Lilliestam 2019). Power and agency shape which climate narratives are told and how prevalent they are (O’Neill and Smith 2014; Schneider-Mayerson et al. 2020). For example, narratives have been used by indigenous communities to imagine climate futures divergent from top-down, government-led narratives (Streeby 2018). The uptake of new climate narratives is influenced by political beliefs and trust. Policy makers can enable emissions reduction by employing narratives that have broad societal appeal, encourage behavioural change and complement regulatory and fiscal measures (Terzi 2020). Justice narratives may not have universal appeal - in a UK study, justice narratives polarised individuals along ideological lines, with lower support amongst individual with right-wing beliefs; by contrast, narratives centred on saving energy, avoiding waste and patriotic values were more widely supported across society

1 (Whitmarsh and Corner 2017). More research is needed to assess if these findings are prevalent in
2 diverse socio-cultural contexts, as well the role played by social media platforms to influence emerging
3 narratives of climate change (Pearce et al. 2019).

4
5 Trust in organisations is a key predictor of the take-up of novel energy services (Lutzenhiser 1993),
6 particularly when financial incentives are high (Stern et al. 1985; Joskow 1995). Research has shown
7 that, if there is low public trust in utility companies, service delivery by community-based non-profit
8 organisations in the US (Stern et al. 1985) or public/private partnerships in Mexico (Friedmann and
9 Sheinbaum 1998), offer more effective solutions, yet only if public trust is higher in these types of
10 organisations. UK research shows that acceptance of shifts to less-resource intensive service provision
11 (e.g. more resource efficient products, extending product lifetimes, community schemes for sharing
12 products) varies depending on factors including trust in suppliers and manufacturers, affordability,
13 quality and hygiene of shared products, and fair allocation of responsibilities (Cherry et al. 2018). Trust
14 in other people plays an important role in the sharing economy (Li and Wang 2020), for example
15 predicting shifts in transport mode, specifically car-sharing involving rides with strangers (Acheampong
16 and Siiba 2019) (sharing economy see Section 5.3.4.2).

17
18 Action on climate mitigation is influenced by our perception of what other people commonly do, think
19 or expect, known as social norms (*high evidence, high agreement*) (Cialdini 2006) (see Table 5.3), even
20 though people often do not acknowledge this (Nolan et al. 2008; Noppers et al. 2014). Changing social
21 norms can encourage societal transformation and social tipping points to address climate
22 mitigation (Nyborg et al. 2016; Otto et al. 2020). Providing feedback to people about how their own
23 actions compare to others can encourage mitigation (Delmas et al. 2013), although the overall effect
24 size is not strong (Abrahamse and Steg 2013). Trending norms are behaviours that are becoming more
25 popular, even if currently practised by a minority. Communicating messages that the number of people
26 engaging in a mitigation behaviour (e.g. giving a financial donation to an environmental conservation
27 organisation) is increasing – a simple low cost policy intervention - can encourage shifts to the targeted
28 behaviour, even if the effect size is relatively small (Mortensen et al. 2019).

29
30 Socially comparative feedback seems to be more effective when people strongly identify with the
31 reference group (De Dominicis et al. 2019). Descriptive norms (perceptions of behaviours common in
32 others) are more strongly related to mitigation actions when injunctive norms (perceptions of whether
33 certain behaviours are commonly approved or disapproved) are also strong, when people are not
34 strongly personally involved with mitigation topics (Göckeritz et al. 2010), when people are currently
35 acting inconsistently with their preferences, when norm-based interventions are supported by other
36 interventions and when the context supports norm-congruent actions (Miller and Prentice 2016). A
37 descriptive norm prime (“most others try to reduce energy consumption”) together with injunctive norm
38 feedback (“you are very good in saving energy”) is a very effective combination to motivate further
39 energy savings (Bonan et al. 2020). Second-order beliefs (perceptions on what others in the community
40 believe) are particularly important for leveraging descriptive norms (Jachimowicz et al. 2018).

41
42 Behavioural contagion, which describes how ideas and behaviours often spread like infectious diseases,
43 is a major contributor to the climate crisis (Sunstein 2019). But harnessing contagion can also mitigate
44 warming. Carbon-heavy consumption patterns have become the norm only in part because we’re not
45 charged for environmental damage we cause (Pigou 1920). The deeper source of these patterns has been
46 peer influence (Frank 1999), because what we do influences others. A rooftop solar installation early in
47 the adoption cycle, for example, spawns a copycat installation in the same neighbourhood within four
48 months, on average. With such installations thus doubling every four months, a single new order results

1 in 32 additional installations in just two years. And contagion doesn't stop there, since each family also
2 influences friends and relatives in distant locations.

3
4 Harnessing contagion can also underwrite the investment necessary for climate stability. If taxed more
5 heavily, top earners would spend less, shifting the frames of reference that shape spending of those just
6 below, and so on—each step simultaneously reducing emissions and liberating resources for additional
7 green investment (Frank 2020). Many resist, believing that higher taxes would make it harder to buy
8 life's special extras. But that belief is a cognitive illusion (Frank 2020). Acquiring special things, which
9 are inherently in short supply, requires outbidding others who also want them. When top tax rates rise
10 in tandem, relative bidding power is completely unchanged, so the same penthouse apartments would
11 end up in the same hands as before. More generally, behavioural contagion is important to leverage all
12 relevant social tipping points for stabilising Earth's climate (Otto et al. 2020).

13
14 For new climate policies and mitigation technologies to be rapidly and extensively implemented, they
15 must be socially acceptable to those who are directly impacted by those policies and technologies
16 (*medium evidence, high agreement*). Policies that run counter to social norms or cultural meanings are
17 less likely to be effective in reducing emissions (Demski et al. 2015; Perlaviciute et al. 2018; Roy et al.
18 2018b). More just and acceptable implementation of renewable energy technologies requires taking
19 account of the cultural meanings, emotional attachments and identities linked to particular landscapes
20 and places where those technologies are proposed (Devine-Wright 2009) and enabling fairness in how
21 decisions are taken and costs and benefits distributed (Wolsink 2007). This is important for achieving
22 the goal of SDG7 (i.e. increased use of renewable energy resources) in developing countries while
23 achieving energy justice (Calzadilla and Mauger 2017). 'Top-down' imposition of climate policies by
24 governments can translate into local opposition when perceived to be unjust and lacking transparency
25 (*high evidence, high agreement*). Policy makers can build trust and increase the legitimacy of new
26 policies by implementing early and extensive public and stakeholder participation, avoiding 'NIMBY'
27 (Not In My Back Yard) assumptions about objectors and adopting 'Just Transition' principles (Owens
28 2000; Wolsink 2007; Wüstenhagen et al. 2007; Dietz and Stern 2008; Devine-Wright 2011; Heffron
29 and McCauley 2018). Participatory mechanisms that enable deliberation by a representative sample of
30 the public (Climate Assembly UK 2020) can inform policy making and increase the legitimacy of new
31 and difficult policy actions (Dryzek et al. 2019).

32
33 Collective action by civil society groups and social movements can work to enable or constrain climate
34 mitigation. Civil society groups can advocate policy change, provide policy research and open up
35 opportunities for new political reforms (high evidence, high agreement) as recognised in previous IPCC
36 reports (IPCC 2007). Grassroots environmental initiatives, including community energy groups, are
37 collective responses to, and critiques of, normative ways that everyday material needs (e.g. food,
38 energy, making) are produced, supplied and circulated (Schlosberg and Coles 2016). Such initiatives
39 can reconcile lower carbon footprints with higher life satisfaction and higher incomes (Vita et al. 2020).
40 Local initiatives such as Transition Towns and community energy can lead to improvements in energy
41 efficiency, ensure a decent standard of living and increase renewable energy uptake, while building on
42 existing social trust, and in turn, building social trust and initiating engagement, capacity building, and
43 social capital formation (Hicks and Ison 2018). Another example are grassroots initiatives that aim to
44 reduce food loss and waste, even as overall evidence on their effectiveness remains limited (Mariam et
45 al. 2020). However, community energy initiatives are not always inclusive and require policy support
46 for widespread implementation across all socio-economic groups (Aiken et al. 2017) In addition, more
47 evidence is required of the impacts of community energy initiatives (Creamer et al. 2018; Bardsley et
48 al. 2019).

1 Civil society social movements are a primary driver of social and institutional change (high evidence,
2 high agreement) and can be differently positioned as, on the one hand, ‘insider’ social movements (e.g.
3 World Wildlife Fund) that seek to influence existing state institutions through lobbying, advice and
4 research and, on the other hand, ‘outsider’ social movements (e.g. Rising Tide, Extinction Rebellion)
5 that advocate radical reform through protests and demonstrations (Newell 2005; Caniglia et al. 2015).
6 Civil society social movements frame grievances that resonate with society, mobilise resources to
7 coordinate and sustain mass collective action, and operate within – and seek to influence - external
8 conditions that enable or constrain political change (Caniglia et al. 2015). When successful, social
9 movements open up windows of opportunity (so called ‘Overton Windows’) to unlock structural change
10 (high evidence, high agreement) (Szalek 2013; Piggot 2018).

11
12 Climate social movements advocate new narratives or framings for climate mitigation (e.g. climate
13 ‘emergency’) (della Porta and Parks 2014); criticise positive meanings associated with high emission
14 technologies or practices (see Diet and Solar PV Case Studies, Box 5.5 and 5.7); show disapproval for
15 high emission behaviours (e.g. through ‘flight shaming’); model behaviour change (e.g. shifting to
16 veganism or public transport – see Case Study on Mobility in Kolkata, Box 5.8); demonstrate against
17 extraction and use of fossil-fuels (Cheon and Urpelainen 2018); and aim to increase a sense of agency
18 amongst certain social groups (e.g. young people or indigenous communities) that structural change is
19 possible. Climate strikes have become internationally prevalent, for example the September 2019 strikes
20 involved participants in more than 180 countries (Rosane 2019; Fisher and Nasrin 2020; Martiskainen
21 et al. 2020). Enabled by digitalisation, these have given voice to youth on climate (Lee et al. 2020) and
22 created a new cohort of active citizens engaged in climate demonstrations (Fisher 2019). Research on
23 bystanders shows that marches increase positive beliefs about marchers and collective efficacy (Swim
24 et al. 2019).

25
26 Countermovement coalitions work to oppose climate mitigation (*high confidence*). Examples include
27 efforts in the US to oppose mandatory limits on carbon emissions supported by organisations from the
28 coal and electrical utility sectors (Brulle 2019) and evidence that US opposition to climate action by
29 carbon-connected industries is broad-based, highly organized, and matched with extensive lobbying
30 (Cory et al., 2021). Social movements can also work to prevent policy changes, for example in France
31 the Gilet Jaunes objected to increases in fuel costs on the grounds that they unfairly distributed the costs
32 and benefits of price rises across social groups, for example between urban, peri-urban and rural areas
33 (Copland 2019).

34
35 Religion could play an important role in enabling collective action on climate mitigation by providing
36 cultural interpretations of change and institutional responses that provide resources and infrastructure
37 to sustain collective actions (Roy et al. 2012; Haluza-DeLay 2014; Caniglia et al. 2015; Hulme 2015).
38 Religion can be an important cultural resource towards sustainability at individual, community and
39 institutional levels (Ives and Kidwell 2019), providing leverage points for inner transformation towards
40 sustainability (Woiwode et al. 2021). Normative interpretations of climate change for and from religious
41 communities are found in nearly every geography, and often observe popular movements for climate
42 action drawing on religious symbols or metaphors (Jenkins et al. 2018). This suggests the value for
43 policy makers of involving religious constituencies as significant civil society organisations in devising
44 and delivering climate response.

45 46 **START BOX 5.7 HERE**

47 48 **Box 5.7 Solar PV and the agency of consumers**

1 As an innovative technology, solar PV was strongly taken up by consumers (Nemet 2019). Several key
2 factors explain its success. First, modular design made it applicable to different scales of deployment
3 in different geographical contexts (e.g. large-scale grid-connected projects and smaller-scale off-grid
4 projects) and allowed its application by companies taking advantage of emerging markets (Shum and
5 Watanabe 2009). Second, culturally, solar PV symbolised an environmentally progressive technology
6 that was valued by users (Morris and Jungjohann 2016). Large-scale adoption led to policy change (i.e.
7 the introduction of feed-in tariffs that guaranteed a financial return) that in turn enabled improvements
8 to the technology by companies. Over time, this has driven large-scale reductions in cost and increase
9 in deployment worldwide. The relative importance of drivers varied across contexts. In Japan, state
10 subsidies were lower yet did not hinder take-up because consumer behaviour was motivated by non-
11 cost symbolic aspects. In Germany, policy change arose from social movements that campaigned for
12 environmental conservation and opposed nuclear power, making solar PV policies politically
13 acceptable. In summary, the seven-decade evolution of solar PV shows an evolution in which the agency
14 of consumers has consistently played a key role in multiple countries, such that deriving 30-50% of
15 global electricity supply from solar is now a realistic possibility (Creutzig et al. 2017). See more in
16 Supplementary Material Chapter 5, SM5.6.1.

17 **END BOX 5.7 HERE**

20 **5.4.3 Business and Corporate Drivers**

21 Businesses and corporate organisations play a key role in the mitigation of global warming, through
22 their own commitments to zero-carbon footprints (Mendiluce 2021) decisions to invest in researching
23 and implementing new energy technologies and energy efficient measures, and the supply side
24 interaction with changing consumer preferences and behaviours, e.g. via marketing. Business models
25 and strategies work both as a barrier to and as accelerator of decarbonisation. Still existing lock-in in
26 infrastructures and business models advantages fossil fuel industry over renewable and energy efficient
27 end use industry (Klitkou et al. 2015). The fossil fuel energy generation and delivery system therefore
28 epitomises a barrier to the acceptance and implementation of new and cleaner renewable energy
29 technologies (Kariuki 2018). A good number of corporate agents have attempted to derail climate
30 change mitigation by targeted lobbying and doubt-inducing media strategies (Oreskes and Conway
31 2011). A number of corporations that are involved in the supply chain of both upstream and downstream
32 of fossil fuel companies, make up the majority of organizations opposed to climate action (Dunlap and
33 McCright 2015; Cory et al. 2021; Brulle 2019). Corporate advertisement and brand building strategies
34 also attempt to deflect corporate responsibility to individuals, and/or to appropriate climate care
35 sentiments in their own brand building; climate change mitigation is uniquely framed through choice
36 of products and consumption, avoiding the notion of the political collective action sphere (Doyle 2011;
37 Doyle et al. 2019).

38
39 Business and corporations are also agents of change towards decarbonisation, as demonstrated in the
40 case of PV and battery electric cars (Teece 2018). Beyond new low-carbon technologies, strong
41 sustainability business models (SSBM) are characterised by identifying nature as the primary
42 stakeholder, strong local anchorage, the creation of diversified income sources, and deliberate
43 limitations on economic growth (Brozovic 2019). However, SSBM are difficult to maintain if generally
44 traditional business models prevail, requiring short-term accounting.

45
46 Liability of fossil fuel business models and insurance against climate damages are key concerns of
47 corporations and business. Limitations and regulation on GHG emissions will compel the demand for
48 fossil fuel companies' products (Porter and Kramer 2006). According to a European Systemic Risk
49 Board (ESRB 2016) report of the Advisory Scientific Committee, insurance industries are very likely

1 to incur losses due to liability risks. The divestment movement adds additional pressure on fossil fuel
2 related investments (Braungardt et al. 2019), even though fossil fuel financing remains resilient (Curran
3 2020). Companies, businesses and organisations might face liability claims for their contribution to
4 changes especially in the carbon intensive energy sector. A late transition to a low-carbon economy
5 would exacerbate the physical costs of climate change on governments, businesses and corporations
6 (ESRB 2016).

7
8 Despite these seemingly positive roles that Businesses and corporate organisations tend to play towards
9 sustainable transitions, there is a need to highlight the dynamic relationship between sustainable and
10 unsustainable trends (Antal et al. 2020). For example, the production of Sports Utility Vehicles (SUVs)
11 in the automobile market at the same time that car manufacturers are producing electric vehicles. An
12 analysis of the role of consumers as drivers of unsustainability for Businesses and Corporate
13 organisations is very important here as this trend will offset the sustainability progress being made by
14 these businesses and organisations (Antal et al. 2020).

15
16 Professional actors, such as building managers, landlords, energy efficiency advisers, technology
17 installers and car dealers, influence patterns of mobility and energy consumption (Shove 2003) by
18 acting as ‘middle actors’ (Janda and Parag 2013; Parag and Janda 2014) or ‘intermediaries’ in the
19 provision of building or mobility services (Grandclément et al. 2015; De Rubens et al. 2018). Middle
20 actors can bring about change in several different directions be it, upstream, or downstream or sideways.
21 They can redefine professional ethics around sustainability issues, and as influencers on the process of
22 diffusion of innovations (Rogers 2003), professionals can enable or obstruct improvements in efficient
23 service provision or shifts towards low-carbon technologies (LCTs) (e.g. air and ground source heat
24 pumps, solar hot water, underfloor heating, programmable thermostats, and mechanical ventilation with
25 heat recovery) and mobility (e.g. electric vehicles) technologies.

26 27 **5.4.4 Institutional Drivers**

28 The allocation of political power to incumbent actors and coalitions has contributed to lock-in of
29 particular institutions, stabilising the interests of incumbents through networks that include
30 policymakers, bureaucracies, advocacy groups and knowledge institutions (*high agreement, high
31 evidence*). There is high evidence and high agreement in that institutions are central in addressing
32 climate change mitigation. Indeed, social provisioning contexts including equity, democracy, public
33 services and high quality infrastructure are found to facilitate high levels of need satisfaction at lower
34 energy use, whereas economic growth beyond moderate incomes and dependence on extractive
35 industries inhibit it (Vogel et al. 2021). They shape and interact with technological systems (Unruh
36 2000; Foxon et al. 2004; Seto et al. 2014) and represent rules, norms and conventions that organise and
37 structure actions (Vatn 2015) and help create new path dependency or strengthen existing path
38 dependency (Mattioli et al. 2020) (also see case studies in Box 5.5-5.8 and Supplementary Material
39 Chapter 5). These drive behaviour of actors through formal (e.g., laws, regulations, and standards) or
40 informal (e.g., norms, habits, and customs) processes, and can create constraints on policy options
41 (Breukers and Wolsink 2007). For example, ‘the car dependent transport system’ is maintained by
42 interlocking elements and institutions, consisting of i) the automotive industry; ii) the provision of car
43 infrastructure; iii) the political economy of urban sprawl; iv) the provision of public transport; v)
44 cultures of car consumption (Mattioli et al. 2020). The behaviour of actors, their processes and
45 implications on policy options and decisions is discussed further in Section 5.6.

46 47 **START BOX 5.8 HERE**

48 49 **Box 5.8 Shifts from private to public transport in Indian megacities**

1 In densely populated, fast-growing megacities, policy makers face the difficult challenge of preventing
2 widespread adoption of petrol or diesel fuelled private cars as a mode of transport. The megacity of
3 Kolkata in India provides a useful case study. As many as twelve different modes of public
4 transportation, each with its own system structure, actors and meanings co-exist and offers means of
5 mobility to its 14 million citizens. Most of the public transport modes are shared mobility options
6 ranging from sharing between two people in a rickshaw or between a few hundred in metro or sub-
7 urban trains. Sharing also happens informally as daily commuters avail shared taxis and neighbours
8 borrow each other's car or bicycle for urgent or day trips.

9
10 A key role is played by the state government, in collaboration with other stakeholders, to improve the
11 system as whole and formalise certain semi-formal modes of transport. An important policy
12 consideration has been to make Kolkata's mobility system more efficient (in terms of speed, reliability
13 and avoidance of congestion) and sustainable through strengthening coordination between different
14 mode-based regimes (Ghosh 2019) and comfortable with airconditioned space in a hot and humid
15 climate (Roy et al. 2018b). Policy makers have introduced multiple technological, behavioural and
16 socio-cultural measures to tackle this challenge. New buses have been purchased by public authorities
17 (Ghosh and Schot 2019). These have been promoted to middle-class workers in terms of modernity,
18 efficiency and comfort, and implemented using premium-fares. Digitalisation and the sharing economy
19 has encouraged take-up of shared taxi rides ('app cabs'), being low cost and fast, but also influenced by
20 levels of social trust involved in rides with strangers (Acheampong and Siiba 2019; Ghosh and Schot
21 2019). Rickshaws have been improved through use of LNG and cycling has been banned from busy
22 roads. These measures contributed positively in bringing down the trend of greenhouse gas emissions
23 per unit of GDP to half in one decade within the Kolkata metropolitan area, with potential for further
24 reduction (Colenbrander et al. 2016). However, social movements have opposed some changes due to
25 concerns about social equity, since many of the new policies cater to middle class aspirations and
26 preferences, at the cost of low income and less privileged communities.

27
28 To conclude, urban mobility transitions in Kolkata shows interconnected policy, institutional and socio-
29 cultural drivers for socio-technical change. Change has unfolded in complex interactions between
30 multiple actors, sustainability values and megatrends, where direct causalities are hard to identify.
31 However, the prominence of policy actors as change-agents is clear as they are changing multiple
32 regimes from within. The state government initiated infrastructural change in public bus systems,
33 coordinated with private and non-governmental actors such as auto-rickshaw operators, app-cab owners
34 who hold crucial agency in offering public transport services in the city. The latter can directly be
35 attributed to the global momentum of mobility-as-a-service platforms, at the intersection of
36 digitalisation and sharing economy trends. More thoughtful action at a policy level is required to sustain
37 and coordinate the diversity of public transport modes through infrastructure design and reflecting on
38 the overall directionality of change (Schot and Steinmueller 2018; Roy et al. 2018b). See more in
39 Supplementary Material Chapter 5, SM5.6.3.

40
41 **END BOX 5.8 HERE**

42 43 **5.4.5 Technological/Infrastructural Drivers**

44 Technologies and infrastructures shape social practices and their design matters for effective mitigation
45 measures (*high evidence, high agreement*). There are systemic interconnections between infrastructures
46 and practices (Cass et al. 2018; Haberl et al. 2021), and their intersection explains their relevance
47 (Thacker et al. 2019). The design of a new electricity system to meet new emerging demand based on
48 intermittent renewable, can lead to a change in consumption habits and the adaption of lifestyles
49 compliant with more power supply interruption (Maïzi et al. 2017; Maïzi and Mazauric 2019). The

1 quality of the service delivery impacts directly the potential user uptake of low-carbon technologies. In
 2 the state of Himachal Pradesh of India, shift from LPG to electricity, with induction stove, has been
 3 successful due to the availability of stable and continuous electricity which has been difficult to achieve
 4 in any other Indian state (Banerjee et al. 2016). In contrast, in South Africa, where people who were
 5 using electricity earlier are now adopting LPG to diversify the energy source for cooking due to high
 6 electricity tariff and frequent blackouts (Kimemia and Annegarn 2016) (see Box 5.5 and Supplementary
 7 Material Chapter 5).

8
 9 From a welfare point of view, infrastructure investments are not constrained by revealed or stated
 10 preferences (*high evidence, high agreement*). Preferences change with social and physical environment,
 11 and infrastructure interventions can be justified by objective measures, such as public health and climate
 12 change mitigation, not only given preferences (*high agreement, high evidence*). Specifically, there is a
 13 case for more investment in low-carbon transport infrastructure than assumed in environmental
 14 economics as it induces low-carbon preferences (Creutzig et al. 2016a; Mattauch et al. 2018,
 15 2016). Changes in infrastructure provision for active travel may contribute to uptake of more walking
 16 and cycling (Frank et al. 2019). These effects contribute to higher uptake of low-carbon travel options,
 17 albeit the magnitude of effects depends on design choices and context (Goodman et al. 2013, 2014;
 18 Song et al. 2017; Javaid et al. 2020; Abraham et al. 2021). Infrastructure is thus not only required to
 19 make low-carbon travel possible but can also be a pre-condition for the formation of low-carbon
 20 mobility preferences (also see mobility case study in Box 5.7).

21
 22 The dynamic interaction of habits and infrastructures also predict CO₂-intensive choices. When people
 23 move from a city with good public transport to a car-dependent city, they are more likely to own fewer
 24 vehicles due to learned preferences for lower levels of car ownership (Weinberger and Goetzke 2010).
 25 When individuals moving to a new city with extensive public transport were given targeted material
 26 about public transport options, the modal share of public transport increased significantly (Bamberg et
 27 al. 2003). Similarly, an exogenous change to route choice in public transport makes commuters change
 28 their habitual routes (Larcom et al. 2017).

29
 30 **Table 5.4 Main features, insights, and policy implications of five drivers of decision and action. Entries in**
 31 **each column are independent lists, not intended to line up with each other.**

Driver	How does driver contribute to status quo bias?	What needs to change?	Driver's policy implications	Examples
Behavioural	Habits and routines formed under different circumstances do not get updated. Present-bias penalises upfront costs and discourages energy efficiency investments. Loss aversion magnifies the costs of change.	New goals (sustainable lifestyle) New capabilities (online real-time communication) New resources (increased education) Use of full range of incentives and mechanisms to change demand-side behaviour	Policies need to be context specific and coordinate economic, legal, social, and infrastructural tools and nudges Relate climate action to salient local risks and issues.	India's new LPG scale up policy uses insights about multiple behavioural drivers of adoption and use. Rooftop solar adoption expanded in Germany, when FITs removed risk from upfront-cost recovery Nuclear power policies in

	When climate change is seen as distant, it is not feared. Nuclear power and accident potential score high on psychological dread			Germany post Fukushima affected by emotional factors
Socio-Cultural	<p>Cultural norms (e.g. status, comfort, convenience) support existing behaviour.</p> <p>Lack of social trust reduces willingness to shift behaviour (e.g. adopt car-sharing).</p> <p>Fear of social disapproval decreases willingness to adopt new behaviours.</p> <p>Lack of opportunities to participate in policy create reactance against 'top down' imposition.</p> <p>Unclear or dystopian narratives of climate response reduce willingness to change and to accept new policies and technologies.</p>	<p>Create positive meanings and norms around low-emission service delivery (e.g. mass transit).</p> <p>Community initiatives to build social trust and engagement, capacity building, and social capital formation.</p> <p>Climate movements that call out the insufficient, highly problematic state of delayed climate action.</p> <p>Public participation in policy making and technology implementation that increases trust, builds capacity and increases social acceptance.</p> <p>Positive narratives about possible futures that avoid emissions (e.g. emphasis upon health and slow/active travel).</p>	<p>Embed policies in supportive social norms.</p> <p>Support collective action on climate mitigation to create social trust and inclusion.</p> <p>Involve arts and humanities to create narratives for policy process</p>	<p>Communicate descriptive norms to electricity end users.</p> <p>Community energy initiative RESCOOP.</p> <p>Friday For Future.</p>
Business and Corporate	Lock-in mechanisms that make incumbent firms reluctant to change: core capabilities, sunk investments in staff and factories, stranded assets.	New companies (like car sharing companies, renewable energy start-ups) that pioneer new business models or energy service provisions.	Influence consumer behaviour via product innovation Provide capital for clean energy innovation.	Electrification of transport opens up new markets for more than a hundred million new vehicles.
Institutional	Lock-in mechanisms related to power struggles, lobbying, political economy.	New policy instruments, policy discussions, policy platforms, implementation agencies, including capacity.	Feed-in Tariffs and other regulations that turn energy consumers into prosumers.	Mobility case study, India's LPG policy sequence.
Infrastructural	various lock-in mechanisms such as	many emerging technologies, which are	systemic governance to	Urban walking and bike paths.

sunk investments, capabilities, embedding in routines/lifestyles.	initially often more expensive, but may benefit from learning curves and scale economies that drive costs down.	avoid rebound effects.	Stable and continuous electricity supply fostering induction stoves.

1

2 5.5 An integrative view on transitioning

3 5.5.1 Demand-side transitions as multi-dimensional processes

4 Several integrative frameworks including social practice theory (Røpke 2009; Shove and Walker 2014),
 5 the energy cultures framework (Stephenson et al. 2015; Jürisoo et al. 2019) and socio-technical
 6 transitions theory (McMeekin and Southerton 2012; Geels et al. 2017) conceptualise demand-side
 7 transitions as multi-dimensional and interacting processes (*high evidence, high agreement*). Social
 8 practice theory emphasises interactions between artefacts, competences, and cultural meanings (Røpke
 9 2009; Shove and Walker 2014)(Shove and Walker 2014; Røpke 2009). The energy cultures framework
 10 highlights feedbacks between materials, norms, and behavioural practices (Stephenson et al. 2015;
 11 Jürisoo et al. 2019). Socio-technical transitions theory addresses interactions between technologies, user
 12 practices, cultural meanings, business, infrastructures, and public policies (McMeekin and Southerton
 13 2012; Geels et al. 2017) and can thus accommodate the five drivers of change and stability discussed in
 14 Section 5.4.

15

16 Section 5.4 shows with *high evidence and high agreement* that the relative influence of different drivers
 17 varies between demand-side solutions. The deployment of ‘improve’ options like LEDs and clean
 18 cookstoves mostly involves technological change, adoption by consumers who integrate new
 19 technologies in their daily life practices (Smith et al. 1993; Sanderson and Simons 2014; Franceschini
 20 and Alkemade 2016), and some policy change. Changes in meanings are less pertinent for those
 21 ‘improve’-options that are primarily about technological substitution. Other improve-options, like clean
 22 cookstoves, involve both technological substitution and changes in cultural meanings and traditions.
 23 Deployment of ‘shift’ options like enhanced public transport involves substantial behavioural change
 24 and transitions to new or expanded provisioning systems, which may include new technologies (buses,
 25 trams), infrastructures (light rail, dedicated bus lanes), institutions (operational licenses, performance
 26 contracts), financial arrangements, and new organisations (with particular responsibilities and
 27 oversight) (*high evidence, high agreement*) (Deng and Nelson 2011; Turnheim and Geels 2019).
 28 Changes in cultural meanings can facilitate ‘shift’ options. Shifts towards low-meat diets, for instance,
 29 are motivated by costs and by beliefs about the undesirability of meat that relate more to issues like
 30 health, nutrition and animal welfare than climate change (De Boer et al. 2014; Mylan 2018).

31

32 ‘Avoid’ options that reduce service levels (e.g. sufficiency or downshifting) imply very substantial
 33 behavioural and cultural changes that may not resonate with mainstream consumers (Dubois et al.
 34 2019). Other ‘avoid’ options like tele-working also require changes in cultural meanings and beliefs
 35 (about the importance of supervision, coaching, social contacts, or office politics), as well as changes
 36 in behaviour, institutions, business, and technology (including good internet connections and office
 37 space at home). Because these interconnected changes were not widespread, tele-working remained
 38 stuck in small niches and did not diffuse widely before the COVID-19 crisis (Hynes 2014, 2016;
 39 Belzunegui-Eraso and Erro-Garcés 2020; Stiles 2020). As preferences change, new infrastructures and
 40 social settings can also elicit new desirabilities associated with emerging low-energy demand service
 41 provisioning systems (see 5.4.5).

1 Demand-side transitions involve interactions between radical social or technical innovations (such as
2 the avoid, shift, improve options discussed in Section 5.3) and existing socio-technical systems, energy
3 cultures, and social practices (*high evidence, high agreement*) (Stephenson et al. 2015; Geels et al.
4 2017). Radical innovations such as tele-working, plant-based burgers, car sharing, vegetarianism, or
5 electric vehicles initially emerge in small, peripheral niches (Kemp et al. 1998; Schot and Geels 2008),
6 constituted by R&D projects, technological demonstration projects (Borghei and Magnusson 2016;
7 Rosenbloom et al. 2018b), local community initiatives or grassroots projects by environmental activists
8 (Hargreaves et al. 2013a; Hossain 2016). Such niches offer protection from mainstream selection
9 pressures and nurture the development of radical innovations (Smith and Raven 2012). Many low-
10 carbon niche-innovations, such as those described in Section 5.3, face uphill struggles against existing
11 socio-technical systems, energy cultures, and social practices that are stabilised by multiple lock-in
12 mechanisms (*high evidence, high agreement*) (Klitkou et al. 2015; Seto et al. 2016; Clausen et al. 2017;
13 Ivanova et al. 2018). Demand-side transitions therefore do not happen easily and involve interacting
14 processes and struggles on the behavioural, socio-cultural, institutional, business and technological
15 dimensions (Nikas et al. 2020) (see also Section 5.4).

16 5.5.2 Phases in transitions

17 Transitions often take several decades, unfolding through several phases. Although there is variability
18 across innovations, sectors, and countries, the transitions literature distinguishes four phases,
19 characterised by generic core processes and challenges: 1) emergence, 2) early adaptation, 3) diffusion,
20 4) stabilisation (*high confidence*) (Rotmans et al. 2001; Markard et al. 2012; Geels et al. 2017) (Cross-
21 Chapter Box 12 in Chapter 16). These four phases do not imply that transitions are linear, teleological
22 processes, because set-backs or reversals may occur as a result of learning processes, conflicts, or
23 changing coalitions (*very high confidence*) (Geels and Raven 2006; Messner 2015; Davidescu et al.
24 2018). There is also no guarantee that technological, social, or business model innovations progress
25 beyond the first phase.

26
27
28 In the first phase, radical innovations emerge in peripheral niches, where researchers, inventors, social
29 movement organisations or community activists dedicate time and effort to their development (*high*
30 *confidence*) (Kemp et al. 1998; Schot and Geels 2008). Radical social, technical and business model
31 innovations are initially characterised by many uncertainties about technical performance, consumer
32 interest, institutions and cultural meanings. Learning processes are therefore essential and can be
33 stimulated through R&D, demonstration projects, local community initiatives or grassroots projects
34 (Borghei and Magnusson 2016; Hossain 2016; Rosenbloom et al. 2018b; van Mierlo and Beers 2020).
35 Typical challenges are fragmentation and high rates of project failure (den Hartog et al. 2018; Dana et
36 al. 2021), limited funding (Auerswald and Branscomb 2003), limited consumer interest, and socio-
37 cultural acceptance problems due to being perceived as strange or unfamiliar (Lounsbury and Glynn
38 2001).

39
40 In the second phase, social or technical innovations are appropriated or purchased by early adopters,
41 which increases visibility and may provide a small but steady flow of financial resources (*high evidence,*
42 *high agreement*) (Zimmerman and Zeitz 2002; Dewald and Truffer 2011). Learning processes,
43 knowledge sharing and codification activities help stabilise the innovation, leading to best practice
44 guidelines, standards, and formalised knowledge (*high evidence, high agreement*) (Raven et al. 2008;
45 Borghei and Magnusson 2018). User innovation may lead to the articulation of new routines and social
46 practices, often in tandem with the integration of new technologies into people's daily lives (Nielsen et
47 al. 2016; Schot et al. 2016). Radical innovations remain confined to niches in the second phase because
48 adoption is limited to small, dedicated groups (Schot et al. 2016), innovations are expensive or do not

1 appeal to wider groups, or because complementary infrastructure are missing (Markard and Hoffmann
2 2016).

3
4 In the third phase, radical innovations diffuse into wider communities and mainstream markets. Typical
5 drivers are performance improvements, cost reductions, widespread consumer interest, investments in
6 infrastructure and complementary technologies, institutional support and strong cultural appeal (*high*
7 *evidence, high agreement*) (Wilson 2012; Markard and Hoffmann 2016; Raven et al. 2017; Malone et
8 al. 2017; Kanger et al. 2019). The latter may be related to wider cultural shifts such as increased public
9 attention to climate change and new framings like ‘climate emergency’ which gained traction before
10 the Covid-19 pandemic (Bouman et al. 2020b). These concerns may not last, however, since public
11 attention typically follows cycles (Downs 1972; Djerf-Pierre 2012).

12
13 This phase often involves multiple struggles: economic competition between low-carbon innovations
14 and existing technologies and practices, business struggles between incumbents and new entrants
15 (Hockerts and Wüstenhagen 2010), cultural and framing struggles in public opinion arenas
16 (Kammermann and Dermont 2018; Rosenbloom 2018; Hess 2019a), and political struggles over
17 adjustments in policies and institutions, which shape markets and innovations (Meadowcroft 2011;
18 Roberts and Geels 2019). The lock-in mechanisms of existing practices and systems tend to weaken in
19 the third phase, either because competing innovations erode their economic viability, cultural legitimacy
20 or institutional support (Turnheim and Geels 2012; Roberts 2017; Kuokkanen et al. 2018; Leipprand
21 and Flachslund 2018) or because exogenous shocks and pressures disrupt the status quo (Kungl and
22 Geels 2018; Simpson 2019).

23
24 In the fourth phase, the diffusing innovations replace or substantially reconfigure existing practices and
25 systems, which may lead to the downfall or reorientation of incumbent firms (Bergek et al. 2013;
26 McMeekin et al. 2019). The new system becomes institutionalised and anchored in professional
27 standards, technical capabilities, infrastructures, educational programs, regulations and institutional
28 logics, user habits, and views of normality, which create new lock-ins (Galaskiewicz 1985; Shove and
29 Southerton 2000; Barnes et al. 2018)

30
31 Avoid, shift and improve options vary with regard to the four transition phases. Incremental ‘improve’
32 options, such as energy-efficient appliances or stand-alone insulation measures, are not transitions but
33 upgrades of existing technologies. They have progressed furthest since they build on existing
34 knowledge and do not require wider changes (Geels et al. 2018). Some radical ‘improve’ options, which
35 have a different technological knowledge base, are beginning to diffuse, moving from phase two to
36 three in multiple countries. Examples are electric vehicles, light-emitting diodes, or passive house
37 designs (Franceschini and Alkemade 2016; Berkeley et al. 2017). Many ‘shift’ and ‘avoid/reduce’
38 options like heat pumps, district heating, passive house designs, compact cities, less meat initiatives,
39 flight and car use reduction have low momentum in most countries, and are mostly in the first phase of
40 isolated initiatives and projects (Bergman 2013; Morris et al. 2014; Bows-Larkin 2015; Bush et al.
41 2016; Kivimaa and Martiskainen 2018; Hoolohan et al. 2018). Structural transitions in Dutch cities,
42 Copenhagen, and more recently Paris, however, demonstrate that transitions towards low-carbon
43 lifestyles, developed around cycling, are possible (Colville-Andersen 2018). Low-carbon demand-side
44 transitions are often still in early phases (*high evidence, high agreement*).

45 46 **5.5.3 Feasible rate of change**

47 Transitional change is usually slow in the first and second transition phase, because experimentation,
48 social and technological learning, and stabilisation processes take a long time, often decades, and
49 remain restricted to small niches (*high confidence*) (Wilson 2012; Bento 2013; Bento et al. 2018b).

1 Transitional change accelerates in the third phase, as radical innovations diffuse from initial niches into
2 mainstream markets, propelled by the self-reinforcing mechanisms, discussed above. The rate of
3 adoption (diffusion) of new practices, processes, artefacts, and behaviours is determined by a wide
4 range of factors at the macro- and micro-scales, which have been identified by several decades of
5 diffusion research in multiple disciplines (for comprehensive reviews see, e.g. (Mansfield 1968;
6 Martino et al. 1978; Davis 1979; Mahajan et al. 1990; Ausubel 1991; Grubler 1991; Feder and Umali
7 1993; Bayus 1994; Comin and Hobijn 2003; Rogers 2003; Van den Bulte and Stremersch 2004; Meade
8 and Islam 2006; Peres et al. 2010)).

9
10 Diffusion rates are determined by two broad categories of variables, those intrinsic to the
11 technology/product/practice under consideration (typically performance, costs, benefits), and those
12 intrinsic to the adoption environment (e.g., socio-economic and market characteristics).

13 Despite differences, the literature offers three robust conclusions on acceleration (*high evidence, high*
14 *agreement*): First, size matters. Acceleration of transitions is more difficult for social, economic, or
15 technological systems of larger size (in terms of number of users, financial investments, infrastructure,
16 powerful industries) (Wilson 2009, Wilson 2012). Size also matters at the level of the systems
17 component involved in a transition. Components with smaller unit-scale (“granular” and thus relatively
18 cheap), such as light bulbs or household appliances, turn over much faster (often within a decade) than
19 large-scale, capital-intensive lumpy technologies and infrastructures (such as transport systems) where
20 rates of change involve typically several decades, even up to a century (Grubler 1991; Leibowicz 2018).
21 Also, the creation of entirely new systems (diffusion) takes longer time than replacements of existing
22 technologies/practices (substitution) (Grubler et al. 1999); and late adopters tend to adopt faster than
23 early pioneers (Wilson 2012; Grubler 1996).

24
25 Arguments about scale in the energy system date back at least to the 1970s when Schumacher, Lovins
26 and others argued the case for smaller-scale, distributed technologies (Schumacher 1974; Lovins 1976,
27 1979). In 'Small is Profitable' Lovins and colleagues evidenced over 200 reasons why decentralised
28 energy resources, from distributed generation to end-use efficiency, made good business sense in
29 addition to their social, human-centred benefits (Lovins et al. 2003). More recent advances in digital,
30 solar and energy storage technologies have renewed technical and economic arguments in favour of
31 adopting decentralised approaches to decarbonisation (Cook et al. 2016; Jain et al. 2017; Lovins et al.
32 2018). Smaller-scale technologies from microprocessors to solar panels show dramatically faster cost
33 and performance improvement trajectories than large-scale energy supply facilities (Trancik 2014;
34 Sweerts et al. 2020, Creutzig et al, 2021, Fig. 5.15). Analysing the performance of over 80 energy
35 technologies historically, Wilson et al. (2020) found that smaller scale, more ‘granular’ technologies
36 are empirically associated with faster diffusion, lower investment risk, faster learning, more
37 opportunities to escape lock-in, more equitable access, more job creation, and higher social returns on
38 innovation investment. These advantages of more granular technologies are consistent with accelerated
39 low-carbon transformation (Wilson et al. 2020a).

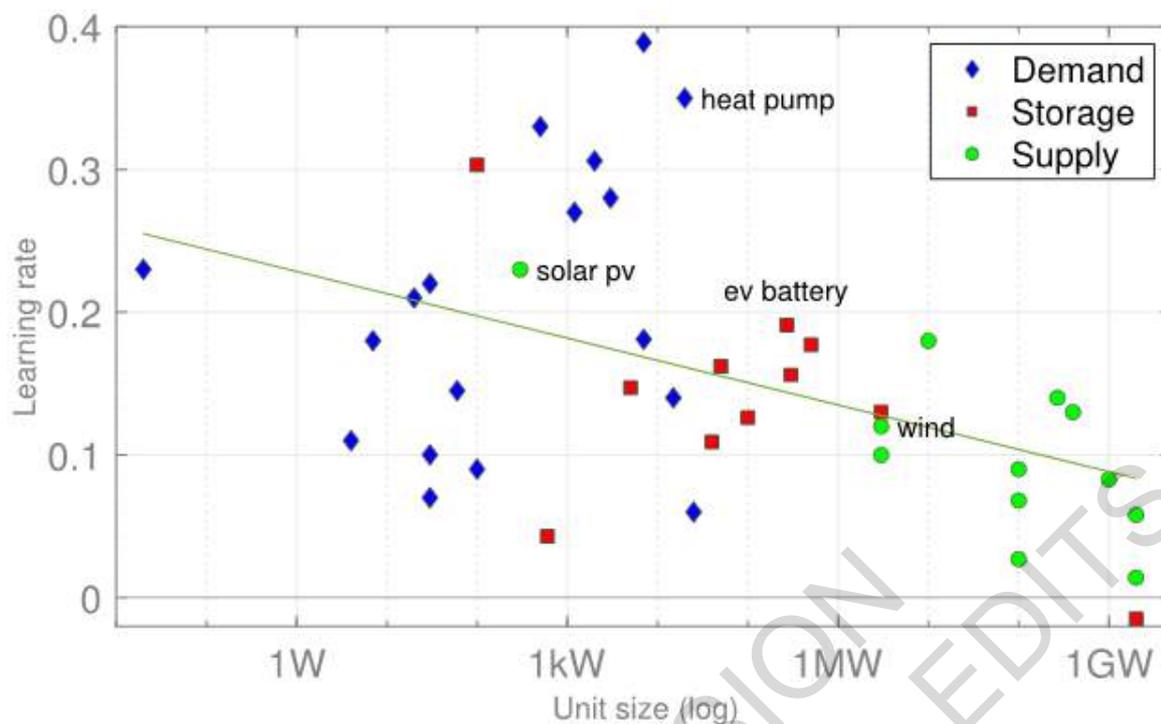

Figure 5.15 Demand technologies show high learning rates. Learning from small-scale granular technologies outperforms learning in larger supply side technologies. Line is linear fit of log unit size to learning rate for all 41 technologies plotted.

Source: Creutzig et al, 2021; based on Sweerts et al 2020.

Second, complexity matters, which is often related to unit-scale (Ma et al. 2008). Acceleration is more difficult for options with higher degrees of complexity (e.g., carbon capture, transport and storage, or a hydrogen economy) representing higher technological and investment risks that can slow down change. Options with lower complexity are easier to accelerate because they involve less experimentation and debugging and require less adoption efforts and risk.

Third, agency, structure and meaning can accelerate transitions. The creation and mobilisation of actor coalitions is widely seen as important for acceleration, especially if these involve actors with technical skills, financial resources and political capital (Kern and Rogge 2016; Hess 2019b; Roberts and Geels 2019). Changes in policies and institutions can also accelerate transitions, especially if these create stable and attractive financial incentives or introduce technology-forcing standards or regulations (Brand et al. 2013; Kester et al. 2018; Roberts et al. 2018). Changes in meanings and cultural norms can also accelerate transitions, especially when they affect consumer practices, enhance social acceptance, and create legitimacy for stronger policy support (Lounsbury and Glynn 2001; Rogers 2003; Buschmann and Oels 2019). Adoption of most advanced practices can support leapfrogging polluting technologies (Box 5.9).

START BOX 5.9 HERE

Box 5.9 Is leapfrogging possible?

The concept of leapfrogging emerged in development economics (Soete 1985), energy policy (Goldemberg 1991) and environmental regulation (Perkins 2003), which provides a first critical review of the concept), and refers to a development strategy that skips traditional and polluting development

1 in favour of the most advanced concepts. For instance, in rural areas without telephone landlines or
2 electricity access (cables), a direct shift to mobile telephony or distributed, locally-sourced energy
3 systems is promoted, or economic development policies for pre-industrial economies forego the
4 traditional initial emphasis of heavy industry industrialisation, instead of focusing on services like
5 finance or tourism. Often leapfrogging is enabled by learning and innovation externalities where
6 improved knowledge and technologies become available for late adopters at low costs. The literature
7 highlights many cases of successful leapfrogging but also highlights limitations (for a review see
8 Watson and Sauter (Watson and Sauter 2011); with example case studies for China e.g. Gallagher
9 (Gallagher 2006) or Chen and Li-Hua (Chen and Li-Hua 2011); Mexico (Gallagher and Zarsky 2007);
10 or Japan and Korea, e.g. Cho et al. (Cho et al. 1998). Increasingly the concept is being integrated into
11 the literature of low-carbon development, including innovation and technology transfer policies (for a
12 review see Pigato (Pigato et al. 2020)), highlighting in particular the importance of contextual factors
13 of successful technology transfer and leapfrogging including: domestic absorptive capacity and
14 technological capabilities (Cirera and Maloney 2017); human capital, skills, and relevant technical
15 know-how (Nelson and Phelps 1966); the size of the market (Keller 2004); greater openness to trade
16 (Sachs and Warner 1995; Keller 2004); geographical proximity to investors and financing (Comin et
17 al. 2012); environmental regulatory proximity (Dechezleprêtre et al. 2015); and stronger protection
18 of intellectual property rights (Dechezleprêtre et al. 2013; Dussaux et al. 2017). The existence of a
19 technological potential for leapfrogging therefore needs to be considered within a wider context of
20 social, institutional, and economic factors that influence if leapfrogging potentials can be realised (*high*
21 *evidence, high agreement*).

22 **END BOX 5.9 HERE**

23 There are also some contentious topics in the debate on accelerated low-carbon transitions. First, while
24 acceleration is desirable to mitigate climate change, there is a risk that accelerating change too much
25 may short-cut crucial experimentation and social and technological learning in “formative phases”
26 (Bento 2013; Bento et al. 2018b) and potentially lead to a pre-mature lock-in of solutions that later turn
27 out to have negative impacts (Cowan 1990, 1991) (*high evidence, medium agreement*).

28
29 Second, there is an ongoing debate about the most powerful leverage points and policies for speeding
30 up change in social and technological systems. Farmer et al. 2019 suggested “sensitive intervention
31 points” for low-carbon transitions, but do not quantify the impacts on transformations. Grubler et al.
32 2018 proposed an end-user and efficiency-focused strategy to achieve rapid emission reductions and
33 quantified their scenario with a leading IAM. However, discussion of the policy implications of such a
34 strategy have only just started (Wilson et al. 2019a) suggesting an important area for future research.
35 The last contentious issue is if policies can/should substitute for lack of economic/social appeal of
36 change or for technological risks. Many large-scale supply-side climate mitigation options such as CCS
37 or nuclear power involve high technological risks, critically depend on a stable carbon price, and are
38 controversial in terms of social and environmental impacts (cf. the reviews in (Sovacool et al. 2014;
39 Wilson et al. 2020a) and the comprehensive discussion in (Smith et al. 2016) (*high evidence, medium*
40 *agreement*). There is continuing debate if and how policies could counterbalance these impacts in order
41 to accelerate transitions (Nordhaus 2019; Lovins 2015). Some demand-side options like large-scale
42 public transport infrastructures such as “Hyperloop” (Decker et al. 2017) or concepts such as “Asian
43 Super Grid” (maglev fast train coupled with superconducting electricity transmission networks) (AIGC
44 2017) may face similar challenges, which adds weight and robustness to those demand-side options that
45 are more decentralised, granular in scale and provide potential tangible consumer benefits besides being
46 low-carbon (like more efficient buildings and appliances, “soft” urban mobility options (walking and
47 cycling), digitalisation, among others, cf. Grubler et al. 2018).

48

1 A robust conclusion from this review is that there are no generic acceleration policies that are
2 independent from the nature of what changes, by whom and how. Greater contextualisation and
3 granularity in policy approaches is therefore important to address the challenges of rapid transitions
4 towards zero-carbon systems (*high evidence, high agreement*).

5.6 Governance and policy

5.6.1 Governing mitigation: participation and social trust

9 In demand side mitigation, governance is key to drive the multidimensional changes needed to meet
10 service needs within a society that provide people with a decent living while increasingly reducing
11 resource and energy input levels (Rojas-Rueda et al. 2012; Batchelor et al. 2018; OECD 2019a).
12 Impartial governance, understood as equal treatment of everyone by the rule of law, creates social trust
13 and is thus a key enabler of inclusive and participatory demand-side climate policies (Rothstein 2011).
14 Inclusive and broad-based participation itself also leads to greater social trust and thus is also a key
15 enabler of demand-side climate mitigation (see Section 5.2 for details). Higher social trust and inclusive
16 participatory processes also reduce inequality, restrain opportunistic behaviour and enhance
17 cooperation (Drews and van den Bergh 2016; Gür 2020) (see also Section 5.2). Altogether, broad-based
18 participatory processes are central to the successful implementation of climate policies (Rothstein and
19 Teorell 2008; Klenert et al. 2018) (*high evidence, medium agreement*). A culture of cooperation feeds
20 back to increase social trust and enables action that reduce GHG emissions (Carattini et al. 2015; Jo and
21 Carattini 2021), and requires including explicit consideration of the informal sector (Box 5.10). More
22 equitable societies also have the institutional flexibility to allow for mitigation to advance faster, given
23 their readiness to adopt locally appropriate mitigation policies; they also suffer less from policy lock-in
24 (Tanner et al. 2009; Lorenz 2013; Chu 2015; Cloutier et al. 2015; Martin 2016; Vandeweerd et al.
25 2016; Turnheim et al. 2018; Seto et al. 2016).

START BOX 5.10 HERE

Box 5.10 The informal sector and climate mitigation

30 The informal economy represents a large and growing portion of socio-economic activities (Charmes
31 2016; Muchie et al. 2016; Mbaye and Gueye 2018), including much of the work done by women
32 worldwide. It accounts for an estimated 61% of global employment in the world; 90% in developing
33 countries, 67% in emerging countries, and 18% in developed countries (Berik 2018), representing
34 roughly 30% of GDP across a range of countries (Durán Heras 2012; Narayan 2017). Due to its
35 importance, policies which support informal-sector climate mitigation activities may be extremely
36 efficient (Garland and Allison M. 2015). For example, environmental and energy taxes may have
37 negative gross costs when the informal sector dominates economic activity since these taxes indirectly
38 tax the informal sector; informal production may substitute for energy-intensive goods, with strong
39 welfare-enhancing effects (Bento et al. 2018a). The informal sector can assemble social and financial
40 capital, create jobs, and build low-carbon local economies (Ruzek 2015). Constraints on small and
41 informal-sector firms' ability to build climate resilience include financial and data barriers, limited
42 access to information technology, and policy exclusion (Kraemer-Mbula and Wunsch-Vincent 2016;
43 Crick et al. 2018a,b).

45 Informal-sector innovation is often underrated. It gives marginalised people access to welfare-
46 enhancing innovations, building on alternative knowledge and socially-embedded reciprocal exchange
47 (Jaffe and Koster 2019; Sheikh 2019; Sheikh and Bhaduri 2020). Large improvements in low-emission,
48 locally-appropriate service provision are possible by facilitating informal-sector service providers'

1 access to low-energy technologies (while taking care not to additionally burden the unpaid and
2 marginalised), through such means as education, participatory governance, government policies to
3 assist the informal sector, social services, healthcare, credit provision, and removing harmful policies
4 and regulatory silos. The importance of the informal economy, especially in low-income countries,
5 opens many possibilities for new approaches to DLS service provision along with climate resilience
6 (Rynkiewicz and Chetaille 2006; Backstränd et al. 2010; Porio 2011; Kriegler et al. 2014; Taylor and
7 Peter 2014; Brown and McGranahan 2016; Chu 2016; Boran 2019; Hugo and du Plessis 2019;
8 Satterthwaite et al. 2018; Schröder et al. 2019; Javaid et al. 2020).

9
10 Public information and understanding of the CO₂-eq emissions implied by consumption patterns can
11 unleash great creativity for meeting service needs fairly and with lower emissions (Darier and Schüle
12 1999; Serman and Sweeney 2002; Lorenzoni et al. 2007; Billett 2010; Marres 2011; Zapico Lamela et
13 al. 2011; Polonsky et al. 2012; Williams et al. 2019). Community-based mapping, social learning, green
14 infrastructure development, and participatory governance facilitate such information-sharing (Tauhid
15 and Zawani 2018; Mazeka et al. 2019; Sharifi 2020), strengthening mitigation policies (Loiter et al.
16 1999; Stokes and Warshaw 2017; Zhou et al. 2019).

17
18 Since informal settlements are usually dense, upgrading them supports low-carbon development
19 pathways which leapfrog less-efficient housing, transport and other service provision, using locally-
20 appropriate innovations (Satterthwaite et al. 2018). Examples of informal-sector mitigation include
21 digital banking in Africa; mobility in India using recycled motors and collective transport; food
22 production, meal provision, and reduction of food waste in Latin America (e.g. soup kitchens in Brazil,
23 community kitchens in Lima, Peru); informal materials recycling, space heating and cooling, and
24 illumination (Hordijk 2000; Baldez 2003; Maumbe 2006; Gutberlet 2008; Chaturvedi and Gidwani
25 2011; Nandy et al. 2015; Rouse and Verhoef 2016; Ackah 2017).

26
27 **END BOX 5.10 HERE**

28 29 **5.6.2 Policies to strengthen Avoid-Shift-Improve**

30 There is high untapped potential of demand-side mitigation options if considered holistically within the
31 domains of avoid-shift-improve (Sections 5.3 and 5.4; Tables 5.1, 5.2, 5.3a, and 5.3b). Within the
32 demand-side mitigation options opportunity space, policies currently focus more on efficiency and
33 ‘improve’ options and relatively less on ‘shift’ and ‘avoid’ options (Dubois et al. 2019; Moberg et al.
34 2019). Current demand side policies are fragmented, piecemeal and too weak to drive demand-side
35 transitions commensurate with 1.5°C or 2°C climate goals (Wilson et al. 2012; Fawcett et al. 2019;
36 Mundaca et al. 2019; Moberg et al. 2019) (*high evidence, high agreement*). However, increasingly
37 policy mix in a number of countries has seen a rise in prohibitions on fossil fuel use as a way to weaken
38 lock-ins, for example, in fossil fuel heating in favour of low carbon alternatives (Rosenbloom et al.
39 2020). Policies that are aimed at behaviour and lifestyle changes carry a perception of political risks
40 for policy makers, which may explain why policy instruments focus more on information provision and
41 adoption of incentives than on regulation and investment (Rosenow et al. 2017; Moberg et al. 2019).
42 Acceleration of demand-side transitions would thus require both a broadening of demand-side options
43 and the creation of comprehensive and targeted policy mixes (Kern et al. 2017; Rosenow et al. 2017;
44 IPCC 2018) that strengthens five drivers of decision and action identified in Section 5.4, Table 5. and
45 in the tables below (*high evidence, high agreement*). Demand-side transitions in developing and
46 emerging economies would also require stronger administrative capacity as well as technical and
47 financial support (UN-Habitat 2013; Creutzig et al. 2016b).

1 Systematic categorisation of demand-side policy options in different sectors and services through the
2 avoid-shift-improve (ASI) framework enables identification of major entry points and possible
3 associated social struggles to overcome for the policy instruments/interventions as discussed below.

4 5 **5.6.2.1 Avoid policies**

6 There is high evidence and agreement that “Avoid” policies that affect lifestyle changes offer
7 opportunities for cost-effective reductions in energy use and emissions, but would need to overcome
8 political sensitivities around government efforts to shape and modify individual-level behaviour (see
9 Table 5.5) (Grubb et al. 2020; Rosenow et al. 2017). These policies include ways to help avoid travel
10 growth through integrated city planning or building retrofits to help avoid demand for transport, heating
11 or cooling (Bakker et al. 2014; Lucon et al. 2014; de Feijter et al. 2019), which interact with existing
12 infrastructure. Dense pedestrianised cities and towns and medium-density transit corridors are better
13 placed to implement policies for car reductions than ‘sprawled’ cities characterised by low-density,
14 auto-dependent and separated land uses (Seto et al. 2014; Newman and Kenworthy 2015; Newman et
15 al. 2017; Bakker et al. 2014).

16
17 Cities face pressing priorities like poverty reduction, meeting basic services and building human and
18 institutional capacity. These are met with highly accessible walkable and cyclable cities, connected with
19 public transit corridors, enabling equal accessibility for all citizens, and enabling a high level of service
20 provisioning (UN-Habitat 2013; Creutzig et al. 2016b). Infrastructure development costs less than for
21 car dependent cities. However, it requires a mindset shift for urban and transport planners (*medium
22 evidence, high agreement*).

23
24 Policies that support the avoidance of higher emission lifestyles and improve wellbeing are facilitated
25 by the introduction of smart technologies, infrastructures and practices (Amini et al. 2019). They
26 include regulations and measures for investment in high-quality ICT infrastructure, regulations to
27 restrict number plates as well as company policy around flexible working conditions (Lachapelle et al.
28 2018; Shabanpour et al. 2018). Working-from-home arrangements may advantage certain segments of
29 society such as male, older, higher educated and highly paid employees, potentially exacerbating
30 existing inequalities in the labour market (Lambert et al. 2020; Bonacini et al. 2021). In the absence of
31 distributive or other equity-based measures, the potential gains in terms of emissions reduction may
32 therefore be counteracted by the cost of increasing inequality. This potential growth in inequality is
33 likely to be more severe in poorer countries that will additionally suffer from a lack of international
34 funding for achieving the SDGs (Barbier and Burgess 2020; UN 2020) (*high evidence, medium
35 agreement*).

36
37 **Table 5.5 Examples of policies to enable “avoid” options**

Mitigation Option	Perceived struggles to overcome	Policy to overcome struggles (Incentives)
Reduce passenger km	Overcoming existing paradigms and planning practices and car dependency (Rosenow et al. 2017; Grubb et al. 2020).	Integrated city planning to avoid travel growth, car reduction, building retrofits to avoid heating or cooling demand (Bakker et al. 2014; Lucon et al. 2014; de Feijter et al. 2019).
	Financial and capacity barrier in many developing countries.	Public-private partnership to overcome financial barrier. (see Box 5.7) (Roy et al. 2018b).
	Status dimension of private cars	Taxation of status consumption; reframing of low-carbon transport as high status (Hoor 2020; Ramakrishnan and Creutzig 2021).

Reduce/avoid food waste	Little visible political and social momentum to prevent food waste in the Global North.	Strengthen national nutrition guidelines for health safety, Improve education/awareness on food waste; policies to eliminate ambiguous food labelling include well-defined and clear date labelling systems for food (Wilson et al. 2017); policies to support R&D to improve packaging to extend shelf life (Thyberg and Tonjes 2016). Charging according to how much food households throw away.
Reduce size of dwellings	Size of residents/dwelling getting smaller in many countries.	Compact city design, taxing residential properties with high per capita area, progressive taxation of high status consumption (Ramakrishnan and Creutzig 2021).
Reduce/avoid heating, cooling and lighting in dwellings	Change in individual behaviour in dress codes and working times	Temperature set point as norm; building energy codes that set building standards; bioclimatic or/and zero emissions; cities and buildings that incorporate features like daylighting and increased building depth, height, and compactness (Steemers 2003; Creutzig et al. 2016a).
Sharing economy for more service per product	Inclusivity and involvement of users in design. Digital divide, unequal access and unequal digital literacy (Pouri and Hilty 2018). Political or power relations among actors involved in the sharing economy (Curtis and Lehner 2019).	Lower prices for public parking, and subsidies towards the purchase of electric vehicles providers of electric vehicle (EV) sharing services were given subsidies towards the purchase of electric vehicles (Jung and Koo 2018).

5.6.2.2 *Shift policies*

As indicated in Table 5.6, ‘Shift’ policies have various forms such as the demand for low carbon materials for buildings and infrastructure in manufacturing and services and shift from meat-based protein, mainly beef, to plant-based diets of other protein sources (Willett et al. 2019; Ritchie et al. 2018; Springmann et al. 2016a) (*high evidence, high agreement*). Governments also play a direct role beyond nudging citizens with information about health and wellbeing. While the effectiveness of these policies on behaviour change overall may be limited (Pearson-Stuttard et al. 2017; Shangguan et al. 2019), there is some room for policy to influence actors upstream, i.e. industry and supermarkets which may give rise to longer-term, structural change.

Table 5.6 Examples of policies to enable “shift” options

Mitigation Option	Perceived struggles to overcome	Policy to overcome struggles (Incentives)
More walking, less car use, train rather air travel	Adequate infrastructure may be absent, speed a part of modern life.	Congestion charges (Pearson-Stuttard et al. 2017; Shangguan et al. 2019); deliberate urban design including cycling lanes, shared micromobility, and extensive cycling infrastructure; synchronised/integrated transport system & timetable . Fair street space allocation (Creutzig et al. 2020).

Multifamily housing,	Zonings that favour single family homes have been dominant in planning (Hagen 2016).	Taxation, relaxation of single-family zoning policies and land use regulation (Geffner 2017).
Shifting from meat to other protein	Minimal meat required for protein intake, especially in developing countries for population suffering from malnutrition and when plant-based protein is lacking (Garnett 2011; Sunguya et al. 2014; Behrens et al. 2017; Godfray et al. 2018); Dominance of market-based instruments limits governments' role to nudging citizens with information about health and wellbeing, and point-of-purchase labelling (Pearson-Stuttard et al. 2017; Shangquan et al. 2019).	Tax on meat/beef in wealthier countries and/or households (Edjabou and Smed 2013; Säll and Gren 2015). Nationally recommended diets (NRDs) (Behrens et al. 2017; Garnett 2011; Sunguya et al. 2014; Godfray et al. 2018).
Material-efficient product design, packaging	Resistance by architects and builders who might perceive risks with lean designs. Cultural/ social norms. Policy measures not keeping up with changes on the ground such as increased consumption of packaging.	Embodied carbon standards for buildings (IEA 2019c).
Architectural design with shading and ventilation	Lack of education, awareness and capacity for new thinking, local air pollution.	Incentives for increased urban density and incentives to encourage architectural forms with lower surface-to-volume ratios and increased shading support (Creutzig et al. 2016a).

1
2 Mobility services is one of the key areas where a combination of market-based and command-and-
3 control measures have been implemented to persuade large numbers of people to get out of their
4 automobiles and take up public transport and cycling alternatives (Gehl et al. 2011). Congestion charges
5 are often complemented by other measures such as company subsidies for bicycles to incentivise the
6 shift to public mobility services. Attracting people to public transport requires sufficient spatial
7 coverage of transport with adequate level of provision, and good quality service at affordable fares
8 (Sims et al. 2014; Moberg et al. 2019) (*high evidence, high agreement*). Cities such as Bogota, Buenos
9 Aires and Santiago have seen rapid growth of cycling, resulting in an 6-fold of cyclists (Pucher and
10 Buehler 2017). Broadly, the history and type of city determines how quickly the transition to public
11 modes of transport can be achieved. For example, cities in developed countries enjoy an advantage in
12 that network of high-quality public transport predating the advent of automobiles, whereas cities in less
13 developed countries are latecomers in large-scale network infrastructure (Gota et al. 2019; UN-Habitat
14 2013).

15 16 **5.6.2.3 Improve policies**

17 'Improve' policies focus on the efficiency and enhancement of technological performance of services
18 (Table). In mobility services, 'improve' policies aim at improving vehicles, comfort, fuels, transport
19 operations and management technologies; and in building, they include policies for improving
20 efficiency of heating systems and retrofitting existing buildings. Efficiency *improvements* in electric
21 cooking appliances, together with the ongoing decrease in prices of renewable energy technologies, is
22 opening policy opportunities to support households to adopt electrical cooking at mass scale (IEA
23 2017c; Puzzolo et al. 2019) (*medium evidence, medium agreement*). These actions towards cleaner
24 energy for cooking often come with cooking-related reduction of GHG emissions, even though the

1 extent of the reductions is highly dependent on context and technology and fuel pathways (Martínez et
 2 al. 2017; Mondal et al. 2018; Rosenthal et al. 2018; Serrano-Medrano et al. 2018; Hof et al. 2019) (*high*
 3 *evidence, high agreement*) (see Box 5.6).

4
5

Table 5.7 Examples of policies to enable “improve” options

Mitigation Option	Perceived struggles to overcome	Policy to overcome struggles (Incentives)
Lightweight vehicle, hydrogen car, electric vehicles, ecodriving	Adequate infrastructure may be absent, speed a part of modern life.	Monetary incentives and traffic regulations favouring EVs; investment in public charging infrastructure; car purchase tax calculated by a combination of weight, CO ₂ and NO _x emissions (Haugneland and Kvisle 2015; Globisch et al. 2018; Gnann et al. 2018; Lieven and Rietmann 2018; Rietmann and Lieven 2019).
Use low carbon materials in dwelling design	Manufacturing and R&D costs, recycling processes and aesthetic performance (Orsini and Marrone 2019). Access to secondary materials in the building sector (Nußholz et al. 2019).	Increasing recycling of construction and demolition waste; Incentives must be available to companies in the waste collection and recovery markets to offer recovered material at higher value (Nußholz et al. 2019).
Better insulation and retrofitting	Policies to advance retrofitting and GHG emission reductions in buildings are laden with high expectations since they are core components of politically ambitious city climate targets (Haug et al. 2010). Bringing building owners to implement measures identified in auditing results Lack of incentive for building owners to invest in higher efficiency than required norms (Trencher et al. 2016).	Grants and loans through Development Banks, building and heating system labels, and technical renovation requirements to continuously raise standards (Ortiz et al. 2019; Sebi et al. 2019); disclosure of energy use, financing and technical assistance (Sebi et al. 2019).
Widen low carbon energy access	Access to finance, capacity, robust policies, affordability for poor households for off-grid solutions until recently (Rolffs et al. 2015; Fuso Nerini et al. 2018; Mulugetta et al. 2019).	Feed-in-tariffs and auctions to stimulate investment. Pay-as-you-go (PAYG) end-user financing scheme where customers pay a small up-front fee for the equipment, followed by monthly payments, using mobile payment system (Yadav et al. 2019; Rolffs et al. 2015).
Improve illumination related emission	Supply side solution for low carbon electricity provision.	Building energy codes that set building standards; grants and other incentives for R&D.
Improve efficiency of cooking appliances	Reliability of power in many countries is not guaranteed; electricity tariff is high in many countries; cooking appliances are mostly imported using scarce foreign currency.	Driven by a combination of government support for appliance purchases, shifting subsidies from kerosene or LPG to electricity; community-level consultation and awareness campaigns about the hazards associated with indoor air pollution from the use of fuelwood, coal and kerosene, as well as education on the

		multiple benefits of electric cooking (Yangka and Diesendorf 2016; Martínez-Gómez et al. 2016; Gould and Urpelainen 2018; Dendup and Arimura 2019; Pattanayak et al. 2019; Martínez et al. 2017).
Shift to LED lamp	People spend increasing amounts of time indoors, with heavy dependence on and demand for artificial lighting environment (Ding et al. 2020).	Government Incentive, utility incentive (Bertoldi et al. 2021). EU bans on directional and non-directional halogen bulbs (Franceschini et al. 2018).
Solar water heating	Dominance of incumbent energy source i.e. electricity; cheap conventional energy; high initial investment costs and long payback (Joubert et al. 2016).	Subsidy for solar heaters (Li et al. 2013; Bessa and Prado 2015; Sgouridis et al. 2016).

1
2 Table 5.7 highlights the significant progress made in the uptake of the Electrical Vehicle (EV) in
3 Europe, driven by a suite of incentives and policies. Increased activity in widening Electric Vehicle
4 (EV) use is also occurring in developing countries. The Indian Government's proposal to reach the
5 target of a 100% electric vehicle fleet by 2030 has stimulated investment in charging infrastructure that
6 can facilitate diffusion of larger EVs (Dhar et al. 2017). Although the proposal was not converted into
7 a policy, India's large and growing two-wheeler market has benefitted from the policy attention on EVs ,
8 showing a significant potential for increasing the share of electric two- and three-wheelers in the short-
9 term (Ahmad and Creutzig 2019). Similar opportunities exist for China where e-bikes have replaced
10 car trips and are reported to act as intermediate links in multimodal mobility (Cherry et al. 2016).

11
12 In recent years, policy interest has arisen to address the energy access challenge in Africa using low-
13 carbon energy technologies to meet energy for poverty reduction and climate action simultaneously
14 (Rolffs et al. 2015; Fuso Nerini et al. 2018; Mulugetta et al. 2019). This aspiration has been bolstered
15 on the technical front by significant advances in appliance efficiency such as light-emitting diode (LED)
16 technology, complemented by the sharp reduction in the cost of renewable energy technologies, and
17 largely driven by market stimulating policies and public R&D to mitigate risks (Alstone et al. 2015;
18 Zubi et al. 2019) (*high evidence, high agreement*).

19 20 **5.6.3 Policies in transition phases**

21 Demand-side policies tend to vary for different transition phases (*high evidence, high agreement*)
22 (Sandin et al. 2019; Roberts and Geels 2019). In the first phase, which is characterised by the emergence
23 or introduction of radical innovations in small niches, policies focus on: a) supporting R&D and
24 demonstration projects to enable learning and capability developments, b) nurturing the building of
25 networks and multi-stakeholder interactions, and c) providing future orientation through visions or
26 targets (Brown et al. 2003; López-García et al. 2019; Roesler and Hassler 2019). In the second phase,
27 the policy emphasis shifts towards upscaling of experiments, standardisation, cost reduction, and the
28 creation of early market niches (Ruggiero et al. 2018; Borghei and Magnusson 2018). In the third and
29 later phases, comprehensive policy mixes are used to stimulate mass adoption, infrastructure creation,
30 social acceptance and business investment (Fichter and Clausen 2016; Strauch 2020; Geels et al. 2018).
31 In the fourth phases, transitions can also be stimulated through policies that weaken or phase-out
32 existing regimes such as removing inefficient subsidies (for cheap petrol or fuel oil) that encourage
33 wasteful consumption, increasing taxes on carbon-intensive products and practices (Box 5.11), or

1 substantially tightening regulations and standards (Kivimaa and Kern 2016; David 2017; Rogge and
2 Johnstone 2017).

3 **START BOX 5.11 HERE**

4

5

Box 5.11: Carbon pricing and fairness

6

7 Whether the public supports specific policy instruments for reducing greenhouse gas emissions is
8 determined by cultural and political world views (Alberini et al. 2018; Cherry et al. 2017; Kotchen et
9 al. 2017) and national position in international climate negotiations with major implications for policy
10 design. For example, policy proposals need to circumvent "solution aversion": that is, individuals are
11 more doubtful about the urgency of climate change mitigation if the proposed policy contradicts their
12 political worldviews (Campbell and Kay 2014). While there are reasons to believe that carbon pricing
13 is the most efficient way to reduce emissions, a recent literature – focusing on populations in Western
14 Europe and North America and carbon taxes – documents that efficiency feature alone is not what
15 makes citizens like or dislike carbon pricing schemes (Kallbekken et al. 2011; Carattini et al. 2017;
16 Klenert et al. 2018).

17

18 Citizens tend to ignore or doubt the idea that pricing carbon emissions reduces GHG emissions
19 (Kallbekken et al. 2011; Douenne and Fabre 2019; Maestre-Andrés et al. 2019). Further, citizens have
20 fairness concerns about carbon pricing (Büchs and Schnepf 2013; Douenne and Fabre 2019; Maestre-
21 Andrés et al. 2019), even if higher carbon prices can be made progressive by suitable use of revenues
22 (Rausch et al. 2011; Williams et al. 2015; Klenert and Mattauch 2016). There are also non-economic
23 properties of policy instruments that matter for public support: Calling a carbon price a "CO₂ levy"
24 alleviates solution aversion (Kallbekken et al. 2011; Carattini et al. 2017). It may be that the word "tax"
25 evokes a feeling of distrust in government and may have high costs, low benefits and distributional
26 effects (Strand 2020). Trust in politicians is negatively correlated with higher carbon prices (Hammar
27 and Jagers 2006; Rafaty 2018) and political campaigns for a carbon tax can lower public support for
28 them (Anderson et al. 2019). Few developing countries have adopted carbon taxes, probably due to high
29 costs, relatively low benefits, and distributional effects (Strand 2020).

30

31 To address these realities regarding support for carbon pricing, some studies have examined whether
32 specific uses of the revenue can increase public support for higher carbon prices (Carattini et al. 2017;
33 Beiser-McGrath and Bernauer 2019). Doubt about the environmental effectiveness of carbon pricing
34 may be alleviated if revenue from carbon pricing is earmarked for specific uses (Kallbekken et al. 2011;
35 Carattini et al. 2017) and higher carbon prices may then be supported (Beiser-McGrath and Bernauer
36 2019). This is especially the case for using the proceeds on "green investment" in infrastructure or
37 energy efficiency programmes (Kotchen et al. 2017). Further, returning the revenues to individuals in
38 a salient manner may increase public support and alleviate fairness proposals, given sufficient
39 information (Carattini et al. 2017; Klenert et al. 2018). Perceived fairness is one of the strongest
40 predictors of policy support (Jagers et al. 2010; Whittle et al. 2019).

41

42 **END BOX 5.11 HERE**

43 **5.6.4 Policy sequencing and packaging to strengthen enabling conditions**

44 Policy coordination is critical to manage infrastructure interdependence across sectors, and to avoid
45 trade-off effects (Raven and Verbong 2007; Hiteva and Watson 2019), specifically requiring the
46 consideration of interactions among supply-side and demand-side measures (Kivimaa and Virkamäki
47 2014; Rogge and Reichardt 2016; de Coninck et al. 2018; Edmondson et al. 2019) (*high evidence, high*

1 *agreement*). For example, the amount of electricity required for cooking can overwhelm the grid which
2 can lead to failure, causing end-users to shift back to traditional biomass or fossil fuels (Ateba et al.
3 2018; Israel-Akinbo et al. 2018); thus grid stability policies need to be undertaken in conjunction.
4 Policy makers operate in a politically dynamic national and international environment, and their policies
5 often reflect their contextual situations and constraints with regards to climate-related reforms (Levin
6 et al. 2012; Copland 2019), including differentiation between developed and developing countries (Beer
7 and Beer 2014; Roy et al. 2018c) (*high evidence, high agreement*). Variables such as internal political
8 stability, equity, informality (Box 5.10), macro-economic conditions, public debt, governance of
9 policies, global oil prices, quality of public services, and the maturity of green technologies play
10 important roles in determining policy directions.

11
12 Sequencing policies appropriately is a success factor for climate policy regimes (*high evidence, high*
13 *agreement*). In most situations policy measures require a preparatory phase that prepares the ground by
14 lowering the costs of policies, communicating the costs and benefits to citizens, and building coalitions
15 for policies, thus reducing political resistance (Meckling et al. 2017). This policy sequencing aims to
16 incrementally relax or remove barriers over time to enable significant cumulative increases in policy
17 stringency and create coalitions that support future policy development (Pahle et al. 2018). German
18 policies into renewables began with funding for RD&D, then subsidies for demonstration projects
19 during the 1970s and 1980s, and continued to larger-scale projects such as ‘Solar Roofs’ programmes
20 in the 1990s, including the scaled-up FITs for solar power (Jacobsson and Lauber 2006). These policies
21 led to industrial expansion in wind and solar energy systems, giving rise to powerful renewables interest
22 coalitions that defend existing measures and lend political support for further action. Policy sequencing
23 has also been deployed to introduce technology bans and strict performance standards with a view to
24 eliminate emissions as the end goal, and may the involve simultaneous support low carbon options
25 while deliberately phasing out established technological regime (Rogge and Johnstone 2017).

26
27 As a key contending policy instrument, carbon pricing also requires embedding into policy packages
28 (*high evidence, medium agreement*). Pricing may be regressive and perceived as additional costs by
29 households and industry, making investments into green infrastructure politically unfeasible, as
30 examples from France and Australia show (Copland 2019; Douenne and Fabre 2020). Reforms that
31 would push up household energy expenses are often left aside for fear of how citizens, especially the
32 poor, would react or cope with higher bills (Martinez and Viegas 2017; Tesfamichael et al. 2021) (*high*
33 *evidence, medium agreement*). This makes it important to precede carbon pricing with investments into
34 renewable energy and low carbon transport modes (Biber et al. 2017; Tvinnereim and Mehling 2018),
35 and especially support developing countries by building up low-carbon energy and mobility
36 infrastructures and technologies, thus reducing resistance to carbon pricing (Creutzig 2019).
37 Additionally, carbon pricing receives higher acceptance if fairness and distributive consideration are
38 made explicit in revenue distribution (see Box 5.11).

39
40 The effectiveness of a policy package is determined by design decisions as well as the wider governance
41 context that include the political environment, institutions for coordination across scales, bureaucratic
42 traditions, and judicial functioning (Howlett and Rayner 2013; Rogge and Reichardt 2013; Rosenow et
43 al. 2016) (*high evidence, high agreement*). Policy packages often emerge through interactions between
44 different policy instruments as they operate in either complementary or contradictory ways, resulting
45 from conflicting policy goals (Cunningham et al. 2013; Givoni et al. 2013). An example includes the
46 acceleration in shift from traditional biomass to the adoption of modern cooking fuel for 80 million
47 households in rural India over a very short period of 4 years (2016-2020), which employed a
48 comprehensive ‘policy package’ including financial incentives, infrastructural support and
49 strengthening of the supply chain to induce households to shift towards a clean cooking fuel from the

1 use of biomass (Kumar 2019). This was operationalised by creating a LPG supply chain by linking oil
2 and gas companies with distributors to assure availability, create infrastructure for local storage along
3 with an improvement of the rural road network, especially in the rural context (Sankhyayan and
4 Dasgupta 2019). State governments initiated separate policies to increase the distributorship of LPG in
5 their states (Kumar et al. 2016). Similarly, policy actions for scaling up electric vehicles need to be well
6 designed and coordinated where EV policy, transport policy and climate policy are used together,
7 working on different decision points and different aspects of human behaviour (Barton and Schütte
8 2017). The coordination of the multiple policy actions enables co-evolution of multiple outcomes that
9 involve shifting towards renewable energy production, improving access to charging infrastructure,
10 carbon pricing and other GHG measures (Wolbertus et al. 2018).

11
12 Design of policy packages should consider not only policies that support low carbon transitions but also
13 those that challenge existing carbon-intensive regimes, generating not just policy “winners” but also
14 “losers” (Carley and Konisky 2020) (*high evidence, high agreement*). The winners include low carbon
15 innovators and entrepreneurs, while the potential losers include incumbents with vested interests in
16 sustaining the status quo (Mundaca et al. 2018; Monasterolo and Raberto 2019). Low carbon policy
17 packages would benefit from looking beyond climate benefits to include non-climate benefits such as
18 health benefits, fuel poverty reductions and environmental co-benefits (Ürge-Vorsatz et al. 2014;
19 Sovacool et al. 2020b). The uptake of decentralised energy services using solar PV in rural areas in
20 developing countries is one such example where successful initiatives are linked to the convergence of
21 multiple policies that include import tariffs, research incentives for R&D, job creation programmes,
22 policies to widen health and education services, and strategies for increased safety for women and
23 children (Kattumuri and Kruse 2019; Gebreslassie 2020).

24
25 The energy efficient lighting transition in Europe represents a good case of the formation of policy
26 coalitions that led to the development of policy packages. As attention for energy efficiency in Europe
27 increased in the 1990s, policymakers attempted to stimulate energy-saving lamp diffusion through
28 voluntary measures. But policies stimulated only limited adoption. Consumers perceived CFLs as
29 giving ‘cold’ light, being unattractively shaped, taking too long to achieve full brightness, unsuitable
30 for many fixtures, and unreliable (Wall and Crosbie 2009). Still, innovations by major CFL and LED
31 multinationals continued. Increasing political attention to climate change and criticisms from
32 environmental NGOs (e.g. WWF, Greenpeace) strengthened awareness about the inefficiency of
33 incandescent light bulbs (ILBs), which led to negative socio-cultural framings that associated ILBs with
34 energy waste (Franceschini and Alkemade 2016). The combined pressures from the lighting industry,
35 NGOs and member states led the European Commission to introduce the 2009 ban of ILBs of more
36 than 80W, progressing to lower-wattage bans in successive years. While the ILB ban initially mainly
37 boosted CFL diffusion, it also stimulated LED uptake. LED prices decreased quickly by more than 85%
38 between 2008 and 2012 (Sanderson and Simons 2014), because of scale economies, standardisation and
39 commoditisation of LED chip technology, and improved manufacturing techniques. Because of further
40 rapid developments to meet consumer tastes, LEDs came to be seen as the future of domestic lighting
41 (Franceschini et al. 2018). Acknowledging these changing views, the 2016 and 2018 European bans on
42 directional and non-directional halogen bulbs explicitly intended to further accelerate the LED
43 transition and reduce energy consumption for residential lighting.

44
45 In summary, more equitable societies are associated with high levels of social trust and enables action
46 that reduce GHG emissions. To this end, people play an important role in the delivery of demand-side
47 mitigation options within which efficiency and ‘improve’ options dominate. Policies that are aimed at
48 behaviour and lifestyle changes come with political risks for policy makers. However, the potential
49 exists for broadening demand-side interventions to include ‘avoid’ and ‘shift’ policies. Longer term

1 thinking and implementation that involves careful sequencing of policies as well as designing policy
2 packages that address multiple co-benefits would be critical to manage interactions among supply-side
3 and demand-side options to accelerate mitigation.
4
5

6 **5.7 Knowledge gaps**

7 **Knowledge gap 1: Better metric to measure actual human well-being**

8 Knowledge on climate action that starts with the social practices and how people live in various
9 environments, cultures, contexts and attempts to improve their well-being, is still in its infancy. In
10 models, climate solutions remain supply-side oriented, and evaluated against GDP, without
11 acknowledging the reduction in well-being due to climate impacts. GDP is a poor metric of human well-
12 being, and climate policy evaluation requires better grounding in relation to decent living standards and
13 or similar benchmarks. Actual solutions will invariably include demand, service provisioning and end
14 use. Literature on how gender, informal economies mostly in developing countries, and solidarity and
15 care frameworks translate into climate action, but also how climate action can improve the life of
16 marginalised groups remains scarce. The working of economic systems under a well-being driven rather
17 than GDP driven paradigm requires better understanding.
18

19 **Knowledge gap 2: Evaluation of climate implication of the digital economy**

20 The digital economy, as well as shared and circular economy, is emerging as template for great
21 narratives, hopes and fears. Yet, there is few systematic evaluations of what is already happening and
22 what can govern it towards a better narrative. Research needs to better gauge energy trends for rapidly
23 evolving systems like data centres, increased use of social media and influence of consumption and
24 choices, AI, blockchain, implication of digital divide among social groups and countries on well-being.
25 Governance decisions on AI, indirectly fostering either climate harming or climate mitigating activities
26 remain unexplored. Better integration of mitigation models and consequential life cycle analysis is
27 needed for assessing how digitalisation, shared economy and circular economy change material and
28 energy demand.
29

30 **Knowledge gap 3: Scenario modelling of services**

31 Scenarios start within parameter-rich models carrying more than a decade-long legacy of supply side
32 technologies that are not always gauged in recent technological developments. Service provisioning
33 systems are not explicitly modelled, and diversity in concepts and patterns of lifestyles rarely
34 considered. A new class of flexible and modular models with focus on services and activities, based on
35 variety of data sources including big data collected and compiled is needed. There is scope for more
36 sensitivity analysis on two aspects to better guide further detailed studies on societal response to policy.
37 These aspects need to explore which socio-behavioural aspects/ organisation changes has biggest
38 impact on energy/emissions reductions, and on the scale for take-back effects, due to interdependence
39 on inclusion or exclusion of groups of people. Models mostly consider behavioural change free, and
40 don't account for how savings due to "avoid" measures may be re-spent. Most quantitatively
41 measurable service indicators e.g. pkm or tkm are also inadequate to measure services in the sense of
42 well-being contributions. More research is needed on how to measure e.g. accessibility, social inclusion
43 etc. Otherwise services will also be poorly represented in scenarios.
44

45 **Knowledge gap 4: Dynamic interaction between individual, social, and structural drivers of change**

46
47 Better understanding is required on: (1) More detailed causal mechanisms in the mutual interactions
48 between individual, social, and structural drivers of change and how these vary over time, i.e. what is

1 their relative importance in different transition phases; (2) how narratives associated with specific
2 technologies, group identities, and climate change influence each other and interact over time to enable
3 and constrain mitigation outcomes; (3) how social media influences the development and impacts of
4 narratives about low carbon transitions; (4) the effects of social movements (for climate justice, youth
5 climate activism, fossil fuel divestment, and climate action more generally) on social norms and
6 political change, especially in less developed countries; (5) how existing provisioning systems and
7 social practices destabilise through the weakening of various lock-in mechanisms, and resulting
8 deliberate strategies for accelerating demand-side transitions; (6) a dynamic understanding of
9 feasibility, which addresses the dynamic mechanisms that lower barriers or drive mitigation options
10 over the barriers. (7) how shocks like prolonged pandemic impacts willingness and capacity to change
11 and their permanency for various social actors and country contexts. The debate on the most powerful
12 leverage point/s and policies for speeding up change in social and technological systems need to be
13 resolved with more evidence. Discussion on the policy interdependence and implications of end-user
14 and efficiency focused strategies have only just started suggesting an important area for future research.
15
16

17 **Frequently Asked Questions (FAQs)**

18 **FAQ 5.1 What can every person do to limit warming to 1.5°C?**

19 People can be educated through knowledge transfer so they can act in different roles, and in each role
20 everyone can contribute to limit global warming to 1.5°C. As citizens, with enough knowledge can
21 organise and put political pressure on the system. Role models can set examples to others. Professionals
22 (e.g., engineers, urban planners, teachers, researchers) can change professional standards in consistency
23 with decarbonisation; e.g., urban planners and architects can design physical infrastructures to facilitate
24 low-carbon mobility and energy use by making walking and cycling safe for children. Rich investors
25 can make strategic plan to divest from fossils and invest in carbon-neutral technologies. As consumers,
26 especially if one belongs to the top 10% of the world population in terms of income, can limit
27 consumption, especially in mobility, and explore the good life consistent with sustainable consumption.
28 Policy makers support individual actions in certain contexts not only by economic incentives, such as
29 carbon pricing, but also by interventions that understand complex decision making processes, habits,
30 and routines. Examples of such interventions include but are not limited to choice architectures and
31 nudges that set green options as default, shift away from cheap petrol or gasoline, increasing taxes on
32 carbon-intensive products, or substantially tightening regulations and standards support shifts in social
33 norms, and thus can be effective beyond the direct economic incentive.
34

35 **FAQ 5.2 How does society perceive transformative change?**

36 Human induced global warming, together with other global trends and events, such as digitalisation and
37 automation, and the COVID-19 pandemic, induces changes in labour markets, and bring large
38 uncertainty and ambiguity. History and psychology reveal that societies can thrive in these
39 circumstances if they openly embrace uncertainty on the future and try out ways to improve life.
40 Tolerating ambiguity can be learned, e.g., by interacting with history, poetry and the arts. Sometimes
41 religion and philosophy also help.
42

43 As a key enabler, novel narratives created in a variety of ways e.g., by advertising, images,
44 entertainment industry, help to break away from the established meanings, values and discourses and
45 the status quo. For example, discourses that frame comfortable public transport service to avoid stress
46 from driving cars on busy, congested roads help avoid car driving as a status symbol and create a new
47 social norm to shift to public transport. Discourses that portray plant based protein and as healthy and
48 natural promote and stabilise particular diets. Novel narratives and inclusive processes help strategies
49 to overcome multiple barriers. Case studies demonstrate that citizens support transformative changes if
50 participatory processes enable a design that meets local interests and culture. Promising narratives

1 specify that even as speed and capabilities differ humanity embarks on a joint journey towards well-
2 being for all and a healthy planet.

3
4 **FAQ 5.3 Is demand reduction compatible with growth of human well-being?**

5 There is a growing realisation that mere monetary value of income growth is insufficient to measure
6 national welfare and individual well-being. Hence, any action towards climate change mitigation is best
7 evaluated against a set of indicators that represent a broader variety of needs to define individual well-
8 being, macroeconomic stability, and planetary health. Many solutions that reduce primary material and
9 fossil energy demand, and thus reduce GHG emissions, provide better services to help achieve well-
10 being for all.

11
12 Economic growth measured by total or individual income growth is a main driver of GHG emissions.
13 Only a few countries with low economic growth rates have reduced both territorial and consumption-
14 based GHG emissions from, typically by switching from fossil fuels to renewable energy and by
15 reduction in energy low/zero carbon fuels, but until now at insufficient rates and levels for stabilising
16 global warming at 1.5°C. High deployment of low/zero carbon fuels and associated rapid reduction in
17 demand and use of coal, gas, and oil can further reduce the interdependence between economic growth
18 and GHG emissions.

1 Executive Summary

2 **Warming cannot be limited to well below 2°C without rapid and deep reductions in energy system**
3 **CO₂ and GHG emissions.** In scenarios limiting likely warming to 1.5°C with limited overshoot (likely
4 below 2°C), net energy system CO₂ emissions (interquartile range) fall by 87% to 97% (60% to 79%)
5 in 2050. In 2030, in scenarios limiting warming to 1.5°C with no or limited overshoot, net CO₂ and
6 GHG emissions fall by 35-51% and 38-52% respectively. In scenarios limiting warming to 1.5°C with
7 no or limited overshoot (likely below 2°C), net electricity sector CO₂ emissions reach zero globally
8 between 2045 and 2055 (2050 and 2080) (*high confidence*) {6.7}

9 **Limiting warming to well below 2°C will require substantial energy system changes over the next**
10 **30 years. This includes reduced fossil fuel consumption, increased production from low- and zero-**
11 **carbon energy sources, and increased use of electricity and alternative energy carriers.** Coal
12 consumption without CCS falls by 67% to 82% (interquartile range) in 2030 in scenarios limiting
13 warming to 1.5°C with no or limited overshoot. Oil and gas consumption fall more slowly. Low-carbon
14 sources produce 93% to 97% of global electricity by 2050 in scenarios that limit likely warming to 2°C
15 or below. In scenarios limiting warming to 1.5°C with no or limited overshoot (likely below 2°C),
16 electricity supplies 48% to 58% (36% to 47%) of final energy in 2050, up from 20% in 2019. (*high*
17 *confidence*) {6.7}

18 **Net Zero energy systems will share common characteristics, but the approach in every country**
19 **will depend on national circumstances.** Common characteristics of net zero energy systems will
20 include: (1) electricity systems that produce no net CO₂ or remove CO₂ from the atmosphere; (2)
21 widespread electrification of end uses, including light-duty transport, space heating, and cooking; (3)
22 substantially lower use of fossil fuels than today (4) use of alternative energy carriers such as hydrogen,
23 bioenergy, and ammonia to substitute for fossil fuels in sectors less amenable to electrification; (5) more
24 efficient use of energy than today; (6) greater energy system integration across regions and across
25 components of the energy system; and (7) use of CO₂ removal (e.g., DACCS, BECCS) to offset any
26 residual emissions. (*high confidence*) {6.6}

27 **Energy demands and energy sector emissions have continued to rise.** From 2015 to 2019, global
28 final energy consumption grew by 6.6%, CO₂ emissions from the global energy system grew by 4.6%,
29 and total GHG emissions from energy supply rose by 2.7%. Methane emissions, mainly fugitive
30 emissions from oil, gas, and coal, accounted for 18% of GHG emissions in 2019. Coal electricity
31 capacity grew by 7.6% between 2015 and 2019, as new builds in some countries offset declines in
32 others. Total consumption of oil and oil products increased by 5%, and natural gas consumption grew
33 by 15%. Declining energy intensity in almost all regions has been balanced by increased energy
34 consumption. (*high confidence*) {6.3}

35 **Prices have dropped rapidly over the last five years for several key energy system mitigation**
36 **options, notably solar PV, wind power, and batteries.** From 2015 to 2020, the prices of electricity
37 from PV and wind dropped 56% and 45%, respectively, and battery prices dropped by 64%. Electricity
38 from PV and wind is now cheaper than electricity from fossil sources in many regions, electric vehicles
39 are increasingly competitive with internal combustion engines, and large-scale battery storage on
40 electricity grids is increasingly viable. (*high confidence*) {6.3, 6.4}

41 **Global wind and solar PV capacity and generation have increased rapidly.** Solar PV grew by 170%
42 (to 680 TWh); wind grew by 70% (to 1420 TWh) from 2015 to 2019. Policy, societal pressure to limit
43 fossil generation, low interest rates, and cost reductions have all driven wind and solar PV deployment.
44 Solar PV and wind together accounted for 21% of total low-carbon electricity generation and 8% of
45 total electricity generation in 2019. Nuclear generation grew 9% between 2015 and 2019 and accounted
46 for 10% of total generation in 2019 (2790 TWh); hydroelectric power grew by 10% and accounted for

1 16% (4290 TWh) of total generation. In total, low- and zero-carbon electricity generation technologies
2 produced 37% of global electricity in 2019. (*high confidence*) {6.3, 6.4}

3 **If investments in coal and other fossil infrastructure continue, energy systems will be locked-in to**
4 **higher emissions, making it harder to limit warming to well below 2°C.** Many aspects of the energy
5 system – physical infrastructure; institutions, laws, and regulations; and behaviour – are resistant to
6 change or take many years to change. New investments in coal-fired electricity without CCS are
7 inconsistent with limiting warming to well below 2°C. (*high confidence*) {6.3, 6.7}

8 **Limiting warming to well below 2°C will strand fossil-related assets, including fossil**
9 **infrastructure and unburned fossil fuel resources.** The economic impacts of stranded assets could
10 amount to trillions of dollars. Coal assets are most vulnerable over the coming decade; oil and gas assets
11 are more vulnerable toward mid-century. CCS can allow fossil fuels to be used longer, reducing
12 potential stranded assets. (*high confidence*) {6.7}

13 **A low-carbon energy transition will shift investment patterns and create new economic**
14 **opportunities.** Total energy investment needs will rise, relative to today, over the next decades, if likely
15 warming is limited to 2°C or below. These increases will be far less pronounced, however, than the
16 reallocations of investment flows that are likely to be seen across sub-sectors, namely from fossil fuels
17 (extraction, conversion, and electricity generation) without CCS and toward renewables, nuclear power,
18 CCS, electricity networks and storage, and end-use energy efficiency. A significant and growing share
19 of investments between now and 2050 will be made in emerging economies, particularly in Asia. (*high*
20 *confidence*) {6.7}

21 **Climate change will affect many future local and national low-carbon energy systems. The**
22 **impacts, however, are uncertain, particularly at the regional scale.** Climate change will alter
23 hydropower production, bioenergy and agricultural yields, thermal power plant efficiencies, and
24 demands for heating and cooling, and it will directly impact power system infrastructure. Climate
25 change will not affect wind and solar resources to the extent that it would compromise their ability to
26 reduce emissions. (*high confidence*) {6.5}

27 **Electricity systems powered predominantly by renewables will be increasingly viable over the**
28 **coming decades, but it will be challenging to supply the entire energy system with renewable**
29 **energy.** Large shares of variable solar PV and wind power can be incorporated in electricity grids
30 through batteries, hydrogen, and other forms of storage; transmission; flexible non-renewable
31 generation; advanced controls; and greater demand-side responses. Because some applications (e.g., air
32 travel) are not currently amenable to electrification, 100% renewable energy systems would likely need
33 to include alternative fuels such as hydrogen or biofuels. Economic, regulatory, social, and operational
34 challenges increase with higher shares of renewable electricity and energy. The ability to overcome
35 these challenges in practice is not fully understood. (*high confidence*) {6.6}

36 **Multiple energy supply options are available to reduce emissions over the next decade.** Nuclear
37 power and hydropower are already established technologies. Solar PV and wind are now cheaper than
38 fossil-generated electricity in many locations. Bioenergy accounts for about a tenth of global primary
39 energy. Carbon capture is widely used in the oil and gas industry, with early applications in electricity
40 production and biofuels. It will not be possible to widely deploy all of these and other options without
41 efforts to address the geophysical, environmental-ecological, economic, technological, socio-cultural,
42 and institutional factors that can facilitate or hinder their implementation. (*high confidence*) {6.4}

43 **Some mitigation options can provide more immediate and cost-effective emissions reductions**
44 **than others, but a comprehensive approach will be required over the next ten years to limit**
45 **warming to well below 2°C.** There are substantial, cost-effective opportunities to reduce emissions
46 rapidly in several sectors, including electricity generation and light-duty transportation. But near-term
47 reductions in these sectors will not be sufficient to limit warming to well below 2°C. A broad-based

1 approach across the energy sector will be necessary to reduce emissions over the next ten years and to
2 set the stage for still deeper reductions beyond 2030. (*high confidence*) {6.4, 6.6, 6.7}

3 **Enhanced integration across energy system sectors and across scales will lower costs and facilitate**
4 **low-carbon energy system transitions.** Greater integration between the electricity sector and end use
5 sectors can facilitate integration of Variable Renewable Energy (VRE) options. Energy systems can be
6 integrated across district, regional, national, and international scales. (*high confidence*) {6.4, 6.6}

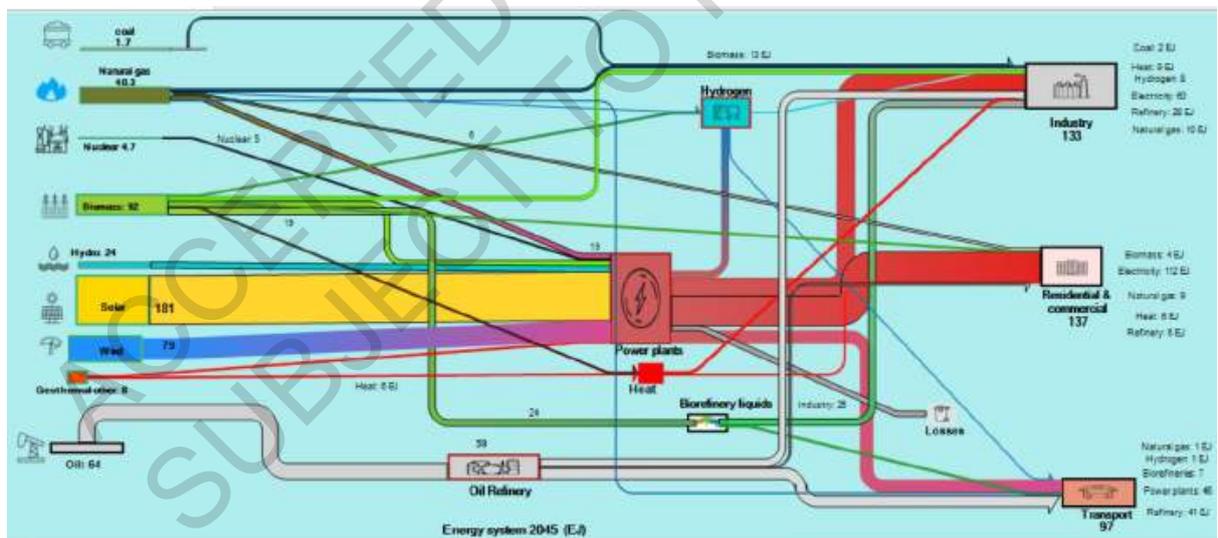

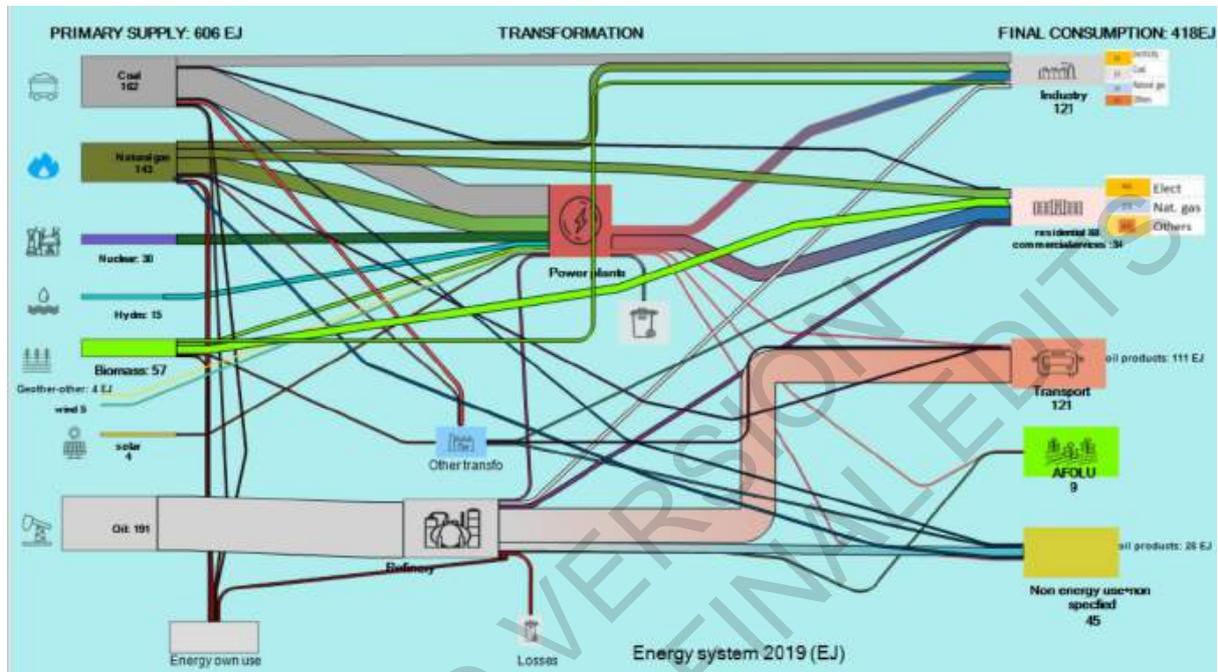

7 **The viable speed and scope of a low-carbon energy system transition will depend on how well it**
8 **can support sustainable development goals (SDGs) and other societal objectives.** Energy systems
9 are linked to a range of societal objectives, including energy access, air and water pollution, health,
10 energy security, water security, food security, economic prosperity, international competitiveness,
11 employment. These linkages and their importance vary among regions. Energy sector mitigation and
12 efforts to achieve SDGs generally support one another, though there are important region-specific
13 exceptions. (*high confidence*) {6.1, 6.7}

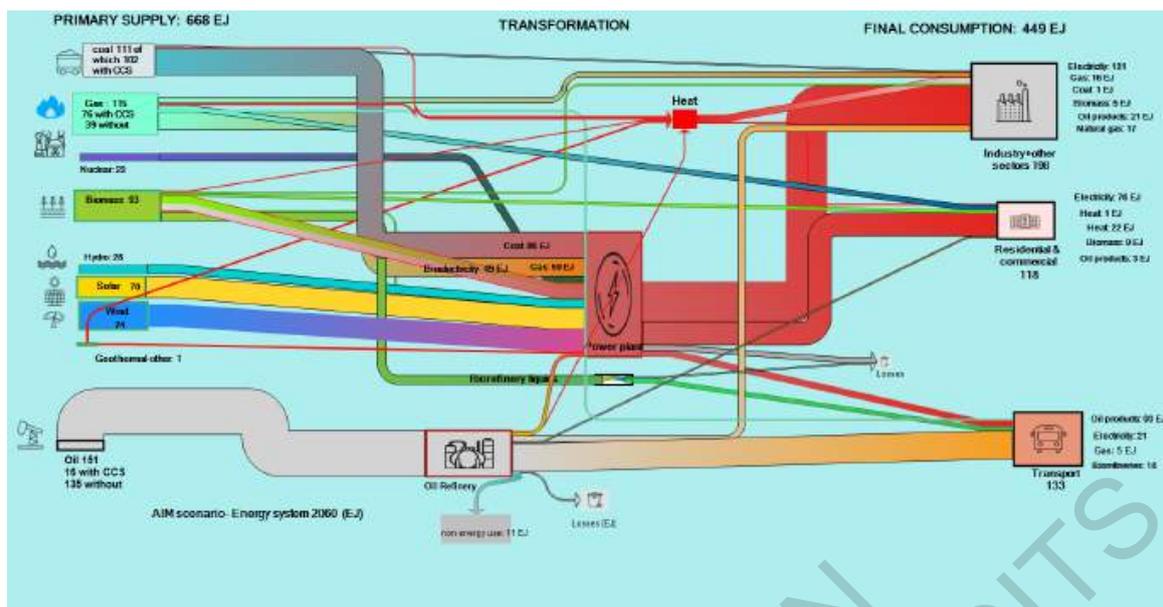

14 **The economic outcomes of low-carbon transitions in some sectors and regions may be on par with,**
15 **or superior to those of an emissions-intensive future.** Cost reductions in key technologies,
16 particularly in electricity and light-duty transport, have increased the economic attractiveness of near-
17 term low-carbon transitions. Long-term mitigation costs are not well understood and depend on policy
18 design and implementation, and the future costs and availability of technologies. Advances in low-
19 carbon energy resources and carriers such as next-generation biofuels, hydrogen produced from
20 electrolysis, synthetic fuels, and carbon-neutral ammonia would substantially improve the economics
21 of net zero energy systems. (*medium confidence*) {6.4, 6.7}

22

1 **6.1 Introduction**

2 The global energy system is the largest source of CO₂ emissions (Chapter 2). Reducing energy sector
 3 emissions is therefore essential to limit warming. The energy systems of the future will be very different
 4 from those of today if the world successfully limits warming to well below 2°C. Energy will be
 5 provided, converted, and used in different ways than it is today (Figure 6.1). Achieving and responding
 6 to these changes presents an impressive range of challenges and opportunities.

6 **IP2. Source: IP1: Luderer et al.(2021); IP2: Riahi, K. et al., 2021;IP2**

7
8 Within this context, this chapter has two main objectives. First, it aims to assess specific, individual
9 mitigation options in energy supply, energy transformation, and energy transportation and transmission.
10 This assessment is complementary to a set of chapters that explore mitigation options in agriculture,
11 forestry, and other land uses (Chapter 7), urban systems and other settlements (Chapter 8), buildings
12 (Chapter 9), transport (Chapter 10), industry (Chapter 11), and cross-sectoral perspectives (Chapter 12).
13 Second, this chapter aims to assess system-level mitigation opportunities and challenges across the
14 entirety of energy systems. These systems include energy supply, transformation, transmission, storage,
15 transportation, and end-uses. They also include the societal systems that interact with the physical
16 energy system. As energy systems become increasingly integrated and interconnected, a system-wide
17 perspective is necessary for understanding mitigation opportunities and challenges.

18 Within this context, this chapter addresses six topics, each of which is addressed in a separate section.
19 First, Section 6.2 defines the scope of the energy system. Section 6.3 then discusses the recent trends in
20 energy systems that might exert the most significant influence on energy system evolution and options
21 for reducing emissions. Section 6.4 assesses the status and potential of individual energy supply,
22 transformation, storage, transportation and transmission, and integration mitigation options in the
23 energy sector. Section 6.5 explores how climate change might affect energy systems and alter potential
24 energy system mitigation options and strategies. Section 6.6 identifies key characteristics of net zero
25 energy systems – those that emit very little or no CO₂. Section 6.7 explores transition pathways toward
26 and through net zero energy systems. Across all of these sections, the chapter aims to explore the ways
27 that energy sector mitigation options and strategies interact with SDGs and other societal and
28 environmental goals.

1 **6.2 The Scope of the Energy System and its Possible Evolution**

2 For this chapter, energy systems are defined broadly to include both physical and societal elements. The
3 physical infrastructure includes all the infrastructure and equipment used to extract, transform,
4 transport, transmit, and convert energy to provide energy services. In addition to the physical system, a
5 broad range of societal systems and dynamics are relevant to the energy system. Human societies use
6 energy to transport themselves and the goods that they use and consume, to heat, cool, and light their
7 homes, to cook their food, and to produce goods and services. Energy systems are therefore tied to the
8 systems involved in the provision of these various goods and services. All energy users engage in the
9 operation of energy systems by demanding energy at particular times and in particular forms. They can
10 adjust their behaviour and demands, for example, by using less energy or by changing when they use
11 energy. Consumers can invest in equipment that reduces their energy needs, and they can invest in
12 technologies that transform energy (e.g., rooftop solar) or store energy (e.g., batteries). Firms and
13 governments invest in equipment to produce, transform, and transport energy such as power plants,
14 refineries, electric transmission lines, and oil tankers. All aspects of energy systems are governed by
15 laws, regulations, and actual institutions that reside within businesses and governments at all levels.
16 This includes, for example, rules for trading emissions permits, deciding when particular electricity
17 generation technologies might come online, water management and related environmental rules that
18 define the availability of hydropower or influence water availability for cooling power plants,
19 regulations for injecting CO₂ into underground reservoirs or disposing of nuclear waste, and even
20 company policies regarding work hours or teleworking, which can have important implications for
21 energy demand profiles. Many people are employed in the energy sector, and energy system mitigation
22 will eliminate some jobs while creating others.

23 This broader view of energy systems is essential for understanding energy system mitigation, as these
24 broader societal and institutional factors can have an important influence on energy system
25 transformations and the potential to rapidly reduce energy CO₂ emissions. Energy system mitigation is
26 as much about the challenges of societal change as it is about the challenges of changes in physical
27 infrastructure, technologies, and operations. While this chapter does not attempt to draw a specific
28 boundary around all the different systems that interact with the energy system, it frequently explores
29 these broader system interactions when assessing different mitigation options and strategies.

30 There is no single spatial scale at which energy systems might be defined and assessed. They can be
31 assessed at the scales of homes, cities, states or provinces, countries, regions, or the entire world. These
32 different scales are frequently both distinct with their own internal dynamics yet also connected to one
33 another. This chapter most frequently assesses energy systems from the country and global perspective.

34 Because the energy system is so complex, it can be hard to define particular parts of it precisely, and
35 there may be competing definitions in the literature. For the purposes of this chapter, “energy supply”
36 encompasses all primary energy, conversion, and transmission processes with the exception of those
37 that use final energy to provide energy services in the end-use sectors (transport, buildings, industry
38 and agriculture). The “energy system” includes energy end uses sectors along with energy supply.
39 “Low-emissions” is used for energy technologies that produce little CO₂ or no CO₂ or that remove CO₂
40 from the atmosphere. Similarly, “low-carbon” transitions is used to describe transitions that limit likely
41 warming to 2°C or below. “Net-zero” energy systems refer to those that produce very little or no CO₂
42 or may even sequester CO₂ from the atmosphere.

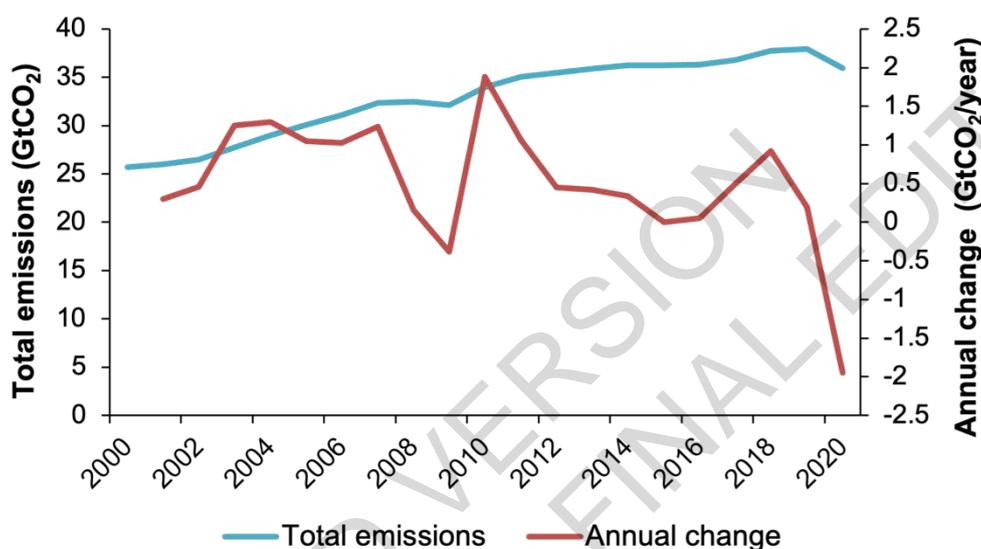

43

44

1 6.3 Recent Energy System Trends and Developments

2 Global energy sector emissions continue to grow but at a decreasing rate

3 Current energy sector emissions trends, if continued, will not limit global temperature change to well
 4 below 2°C (*high confidence*). Global energy system fossil fuel CO₂ emissions grew by 4.6% between
 5 2015 and 2019 (1.1% yr⁻¹), reaching 38 GtCO₂ yr⁻¹ and accounting for approximately two-thirds of
 6 annual global anthropogenic GHG emissions. In 2020, with the worldwide COVID pandemic, energy
 7 sector CO₂ emissions dropped by roughly 2 GtCO₂ yr⁻¹ (Figure 6.2). However global energy-related
 8 CO₂ emissions are projected to rebound by nearly 5% in 2021, approaching the 2018-19 peak (IEA
 9 2021d)

10
 11 **Figure 6.2 Global energy sector fossil fuel CO₂ emissions and annual change 2000-2019 (MtCO₂ yr⁻¹).**
 12 (Source: adapted from (Minx et al. 2021a; Crippa et al. 2021)

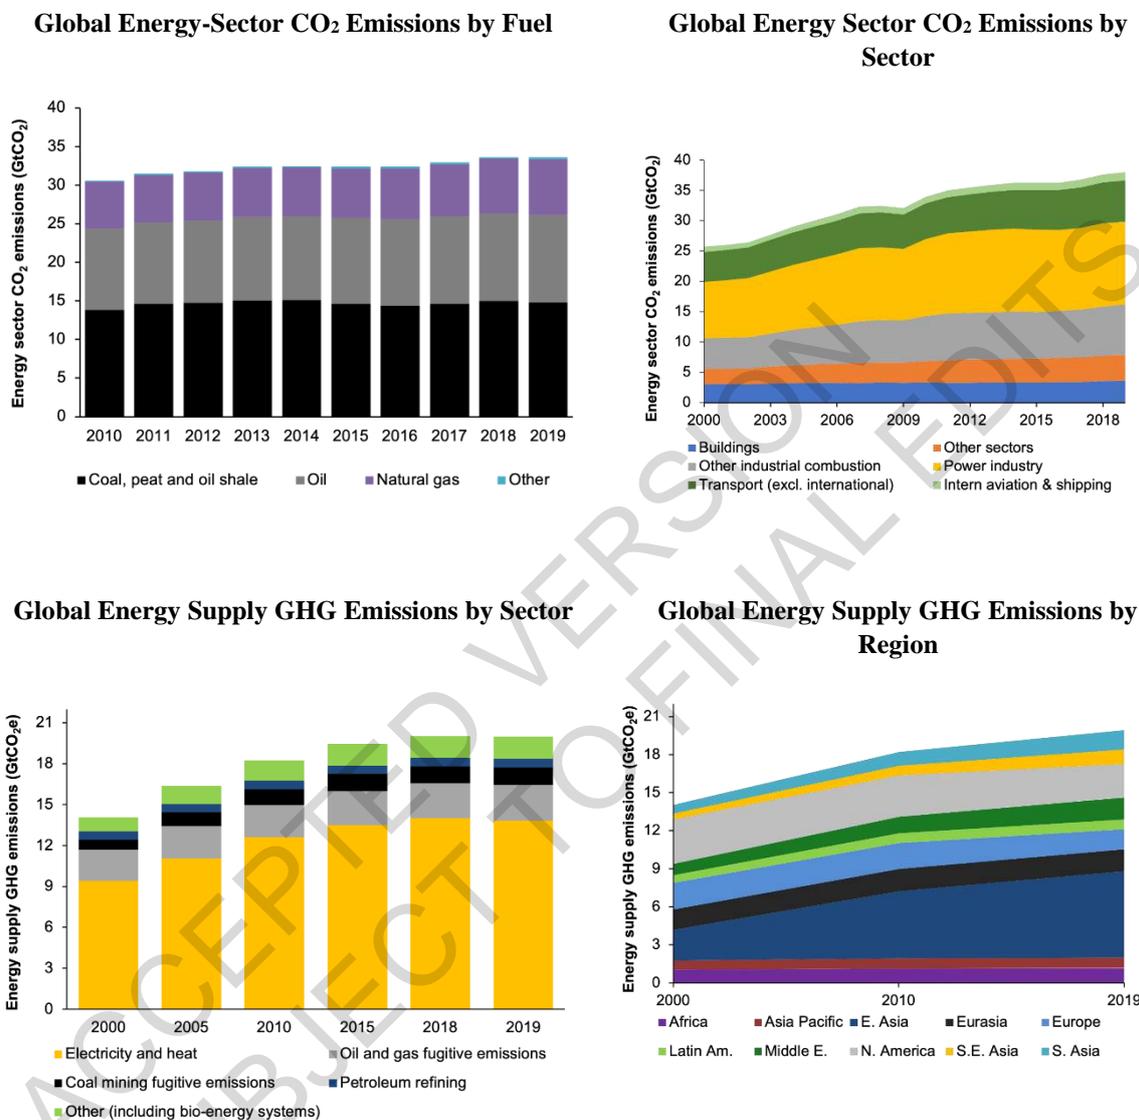

13 Coal was the single largest contributor to energy sector CO₂ emissions between 2015 and 2019,
 14 accounting for about 44% of energy sector CO₂ emissions in 2019. Oil accounted for about 34% and
 15 natural gas accounted for about 22% of energy sector CO₂ emissions. Coal, oil and natural gas CO₂
 16 emissions grew respectively by 1.2%, 2% and 12.7% (annual rates of 0.31%, 0.5% and 3%) (Figure
 17 6.3). The electricity sector remains the single largest source of energy sector CO₂ emissions, accounting
 18 for about 36% in 2019, followed by industry at 22% and transport (excluding international shipping and
 19 aviation transport) at about 18% (Figure 6.3). Shipping and aviation accounted for a little over 3%.
 20 These proportions have remained relatively unchanged over the last decade. Recent trends reinforce the
 21 near-term challenges facing energy sector mitigation - electricity sector emissions continue to rise
 22 despite rapid deployment of wind and solar power (see below); transportation emissions continue to
 23 rise, and petroleum remains the dominant fuel, despite advances in batteries and electric cars (see
 24 below). Some specific sectors, such as shipping and aviation, may present longer-term challenges.

25 Energy supply GHG emissions, including CO₂ and non-CO₂ greenhouse gases, reached 20 GtCO₂-eq
 26 yr⁻¹ in 2019, rising by 2.7% between 2015 and 2019 (0.66% yr⁻¹). Approximately 18% of energy supply
 27 emissions were non-CO₂ emissions. Electricity and heat contributed approximately 69% of total energy
 28 supply GHG emissions in 2019 (Figure 6.3). This growth has occurred despite the high penetration of
 29 solar PV and wind power, particularly in Asia and developed countries.

30 Fugitive emissions from fossil fuel production, primarily methane, accounted for about 18% of sector
 31 supply emissions in 2019, with 2.6 Gt CO₂eq yr⁻¹ linked to oil and gas production and 1.3 Gt CO₂eq yr⁻¹

1 ¹ to coal mining (Crippa et al. 2021). Oil and gas operations produced 2.9 GtCO₂eq yr⁻¹ in 2019 (82 Mt
 2 yr⁻¹ as methane), split roughly equally between the two (IEA 2020a). There remains a high degree of
 3 uncertainty in methane emissions estimates from oil and gas operations despite the emergence of new
 4 data from satellites and other measurement campaigns. According to a recent study (Hmiel et al. 2020),
 5 methane emissions are underestimated by about 25 to 40%.

6

7 **Figure 6.3 Global energy sector CO₂ emissions and global energy supply GHG emission. Panel a:** (IEA
 8 2020a), **other panels** (Crippa et al. 2021)

9 Increasing global energy sector GHG emissions have been driven by rising emissions in some large
 10 developing and emerging countries; however, per capita emissions in these countries remain well below
 11 those in developed countries (Yu et al. 2019). From 2015 to 2019, Eastern Asia, Southern Asia, and
 12 South-East Asia energy sector CO₂ emissions grew by 2.4% yr⁻¹, 2.6% yr⁻¹, and 5.1% yr⁻¹, respectively.
 13 The relative and absolute shares of Europe and North America have continued to decline, partly due to
 14 the growth in other countries (Figure 6.3).

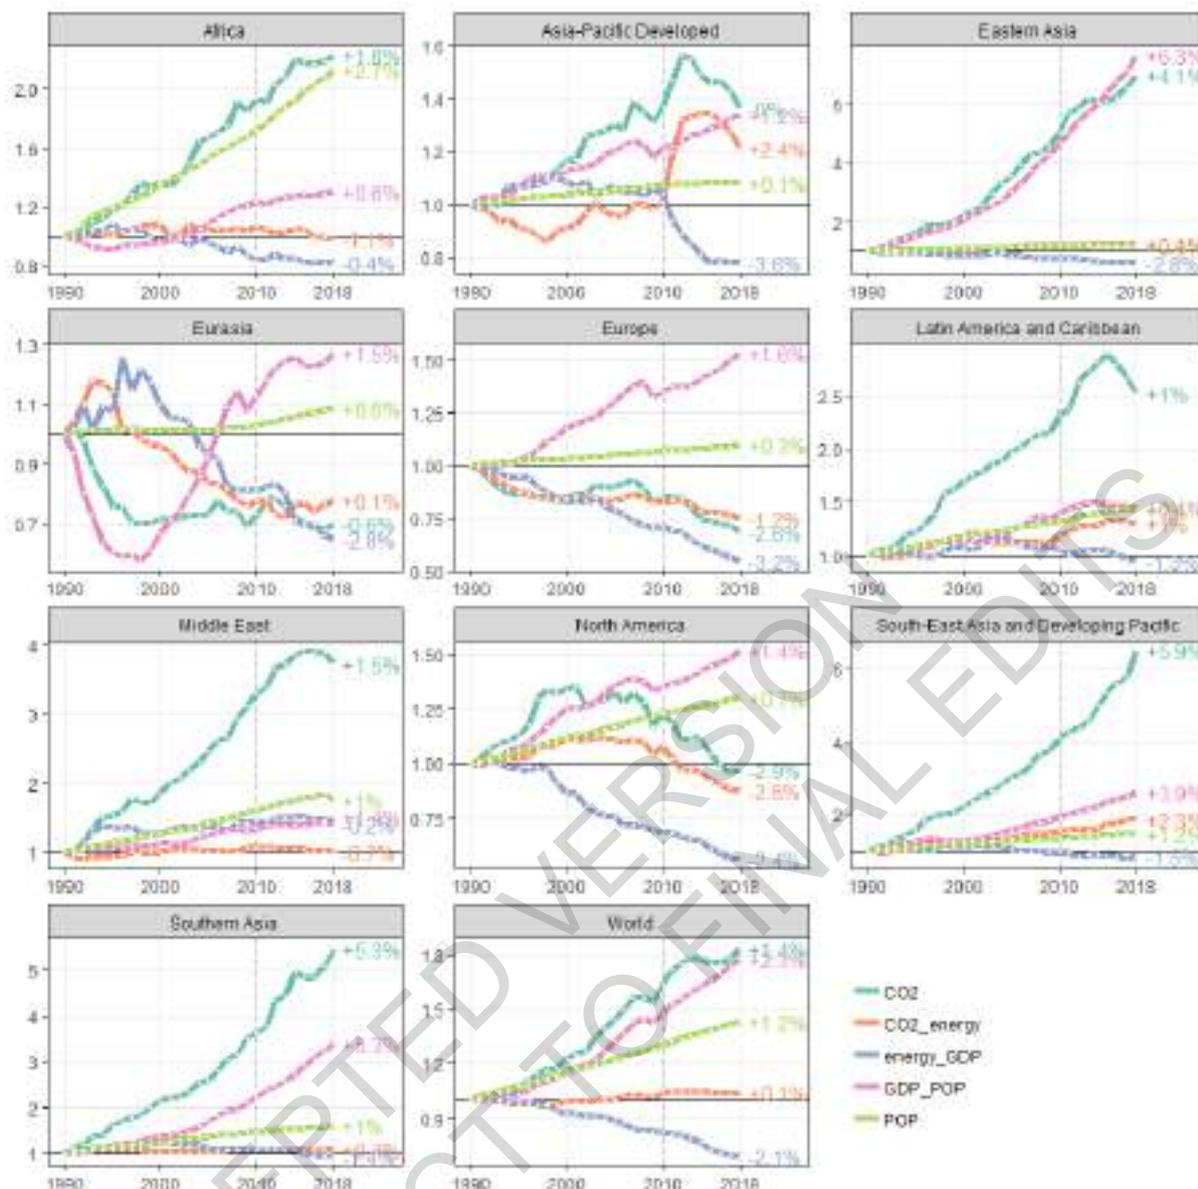

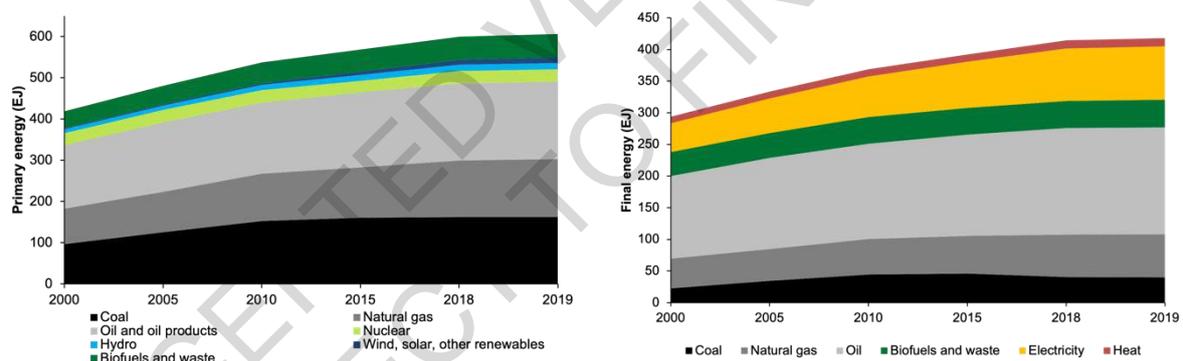

Figure 6.4 Drivers of greenhouse gas emissions across selected regions (Lamb et al. 2021).

Despite the declining energy intensity, global energy system CO₂ emissions have closely tracked GDP per capita (Figure 6.4). This is especially true in the Asian economies, which have experienced rapid GDP per capita growth in the past decades and a massive rise in energy demand. Similarly, emissions have declined in times of economic downturns – for example, in Eurasia in the 1990s and globally in 2009 and 2020. Population growth has also contributed to emissions growth globally and in most regions, particularly Africa, but the effect of population growth has been less than that of economic growth. Since 2015, energy intensity has been declining (IEA 2020b), limiting the impact of economic and population growth. However, there is no region where this factor alone would have been sufficient to decrease CO₂ emissions from the energy system. In Europe and North America, the only two regions where emissions decreased meaningfully since 2010, a steady decrease in the carbon intensity of energy was a significant downward driver. The reduction in carbon intensity in the EU is due primarily to the increase of renewable electricity production coupled with the low levels of fossil fuel-based production in the energy mix (Dyrstad et al. 2019).

1 Global energy production and demand continue to grow, but at a declining rate

2 Recent changes in the energy system can be viewed within the context of longer-term trends in energy
 3 supply and use. Over the last decade, there has been a significant increase in the total primary energy
 4 supply (TPES) and major changes in energy sources. From 2015 to 2019, TPES grew by 6.6% (1.6%
 5 yr^{-1}) from 569 EJ yr^{-1} to 606 EJ yr^{-1} . Natural gas consumption grew most quickly during this period, at
 6 3.5% yr^{-1} . Coal, oil and oil products grew at annual rates of 0.23% yr^{-1} and 0.83% yr^{-1} , respectively. In
 7 2019, the shares of coal, oil, and natural gas in global TPES were 27%, 31% and 23%, representing
 8 only a modest shift from 2015, when the shares were 28%, 32% and 22%, respectively. Renewables,
 9 excluding hydropower, grew at an annual rate of 12% yr^{-1} during this period; however, their share
 10 remains marginal in 2019 with just 2.2% of the TPES compared to 1.5% in 2015 (Figure 6.5). Bioenergy
 11 (including traditional bioenergy) accounted for 9.4% of the TPES, a similar share compared with 2015.

12 The total final energy consumption (TFC) grew by 6.6% (1.6% yr^{-1}) from 2015 to 2019, rising from
 13 392 EJ yr^{-1} to 418 EJ yr^{-1} . This is a slower growth rate than the previous decade (2.8 % yr^{-1}) (Figure
 14 6.5). In 2019, oil products used for transportation accounted for 41% of TFC. The penetration of non-
 15 fossil fuels is still marginal despite the significant growth of electric vehicles in recent years. Coal still
 16 accounted for 9.5% of TFC in 2019, dropping from 11.7% in 2015. Coal is mainly used as a primary
 17 energy source in industry and to a lesser extent in the residential sector. The share of electricity
 18 increased modestly, from 18.6% in 2015 to 20.2% in 2019, reflecting increasing access in developing
 19 countries and increasing use of electricity for a wide variety of end uses in the residential sector (see
 20 Box 6.1). Heat accounts for approximately 3% of TFC, used mainly in industry and the residential
 21 sector. Biofuels and waste accounted for 10.4% of TFC in 2019, only modestly changed compared with
 22 2015.

23 **Figure 6.5 World Total Primary Energy Supply (TPES) (EJ) and total final energy consumption (TFC)**
 24 **2000-2019 (adapted from IEA world energy balances (Minx et al. 2021b) database for IPCC)**

25 There are important differences in fuel use across countries. While developed countries almost
 26 exclusively use modern fuels, many countries still obtain a significant fraction of their energy from
 27 traditional bioenergy (fuelwood and charcoal). Traditional bioenergy (fuelwood and charcoal) is
 28 particularly important in sub-Saharan countries and some Asian countries such as India, particularly in
 29 the residential sector for cooking. Africa is still characterized by a high share of traditional bioenergy
 30 in TPES and TFC. In 2019, biomass and waste in Africa accounted for 44% of the TPES. The global
 31 average was 9.4%.

32 Asia has been particularly important in TFC growth since 2015. In 2019, Eastern Asia accounted for
 33 more 24% of TFC (1.52% annual growth from 2015). In contrast, TFC has increased by only 0.58% in
 34 Europe and 1.24% in North America. Despite an increase of 2.05% over the same period, Africa's TFC
 35 remains relatively low (6.1% of global TFC), particularly in sub-Saharan countries. Approximately 860
 36 million people, mostly in sub-Saharan Africa and some Asian countries, lacked access to electricity and

1 about 2.65 billion to clean-cooking facilities in 2018 (IEA 2019a). Achieving universal energy access
2 (SDG-7) will require energy transitions in the domestic sector, including new developments in off-grid
3 energy technologies, emphasis on rationalizing energy subsidies, and increasing efforts to address
4 health concerns related to the use of traditional fuels (Box 6.1).

5 **Non-climate factors continue to drive energy systems changes**

6 While energy system changes are vital to climate mitigation, recent energy system changes have arisen
7 in response to a much broader set of factors. Important factors include economic growth, energy access,
8 energy justice, energy security, air pollution, technological progress in low-emissions technologies,
9 local job creation. Several of these are discussed here.

10 *Energy Access.* Between 2000 and 2019, the proportion of the population with access to electricity
11 increased from 73% to 90% (IEA 2020c). Although most of those people gaining access to energy have
12 gained access to fossil fuel-based electricity, an increasing number are gaining access to electricity from
13 renewable sources. Low-emissions, decentralised systems are proving a cost-effective way to provide
14 electricity in rural areas (Scott et al. 2016; IEA 2019b; Muchunku et al. 2018), although the use of diesel
15 generators continues in some remote areas. Between 2000 and 2019 the proportion of the population
16 with access to clean cooking (modern fuels and/or improved biomass cookstoves) rose from 52% to
17 66%.

18 *Energy Security.* The ability of countries to maintain access to reliable and affordable energy resources
19 continues to shape energy policy. Energy security is perceived as a national security issue and often
20 prioritized over climate concerns (Nyman 2018). The linkage between climate and energy security is
21 now widely recognized (Toke and Vezirgiannidou 2013, Fu et al. 2021; La Viña et al. 2018; Blarke and
22 Lund 2007; World Energy Council 2020; United Nations 2021). Approaches to energy security are
23 frequently driven by the scope of domestic energy resources. For example, energy security concerns
24 have led to continued reliance on domestic coal production and consumption (Jakob et al. 2020) and
25 increased investment in domestic renewable generation (Konstantinos & Ioannidis, 2017). LNG
26 Importers have diversified their sources as reliance on LNG has increased (Vivoda 2019).

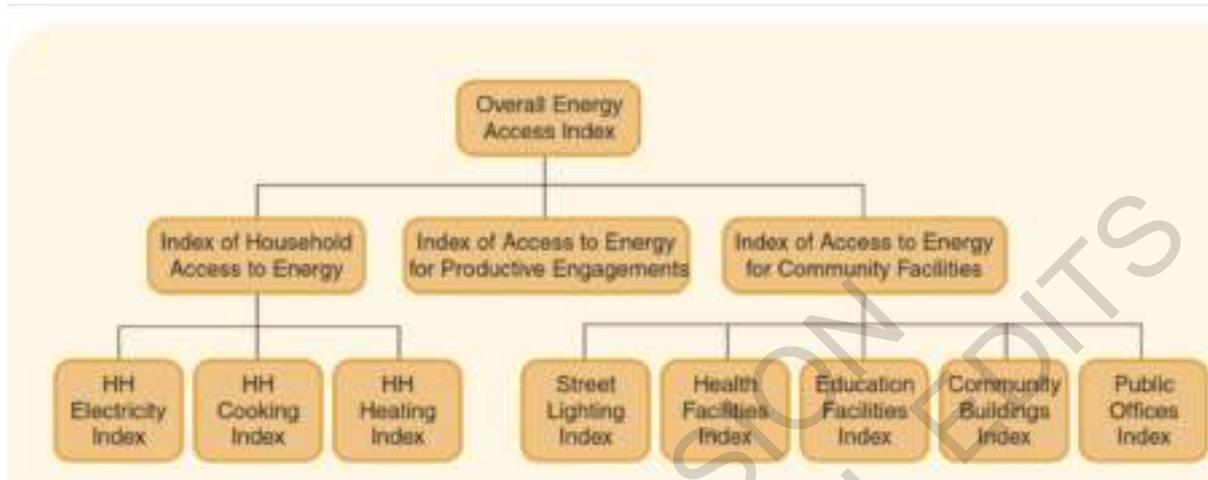

27 *Air Pollution.* The energy system is an important source of air pollution, including both indoor and
28 outdoor air pollution. Efforts to address air pollution in several countries and regions (the U. S., Mexico,
29 China, India, European Union, Africa, Southeast Asia, among others) have had an importance influence
30 on energy system changes (Bollen and Brink 2014, Fang et al. 2019). Policies aimed at controlling NO_x
31 and SO₂ emissions have driven emissions abatement efforts and coal fleet retirements (Drake & York,
32 2021) (Singh and Rao 2015). In some places, the prospect of reducing local air pollution remains more
33 salient to policymakers and the public than climate mitigation when deciding to tighten regulations on
34 coal use (Brauers & Oei, 2020).

35 *Technology and costs.* Costs for renewable technologies have fallen significantly in recent years,
36 driving significant changes in electricity production and transportation (see below). These advances are
37 not divorced from climate and other environmental concerns (Kuik, Branger, & Quirion, 2019;
38 Timilsina & Shah, 2020). Recent advances in PV cells, for example, can be traced in part to aggressive
39 deployment policies spurred by energy security, climate, and other environmental concerns (Kreuz and
40 Müsgens 2017, 6.3.5, 6.4.2). The falling costs of batteries, mainly Li-ion batteries, has boosted the
41 competitiveness of electric vehicles (6.3.7. Nykvist et al. 2015).

42 **START BOX 6.1 HERE**

43 **Box 6.1 Energy access, energy systems, and sustainability**

1 Successful mitigation must work in tandem with fundamental development goals such as access to
 2 modern forms of energy. In many developing countries, access to electricity, clean cooking fuels, and
 3 modern and efficient energy remain an essential societal priority. This is particularly true in sub-Saharan
 4 Africa and several Asian countries. SDG7 on universal access to modern energy includes targets on
 5 modern energy services, renewable energy, and energy efficiency, which implies a profound
 6 transformation of the current energy systems. Although there are different definitions of energy access,
 7 the ultimate goal is universal access to clean and modern fuels.

8
 9 **BOX 6.1 Figure 1 Measuring access to energy (ESMAP-World Bank, 2015)**

10 Despite progress in some countries such as India, Bangladesh and Kenya, 860 million people were
 11 without access to electricity in 2018, compared with 1.2 billion in 2010. About 2.65 billion households
 12 were cooking with solid fuels, distributed across Asia and Africa (IEA et al. 2020). Around 850 million
 13 people in sub-Saharan Africa relied on traditional biomass (firewood and charcoal) for cooking, and 60
 14 million relied on kerosene and coal to meet their energy needs (IEA 2018a). Air pollution was likely
 15 responsible for 1.1 million deaths across Africa in 2019 (Fisher et al. 2021). It has been estimated that
 16 2.2 billion people will still be dependent on inefficient and polluting energy sources for cooking by
 17 2030, mainly in Asia and Sub-Saharan Africa, and 650 million people are likely to remain without
 18 access to electricity in 2030, 90% of whom will reside in Sub-Saharan Africa (IEA et al. 2020).

19 Research indicates that decentralised and on-grid renewables are likely the least cost options to provide
 20 universal access to electricity by 2030 (Section 6.4.2). Natural gas, LPG, and improved biomass
 21 cookstoves are the most important options for cooking. Universal access to electricity and clean cooking
 22 requires a rapid shift from traditional biomass to cleaner fuels and/or clean cooking technologies (IEA
 23 et al. 2020). It has been estimated that the provision of electricity and clean cooking for all would require
 24 USD 786 billion in cumulative investment to 2030, equal to 3.4% of total energy sector investment over
 25 the period (IEA 2017).

26 Even without universal access to modern energy, increased access will substantially affect energy
 27 systems, particularly electricity systems through the deployment of renewable energy, LPG, and
 28 biomass supply chains. Universal access for households, however, will have a minimal impact on global
 29 energy demand; it has been estimated that universal access for household will increase energy demand
 30 by 0.2% in 2030 (37 Mtoe yr⁻¹) relative to a future without any change in access to modern energy
 31 (citation)

32 **[END BOX 6.1 HERE]**

33 **There have been initial efforts to phase out coal but only modest declines in use**

1 Global coal consumption has been declining, with small fluctuations, since it peaked in 2013 (IEA
2 2020d). Coal is faring differently across regions. Coal use has been decreasing in the OECD regions,
3 particularly in the U.S. and the European Union, while remaining mostly flat in China after a period of
4 growth, and it is continuing to increase in other major developing Asian economies (IEA 2020d). Trends
5 in the electricity sector, where most coal is being consumed, are similar. Growth in coal-fired electricity
6 generation capacity in the Asia Pacific region has offset retirements in North America and Europe
7 (Jakob et al. 2020).

8 Reductions in coal consumption have been driven in large part by non-climate factors, most notably
9 environmental regulations to address air pollution, rapidly declining costs of renewables, and lower
10 natural gas prices, especially inexpensive unconventional gas in the U.S. (Diluiso et al 2021;
11 Vinichenko et al., 2021; Culver and Hong 2016). Older coal-fired power plants that cannot meet new
12 environmental regulations or have become unprofitable or uncompetitive have been closed in many
13 regions. Moreover, coal power expansion has slowed down in Asia, as countries have suspended and
14 cancelled new projects for reasons such as overcapacity, environmental constraints, and the
15 development of renewables (see Box 6.2).

16 Different regions have replaced retired coal with different energy sources. Old coal fleets have been
17 replaced approximately half by gas and half by renewables in the U.S., mainly by renewables in the
18 European Union, and by advanced coal plants and renewables in Asia (EMBER 2020). Replacing old
19 coal with new coal facilities is inconsistent with limiting warming to 2°C or below *{high confidence}*
20 (Pfeiffer et al. 2016, 2018; Smith et al. 2019; Tong et al. 2019, Section 6.7.4).

21 Major coal consuming countries with abundant coal reserves remain far from phasing out coal (Spencer
22 et al. 2018; Edenhofer et al. 2018). In most developing countries with large coal reserves, coal use has
23 been increasing to support energy security and because it is perceived to have lower costs than
24 alternatives (Steckel et al. 2015; Kalkuhl et al 2019). However, coal faces increasing business risks
25 from the decreasing costs of alternative, low-emissions energy sources and increasing focus on air
26 pollution and other environmental impacts from coal mining and use (Garg et al. 2017; Sovacool et al
27 2021). Continued coal builds, mostly in developing countries, will increase the risks of stranded assets
28 (see Box 6.13) (Farfan Orozco 2017; Saygin et al. 2019; Cui et al. 2019).

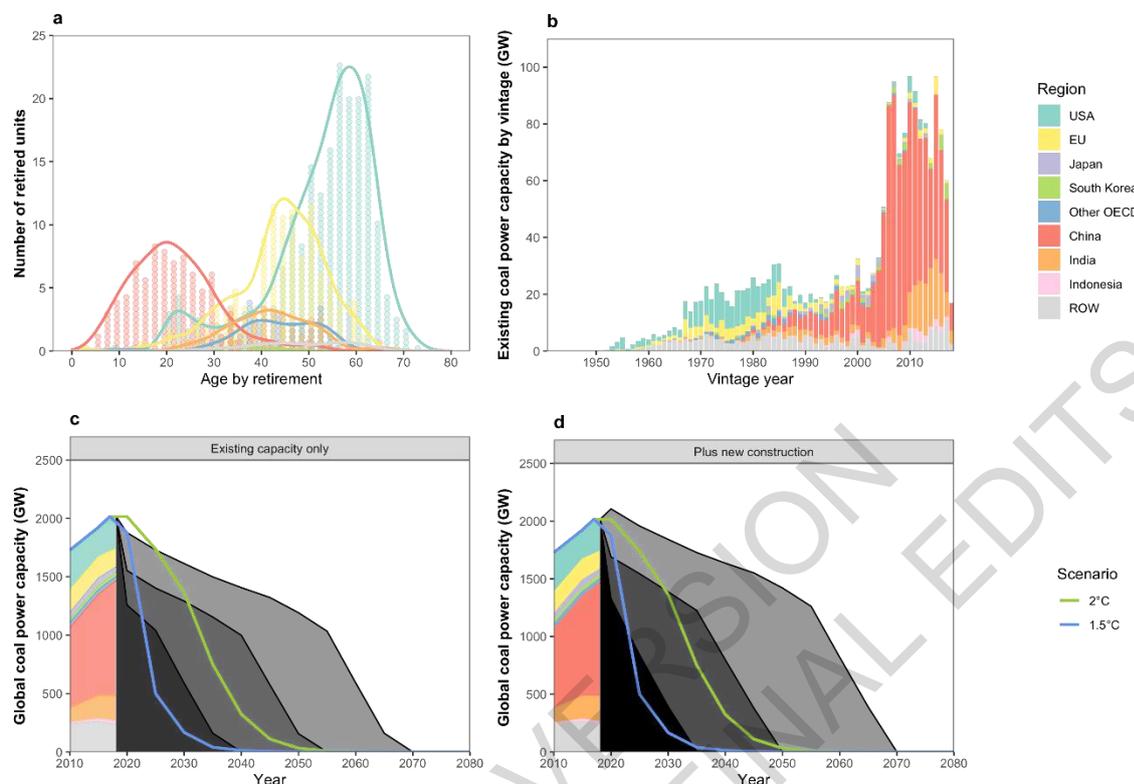

29 Economic, social, and employment impacts of accelerated coal phaseouts tend to be significant in coal-
30 dependent regions. Tailored reemployment has been used to support coal transitions in some regions.
31 Although some estimates show higher employment opportunities from low-carbon energy (Garrett-
32 Peltier 2017), results vary across regions. Moreover, even with a net increase in total employment, in
33 the long run, renewable jobs are often located outside of coal regions and require different skill sets
34 from the coal industry (Spencer et al. 2018). In a broader sense, achieving a “just transition” also
35 requires managing the impacts on regional economic development for coal-dependent communities and
36 the effects of higher energy prices for consumers and energy-intensive industries through a
37 comprehensive policy package (see Box 6.2) (Jakob et al. 2020; Green and Gambhir 2020).

38 **[START BOX 6.2 HERE]**

39 **Box 6.2 Status and Challenges of a Coal Phase-Out**

40 Limiting global warming to 2°C or below requires a rapid shift away from unabated coal consumption
41 (coal without CCS) in the energy system by 2050 (IPCC 2018a Section 6.7, Chapter 3). This will require
42 cancellation of new coal power projects and accelerated retirement of existing coal plants (Pfeiffer et
43 al. 2018; Edenhofer et al. 2018; Tong et al. 2019, Kriegler et al. 2018; Smith et al. 2019). To limit
44 warming to 2°C or below, and without new builds, existing coal plants will need to retire 10 to 25 years
45 earlier than the historical average operating lifetime. Completing all planned projects will further reduce
46 the viable lifetime of all plants by 5 to 10 years if warming is to be limited to 2°C or below (Cui et al.

- 1 2019). Phasing-out coal in the next few decades will present economic, social, and security challenges.
 2 These will vary across regions based on the characteristics of existing coal infrastructure, the availability
 3 of alternatives, economic development, and technological and institutional lock-in (Jakob et al. 2020).

4
 5
 6 **Box 6.2 Figure 1 Retirement of coal-fired power plants to limit warming to 1.5°C and likely 2°C. (a)**
 7 **Historical facility age at retirement (b) the vintage year of existing units, (c) global coal capacity under**
 8 **different plant lifetimes, compared to capacity levels consistent with a well-below 2°C (green) and 1.5°C**
 9 **(blue) pathway assuming no new coal plants, and (d) and assuming plants currently under construction**
 10 **come online as scheduled, but those in planning or permitting stages are not built. (Source: (Cui et al.**
 11 **2019)).**

12 Between 2015 and 2019, global coal power capacity grew by 146 GW, or 7.6%, as new builds offset
 13 retirements in some countries (Global Energy Monitor et al. 2021). Meanwhile, an increasing number
 14 of countries and regions have committed to or operationalised coal phase-outs (Jewell et al. 2019; Watts
 15 et al. 2019; Littlecott et al. 2021). Actions are being taken by various international and subnational
 16 actors, including national and subnational governments, public and private power companies, and
 17 financial institutions and pension funds that have committed not to fund new coal or coal-based
 18 infrastructure (yan Nie et al. 2016; Buckley 2019; Auger et al. 2021). Although these initial efforts are
 19 not yet sufficient in limiting warming to 1.5°C, and most have occurred in regions with older coal fleets,
 20 these examples provide insight into possible coal phaseout strategies (Spencer et al. 2018) and help
 21 identify the mechanisms driving the move away from coal, such as market, technology, policy, or other
 22 societal objectives. They also enable better understanding of the possible character of oil and gas phase-
 23 downs that would ultimately be needed to limit warming two well below 2°C (Section 6.7.4; (Raimi et
 24 al. 2019)).

25 **Europe:** Several European countries are part of the Powering Past Coal Alliance (PPCA) and have
 26 committed to phase-out unabated coal on or before 2030 (Jewell et al. 2019). Because these countries
 27 represent a small share of global coal generation capacity and have mostly ageing coal plants, they tend

1 to face fewer changes in phasing out coal. The effectiveness of PPCA in countries with younger coal
2 fleets has thus been questioned (Jewell et al. 2019; Blondeel et al. 2020). Germany recently joined the
3 PPCA and has committed to phaseout unabated coal by 2038. As part of its commitment to phase out
4 coal, Germany is implementing a set of measures that include compensation for power plant closures,
5 labour market measures for coal workers, and substantial support of structural change in coal-mining
6 regions. Poland, another coal-heavy country in Europe, has not indicated a coal phaseout target and
7 faces substantial challenges (Whitley et al. 2017; Antosiewicz et al. 2020). European efforts to phase
8 out coal indicate that appropriate financial instruments are needed (Rentier et al. 2019), and a just
9 transition for workers are important to gain broad public support and help those most affected by the
10 phaseout (Johnstone and Hielscher 2017; Osička et al. 2020).

11 **North America:** Coal use has been declining in North America. In the U.S., the primary driver has
12 been the availability of cheap shale gas and ageing coal fleets. Coal use in the US has dropped by over
13 50% since 2008 (EIA 2019). The recently announced NDC by the Biden Administration sets a 100%
14 carbon-free electricity goal by 2035 (The White House 2021), indicating a phaseout not only of
15 unabated coal electricity generation, but also of natural gas generation. As one of the two founding
16 countries of the PPCA, Canada has committed to phasing out unabated coal power by 2030
17 (Government of Canada 2018). Declining coal use in both the U.S. and Canada has decreased GHG
18 emissions, local air pollutants, and cooling water use (Harris et al. 2015; Kondash et al. 2019). However,
19 there have been concerns about social and economic consequences, particularly at the local level. For
20 instance, the U.S. has lost about 50,000 coal mining jobs between 2011 and 2021 (U.S. Bureau of Labor
21 Statistics, 2021), with significant regional and economic inequities (Bodenhamer 2016; Abraham 2017;
22 Greenberg 2018). Comprehensive social programs, such as retirement compensation, training for
23 reemployment, and business support for economic diversification, have been suggested as means to
24 support a just transition (Patrizio et al. 2018; Homagain et al. 2015; Grubert 2020).

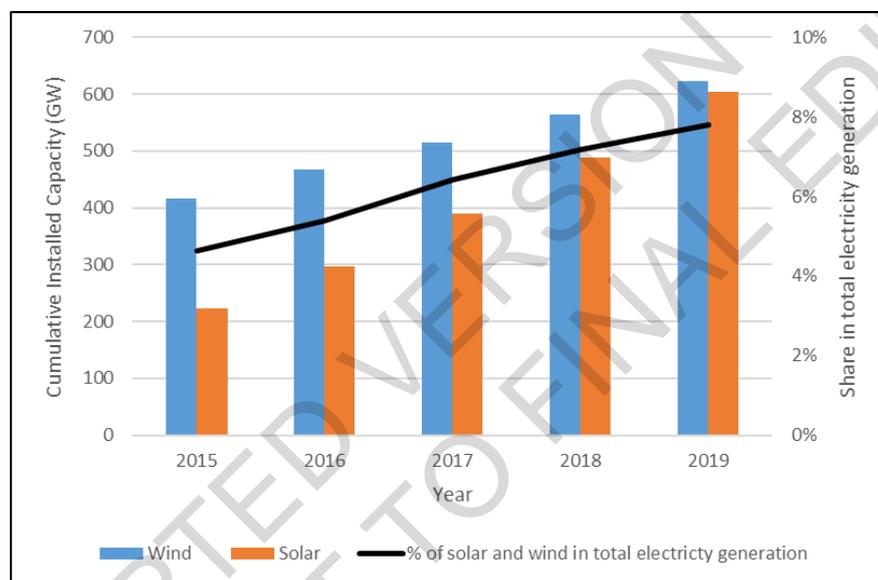

25 **Asia:** After a period of rapid growth, coal expansion has slowed in Asia, but it still the primary driver
26 of the global increase in coal demand (IEA 2020e). China's coal consumption reached a plateau under
27 policy efforts during the 13th Five-Year Plan (2016-2020), and new coal plants are being built at a slower
28 rate than previously. Both China and India have suspended and cancelled many new coal power projects
29 and retired a small set of old, dirty, inefficient coal plants (Global Energy Monitor et al. 2021; CEA
30 2019). These efforts are largely due to non-climate reasons, such air pollution and health (Singh and
31 Rao 2015; Gass et al. 2016; Peng et al. 2018; Malik et al. 2020), overcapacity (Blondeel and Van de
32 Graaf 2018), and rural electrification and renewable investments (Aklin et al. 2017; Thapar et al. 2018).
33 However, as new builds offset retirements, coal generation capacity has continued to grow in both
34 countries since 2015 (Global Energy Monitor et al. 2021). Other fast-growing Southeast Asian
35 countries, such as Indonesia, Vietnam, and Philippines have experienced strong growth in coal use (IEA
36 2020b), but an increasing number of new coal power projects are being cancelled (Littlecott et al. 2021).
37 Coal projects in these countries are decreasingly likely to proceed because they rely on international
38 financing, and China, Japan, United States, and other G7 countries have pledged to end overseas coal
39 financing (Schiermeier 2021).

40 **Africa:** New coal power projects in Africa have been declining since 2016, with only South Africa and
41 Zimbabwe currently building new coal plants and several others has planned projects (Littlecott et al.
42 2021). However, these projects also largely depend on international financing and are thus less likely
43 to be implemented (see above). In South Africa, employment in the coal mining sector has dropped by
44 almost half since the 1980s and is has been estimated to fall from 77,00 today to 22,000 to 42,000 by
45 2050 (Strambo et al. 2019; Cock 2019). Policy and financial support are essential to ensure a sustainable
46 transition for these workers (Swilling et al. 2016).

47 **[END BOX 6.2 HERE]**

1 Solar and wind energy have grown dramatically, but global shares remain low relative to other 2 sources

3 Global PV and wind electric capacities grew 170% and 70%, respectively, between 2015 and 2019.
4 Total solar and wind capacities in 2019 were 609 GW and 623 GW (Figure 6.6) and generation was
5 680 TWh yr⁻¹ and 1420 TWh yr⁻¹. The combined share of solar and wind in the total global electricity
6 generation in 2019 was around 8% (5.5% wind, 2.5% solar), up from around 5% in 2015 (IEA 2021a).
7 Since 2015, the cost of solar PVs has declined by over 60%. Offshore wind costs have fallen by 32%,
8 and onshore wind costs have fallen by 23% (Section 6.4). PV was around 99% of total solar capacity in
9 2019; onshore wind was about 95% of total wind capacity. Concentrating solar power (CSP)
10 deployment has also continued to grow, but it remains far below PV. Prior to 2010, 50% of all wind
11 capacity was in Europe, but, since then, capacity growth in Asia, led by China, has surpassed the growth
12 in Europe. As a consequence, Europe's share in global solar capacity has declined from 74% in 2010
13 to 24% in 2019. Asia's share in wind and solar capacity in 2019 was 41% and 56%, followed by Europe
14 (31% and 24%) and North America (20% and 12%) (IRENA 2021a, 2020a).

15

16 **Figure 6.6 Global solar and wind electricity installed capacities (GW) from 2015–2019 and their**
17 **combined share in total electricity generation Source: data from (IEA 2021a) IRENA, 2021).**

18 Although the shares of wind and solar remains low in the global total electricity generation, recent
19 growth rates signal the potential for these technologies to support substantial mitigation. The prospects
20 for a continuation of recent growth rates will depend on meeting key challenges such as rapidly
21 integrating wind and solar into electricity grids (Section 6.6.2, Box 6.8) and retiring fossil power plants
22 (see above).

23 Low-carbon energy sources beyond wind and solar have continued to grow

24 Low-carbon energy sources such as nuclear, hydropower, bioenergy, geothermal, marine, and fossil or
25 bioenergy with CCUS have continued to grow since 2015 (IEA, 2017; IEA, 2021a). Hydroelectric
26 power grew from 3890 TWh yr⁻¹ (14.0 EJ yr⁻¹) in 2015 to 4290 TWh yr⁻¹ (15.5 EJ yr⁻¹) in 2019, or
27 10.3%; nuclear power grew from 2570 TWh yr⁻¹ (9.3 EJ yr⁻¹) to 2790 TWh yr⁻¹ (10.1 EJ yr⁻¹), or 8.6%.
28 Hydroelectric and nuclear shares in global total electricity generation remained around 16% and 10%,
29 respectively (IEA, 2017; IEA 2021a). Global biofuels production grew from 3.2 EJ yr⁻¹ to 4.0 EJ yr⁻¹
30 from 2015 to 2019 (IEA, 2017; IEA 2021a). Bioenergy accounted for 2.4% of electricity generation in
31 2019. Geothermal energy sources produced 92 TWh yr⁻¹ (0.33 EJ yr⁻¹) of electricity in 2019, up from
32 80 TWh yr⁻¹ (0.28 EJ yr⁻¹) in 2015 (IEA, 2017; IEA 2021a). At present, there are 28 commercially

1 operating CCUS facilities with a CO₂ removal capacity of around 40 million tonnes yr⁻¹ (Mtpa). Only
2 two of these are associated with electricity production; the majority are in industrial applications. 37
3 commercial projects, accounting for about 75 Mtpa, are in various stages of development and
4 construction (Global CCS Institute 2020). The share of marine energy in the global electricity
5 generation has remained at approximately 1 TWh yr⁻¹ since 2015. In total, low- and zero-carbon
6 electricity generation technologies produced 37% of global electricity in 2019.

7 **Battery prices have dropped substantially, spurring deployment in electricity and transportation**

8 Recent years have seen a rapid decline in the cost of energy storage, particularly batteries (see Section
9 6.4.4). The price of lithium-ion batteries (LIBs) has declined by 97% in the past three decades and by
10 90% in the past decade alone (IEA 2021a; Ziegler and Trancik 2021) These declines have important
11 implications for the energy systems, most notably in supporting increased deployment of variable
12 renewable electricity (VRE) generation and electrification of the vehicle fleet.

13 Battery electricity storage has emerged as an important for supporting the flexibility of electricity
14 systems as they accommodate rising shares of VRE. Although pumped-storage hydropower systems
15 accounted for 160 GW, or over 90%, of total energy storage capacity in 2019 (IEA 2020c), battery
16 energy storage systems, led by Li-ion technology, have accounted for over 90% of new capacity
17 addition since 2015 (IRENA 2019a). In 2019, 10 GW of batteries were connected at the grid and
18 consumer level, rising from 0.6 GW in 2015 (IEA 2020c; IEA WEO 2019).

19 In California, in the U.S., legislation was passed to procure around 1.3 GW energy storage (excluding
20 pumped storage) by 2020. One of the largest utility-scale battery storage facilities (300 MW) recently
21 went online in California (Vistra Corp. 2021). Other major projects are in Florida in the US (409 MW),
22 London in the UK (320 MW), Lithuania (200 MW), Australia (150 MW), Chile (112 MW) and
23 Germany (90 MW), (Katz 2020; ARENA 2020; IRENA 2019a).

24 The drop in battery prices has also had important implications in the transportation sector. Automotive
25 LIB production rose from around 40 GWh in 2015 to 160 GWh in 2020 (32%). The stock of battery
26 electric vehicles (BEVs) grew from around 0.7 million in 2015 to 4.8 million in 2019 (IEA 2020d). The
27 number of publicly accessible vehicle chargers reached 1.3 million in 2020, 30% of which were fast
28 chargers. The average battery size of BEVs reached 67 kWh in 2019 due to consumer preferences and
29 government incentives for long-range vehicles (Agency 2020; IEA 2021b).

30 **The energy policy landscape continues to evolve**

31 The current energy sector policy landscape consists of policy mixes or policy packages, including
32 regulatory, market-based and other approaches. These mixes have evolved over time and include many
33 sectoral but also some economy-wide policy instruments, such as carbon pricing, subsidies.

34 Governments have chosen a mix of policies and institutional mechanisms that consists of regulatory
35 instruments, like efficiency and technology standards, economic instruments (e.g. carbon pricing,
36 subsidies) (Bertram et al. 2015; Martin and Saikawa 2017) and other policies, such as government
37 interventions to provide infrastructure, information policies, and voluntary actions by non-government
38 actors (Somanathan et al. 2014). In recent years, regulatory instruments to promote low-carbon
39 infrastructure have gained traction in developing countries (Finon 2019). The choice of policies has
40 depended on institutional capacities, technological maturity and other developmental priorities of
41 governments. For example, governments have favoured regulatory instruments over economic
42 instruments when there has been sufficient institutional capacity to implement and monitor the
43 regulations and standards (Hughes and Urpelainen 2015). Furthermore, institutional capacity has also
44 determined the extent of implemented measures (Adenle et al. 2017). Market conditions and
45 technological maturity are other important determinants of policy mixes being deployed in the energy

1 sector. For example, subsidies for mitigation like feed-in-tariffs (FIT) have worked best when the
2 technologies are in nascent stages of development (Gupta et al. 2019a).

3 On the other hand, market-based instruments like emission trading schemes (ETS) and auctions coupled
4 with a regulatory framework have been a favourable strategy for more mature technologies (Polzin et
5 al. 2015; Kitzing et al. 2018). FIT, tax incentives, and renewable portfolio standards - despite potentially
6 substantial program costs (Andor and Voss 2016; Abrell et al. 2019) - have played a significant role in
7 attracting foreign direct investments in the renewable sector (Wall et al. 2019). Subsidies and carbon
8 pricing have also played an important role in mainstreaming these renewable energy sources (Best and
9 Burke 2018). Recently, subsidy-free investments in renewables, e.g. wind offshore (Jansen et al. 2020),
10 backed by power purchase agreements, have gained momentum (Frankfurt School-UNEP Centre and
11 BNEF 2020). Similar considerations apply for policy mixes targeted to other sectors, for example
12 transport and buildings.

13 The role of carbon pricing is still limited though increasing. Different measures have been suggested to
14 improve the performance of the ETS, such as “price floors and caps” and other carbon pricing schemes
15 (Bataille et al. 2018; Campiglio 2016; Goulder and Morgenstern 2018). In 2020, 61 regional, national
16 and sub-national carbon pricing instruments, representing 22% of the global GHG emissions, were in
17 action or scheduled for implementation (World Bank 2019). Over 51% of emissions covered are priced
18 at less than USD 10 per tCO₂-e.. At present, however, only 5% of the global emissions covered under
19 carbon pricing initiatives are consistent with the range of carbon prices that have been suggested as
20 needed to limit warming to well below 2°C (Stiglitz and Stern 2017). Most of the carbon pricing
21 schemes have taken place in the OECD countries. The limited application of carbon pricing instruments
22 in developing, and emerging economies may be due to political economy constraints (Campiglio 2016;
23 Finon 2019). Carbon pricing had a sizeable impact on emissions, e.g. the EU ETS impacts emissions
24 from electricity in Germany (Schäfer 2019) and manufacturing in France (Colmer et al.), respectively.
25 Emission reductions could be increased with higher carbon prices and without free allocation of
26 allowances.

27 In the absence of a global comprehensive carbon price, regional regulatory policies for fossil fuels
28 supply and key demand sectors like transport, industry and buildings (Chapters 9-11), coupled with
29 regional carbon pricing instruments, were implemented to help initiating the climate actions consistent
30 with the Paris agreement (Kriegler et al. 2018). However, differences in the stringency of climate
31 regulation has triggered fear that regulation reduces the competitiveness of industries in regulated
32 countries and lead to industry re-location and “carbon leakage” (Schenker et al. 2018). In recent years,
33 however, there is little evidence of carbon leakage (Schäfer 2019; Naegele and Zaklan 2019), and even
34 positive effects of carbon pricing on efficiency have been observed (e.g., Löschel et al. 2019, for
35 German manufacturing firms, and (Germeshausen 2020) for German power plants). However, with
36 asymmetric rising carbon prices, discussions about specific policy mechanisms to address carbon
37 leakage like carbon border adjustments (Cosbey et al. 2019) were amplified. Furthermore, multiple
38 policies - often implemented by different governmental levels (national vs subnational) - interacted with
39 each other and thereby affected their environmental and economic effectiveness. Recent examples
40 include interactions of ETS with renewable support policies (e.g. Boehringer and Behrens 2015; Del
41 Rio 2017), energy efficiency policies (e.g. Wiese et al. 2018) or electricity market reform (e.g. Teng et
42 al. 2017), respectively.

43 Apart from explicit carbon pricing, various implicit carbon pricing mechanisms such as fossil fuel taxes
44 and removal of fossil fuel subsidies (see Box 6.3) and regulatory instruments are used by many countries
45 as part of their climate policies. In addition, public provision and procurement of low-carbon
46 infrastructure and technologies such as energy-efficient devices, renewable energy, and upgrades in
47 electricity grids through state-sponsored institutions and public-private partnerships have played an
48 important role in low-carbon development (e.g., (Baron 2016)).

1 [START BOX 6.3 HERE]

2 **Box 6.3 Energy Subsidies**

3 Energy subsidies continue to be widely applied. Global fossil fuel subsidies represent more than half of
4 total energy subsidies with predominantly adverse environmental, economic, and social effects (*high*
5 *confidence*).

6 Energy subsidies can be defined as policy measures in the energy sector to lower the prices for
7 consumers, raise the prices for producers, or reduce energy production costs (IEA 1999). There are
8 subsidies for fossil fuels, renewables, and energy efficiency measures. The majority of the renewable
9 subsidies are generation-based incentives for solar, wind or biomass in the form of feed-in-tariffs (FIT)
10 (Chapter 13), with total annual renewable subsidy estimates of about USD 150 billion yr⁻¹ globally
11 (IEA 2018b). Estimates of fossil fuel subsidies can vary by an order of magnitude. For the year 2017,
12 the IEA estimated fossil fuel subsidies of USD 300 billion using IEA's pre-tax, price-gap method (IEA
13 2018b), while the IMF included unpriced externalities in calculating subsidies of USD 5.2 trillion or
14 6.5% of global GDP (World Bank 2019; Coady et al. 2017, 2019). It has been estimated that the amount
15 spent on fossil fuel subsidies was around double the amount of subsidies spent on renewables (IEA
16 2018b). There are adverse environmental, economic and social consequences of fossil fuel subsidies
17 (Rentschler and Bazilian 2017). More than 75% of the distortions created by fossil fuel subsidies are
18 domestic, and studies indicate that reforming them can have substantial in-country benefits (Coady et
19 al. 2019, 2017). Some of the G-20 countries have implemented subsidy reforms based on low oil prices
20 (Jewell et al. 2018).

21 Fossil fuel subsidies most commonly pursue non-climate objectives, for example, enhanced access to
22 energy sources (*high confidence*). In some cases, these energy access subsidies have helped extend
23 modern energy sources to the poor (Kimemia and Annegarn 2016) and thereby contribute to SDG-7.
24 However, the subsidies have proven to be regressive in most cases, with little benefit reaching the poor
25 (Lockwood 2015). For example, Indonesia has introduced liquefied petroleum gas (LPG) subsidies for
26 cooking. The kerosene to LPG conversion program ("Zero Kero") was launched in 2007 and provided
27 mainly households with free initial LPG equipment and LPG at a low subsidized price (Thoday et al.
28 2018; Imelda et al. 2018b). Besides the national government, provincial governments and industry
29 played a crucial role in implementation. Overall, the LPG conversion program in Indonesia reduced
30 cooking kerosene use (Andadari et al. 2014; Imelda et al. 2018b) and GHG emissions (Permadi et al.
31 2017) with positive health effects (Thoday et al. 2018; Imelda et al. 2018b). However, the program is
32 generally viewed as regressive and has failed to reduce traditional solid fuel use (Andadari et al. 2014;
33 Toft 2016; Thoday et al. 2018). Furthermore, even if the program decreased greenhouse gas emissions
34 relative to continued kerosene use, these subsidies are still targeted at fossil fuels and contribute to GHG
35 emissions.

36 India started a large LPG program in 2015 that provided a capital cost subsidy to poor households (e.g.
37 Kar et al. 2019; Jose et al. 2018; Gould 2018). While the program has increased adoption of LPG in
38 India (e.g. Sharma et al. 2019), it has not yet achieved a sustained use of LPG and replacement of solid
39 fuels for cooking, amplifying the need for complementary policy measures (Gould 2018; Kar et al.
40 2019; Mani et al. 2020). The climate impacts of switching from biomass to LPG depend on the degree
41 of biomass combustion in stoves and the extent to which biomass originates from non-renewable
42 sources (Jose et al. 2018; Singh and Rao 2015). Barriers to increasing LPG use for cooking further
43 included abundance of solid fuels at zero (monetary) costs (Mani et al. 2020) as well as benefits of solid
44 fuels, such as maintaining the traditional taste of food and space heating in colder seasons (Gould 2018;
45 Sharma et al. 2020).

46 [END BOX 6.3 HERE]

6.4 Mitigation Options

6.4.1 Elements of Characterization

This section characterizes energy system mitigation options and discusses which factors enable and inhibit their implementation. We touch on a broad range of factors that may enable and inhibit the implementation of mitigation options by considering six dimensions that affect their feasibility (Table 6.1, Annex II.11). The assessment aims to identify which mitigation options can be readily implemented and which face barriers that would need to be overcome before they can be deployed at scale.

Table 6.1 Dimensions and indicators to assess the barriers and enablers of implementing mitigation options in low carbon energy systems.

Metric	Indicators
Geophysical: Are the required resources available?	Physical potential: physical constraints to implementation Geophysical resources (including geological storage capacity): availability of resources needed for implementation Land use: claims on land where an option would be implemented
Environmental-ecological: What are the wider environmental and ecological impacts of the option?	Air pollution: increase or decrease in air pollutants, such as NH ₄ , CH ₄ and fine dust Toxic waste, mining, ecotoxicity and eutrophication Water quantity and quality: changes in the amount of water available for other uses Biodiversity: changes in conserved primary forest or grassland that affect biodiversity, and management to conserve and maintain land carbon stocks
Technological: Can the required option be upscaled soon?	Simplicity: is the option technically simple to operate, maintain and integrate Technology scalability: can the option be scaled up, technically Maturity and technology readiness: R&D and time needed to implement the option
Economic: What economic conditions can support or inhibit the implementation of the option?	Costs in 2030 and in the long term: investment costs, costs in USD tCO ₂ -eq ⁻¹ Employment effects and economic growth: decrease or increase in jobs and economic welfare
Socio-cultural: What social conditions could support or inhibit acceptance, adoption, and use of the option?	Public acceptance: the extent to which the public supports the option and will change their behaviour accordingly Effects on health and wellbeing Distributional effects: equity and justice across groups, regions, and generations, including energy, water, and food security and poverty
Institutional: What institutional conditions could support or inhibit the implementation of the option?	Political acceptance: the extent to which politicians support the option Institutional capacity and governance, cross-sectoral coordination: capability of institutions to implement and handle the option Legal and administrative capacity

6.4.2 Energy Sources and Energy Conversion

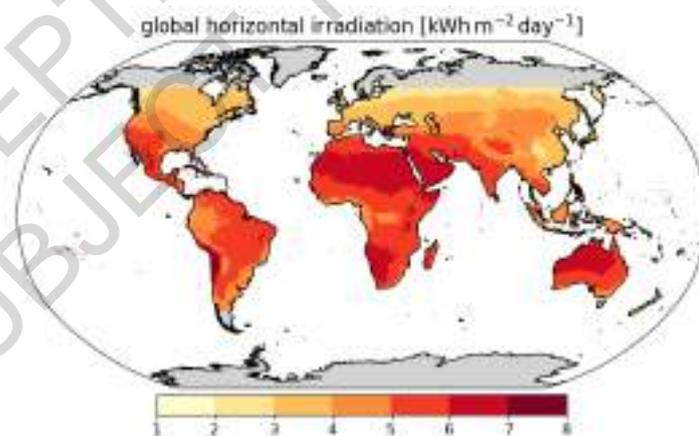

6.4.2.1 Solar Energy

Solar PV is increasingly competitive with other forms of electricity generation and is the low-cost option in many applications (*high confidence*). Costs have declined by 62% since 2015 (*high confidence*) and

1 are anticipated to decline by an additional 16% by 2030 if current trends continue (*low confidence*,
2 *medium evidence*). Key areas for continued improvement are grid integration and non-module costs for
3 rooftop systems (*high confidence*). Most deployment is now utility-scale (*high confidence*). Global
4 future potential is not limited by solar irradiation, but by grid integration needed to address its
5 variability, as well as access to finance, particularly in developing countries (*high confidence*).

6 The global technical potential of direct solar energy far exceeds that of any other renewable energy
7 resource and is well beyond the total amount of energy needed to support ambitious mitigation over the
8 current century (*high confidence*). Estimates of global solar resources have not changed since AR5
9 (Lewis 2007; Besharat et al. 2013) even as precision and near-term forecasting have improved (Abreu
10 et al. 2018; Diagne et al. 2013). Approximately 120,000 TW of sunlight reaches the Earth's surface
11 continuously, almost 10,000 times average world energy consumption; factoring in competition for
12 land-use leaves a technical potential of about 300 PWh yr⁻¹ (1080 EJ yr⁻¹) for solar PV, roughly double
13 current consumption (Dupont et al. 2020). The technical potential for concentrating solar power (CSP)
14 is estimated to be 45–82 PWh yr⁻¹ (162–295 EJ yr⁻¹) (Dupont et al. 2020). Areas with the highest solar
15 irradiation are western South America; northern, eastern and southwestern Africa; and the Middle East
16 and Australia (Figure 6.7) (Prävālie et al. 2019).

17 In many parts of the world, the cost of electricity from PV is below the cost of electricity generated
18 from fossil fuels, and in some, it is below the operating costs of electricity generated from fossil fuels
19 (*high confidence*). The weighted average cost of PV in 2019 was USD 68 MWh⁻¹, near the bottom of
20 the range of fossil fuel prices (IRENA 2019b). The cost of electricity from PV has fallen by 89% since
21 2000 and 69% since AR5, at a rate of –16% per year. The 5:95 percentile range for PV in 2019 was
22 USD 52–190 MWh⁻¹ (IRENA 2021b). Differences in solar insolation, financing costs, equipment
23 acquisition, installation labour, and other sources of price dispersion explain this range (Nemet et al.
24 2016; Vartiainen et al. 2020) and scale. For example, in India, rooftop installations cost 41% more than
25 utility-scale installations, and commercial-scale costs are 39% higher than utility-scale. Significant
26 differences in regional cost persist (Kazhamiaka et al. 2017; Vartiainen et al. 2020), with particularly
27 low prices in China, India, and parts of Europe. Globally, the range of global PV costs is quite similar
28 to the range of coal and natural gas prices.

29

30 **Figure 6.7 Distribution of the daily mean global horizontal irradiation (GHI, kWh m⁻² day⁻¹).**

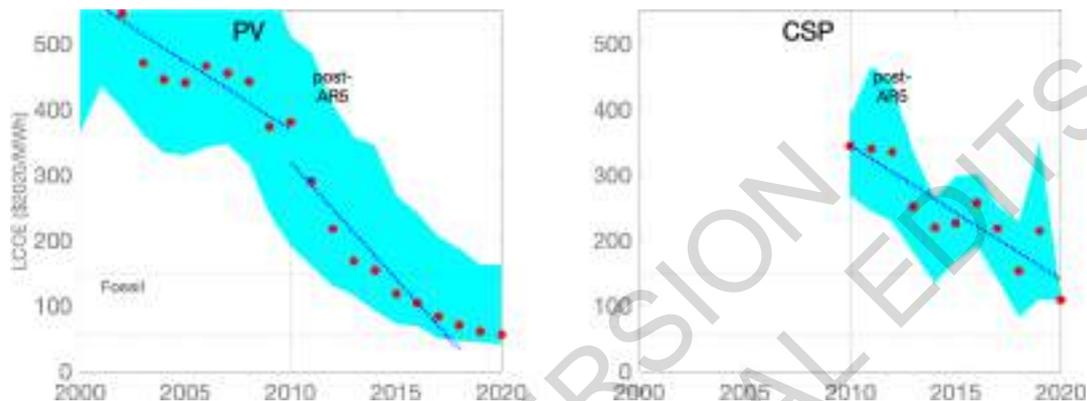

31 Source: Global Solar Atlas (ESMAP 2019)

32 PV costs (Figure 6.8) have fallen for various reasons: lower silicon costs, automation, lower margins,
33 automation, higher efficiency, and a variety of incremental improvements (Fu et al. 2018; Green 2019)
34 (Chapter 16). Increasingly, the costs of PV electricity are concentrated in the installation and related
35 “soft costs” (marketing, permitting) associated with the technology rather than in the modules
36 themselves, which now account for only 30% of installed costs of rooftop systems (O’Shaughnessy et

1 al. 2019; IRENA 2021b). Financing costs are a significant barrier in developing countries (Ondraczek
2 et al. 2015) and growth there depends on access to low-cost finance (Creutzig et al. 2017).

3 CSP costs have also fallen, albeit at about half the rate of PV: -9% yr^{-1} since AR5. The lowest prices
4 for CSP are now competitive with more expensive fossil fuels, although the average CSP cost is above
5 the fossil range. Other data sources put recent CSP costs at USD 120 MWh^{-1} , in the middle of the fossil
6 range (Lilliestam et al. 2020). Continuing the pace of change since AR5 will make CSP competitive
7 with fossil fuels in sunny locations, although it will be difficult for CSP to compete with PV and even
8 hybrid PV-battery systems. CSP electricity can be more valuable, however, because CSP systems can
9 store heat longer than PV battery systems.

10

11

13 **fuel LCOE indicated as dashed lines USD 50–177 MWh^{-1} . Linear fit lines were applied to data for AR4–**
14 **AR5 and post-AR5 (2012). Red dots are capacity-weighted global averages for utility-scale installations.**
15 **The blue area shows the range between the 5th and 95th percentile in each year. Data: (IRENA 2021b).**

16 The share of total costs of PV-intensive electricity systems attributed to integration costs has been
17 increasing but can be reduced by enhancing grid flexibility (Section 6.4.3, 6.6, Box 6.8) (*high*
18 *confidence*). The total costs of PV include grid integration, which varies tremendously depending on
19 PV's share of electricity, other supply sources like wind, availability of storage, transmission capacity,
20 and demand flexibility (Heptonstall and Gross 2020). Transmission costs can add USD 1–10 MWh^{-1} or
21 3–33% to the cost of utility-scale PV (Gorman et al. 2019). Distributed (rooftop) PV involves a broader
22 set of grid integration costs - including grid reinforcement, voltage balancing and control, and impacts
23 on other generations - and has a larger range of integration costs from USD 2–25 MWh^{-1} , which is -3%
24 to $+37\%$ (Hirth et al. 2015; Wu et al. 2015; Gorman et al. 2019). Other meta-analyses put the range at
25 USD 1–7 MWh^{-1} in the USA (Luckow et al.; Wiser et al. 2017), while a comprehensive study put the
26 range at USD 12–18 MWh^{-1} for up to 35% renewables and USD 25–46 MWh^{-1} above 35% renewables
27 (Heptonstall and Gross 2020). Increased system flexibility can reduce integration costs of solar energy
28 (Wu et al. 2015) including storage, demand response, sector-coupling (Bogdanov et al. 2019; Brown et
29 al. 2018), and increase complementarity between wind and solar (Heide et al. 2010) (Sections 6.4.3 and
30 6.4.4).

31 Since solar PV panels have very low-operating costs, they can, at high penetrations and in the absence
32 of adequate incentives to shift demand, depress prices in wholesale electricity markets, making it
33 difficult to recoup investment and potentially reducing incentives for new installations (Hirth 2013;
34 Millstein et al. 2021). Continued cost reductions help address this issue of value deflation, but only
35 partially. Comprehensive solutions depend on adding transmission and storage (Das et al. 2020) and,
36 more fundamentally, adjustments to electricity market design (Bistline and Young 2019; Roques and
37 Finon 2017).

1 The most important ways to minimize PVs impact on the environment lie in recycling materials at end
2 of life and making smart land-use decisions (*medium confidence*). A comprehensive assessment of PVs
3 environmental impacts requires life-cycle analysis (LCA) of resource depletion, land-use, ecotoxicity,
4 eutrophication, acidification, ozone, and particulates, among other things (Mahmud et al. 2018). LCA
5 studies show that solar PVs produce far less CO₂ per unit of electricity than fossil generation, but PV
6 CO₂ emissions vary due to the carbon intensity of manufacturing energy and offset electricity (Grant
7 and Hicks 2020). Concerns about systemic impacts, such as reducing the Earth's albedo by covering
8 surfaces with dark panels, have shown to be trivial compared to the mitigation benefits (Nemet 2009)
9 (Box 6.7). Even though GHG LCA estimates span a considerable range of 9–250 gCO₂ kWh⁻¹ (de Wild-
10 Scholten 2013; Kommalapati et al. 2017), recent studies that reflect higher efficiencies and
11 manufacturing improvements find lower life-cycle emissions, including a range of 18–60 gCO₂ kWh⁻¹
12 (Wetzel and Borchers 2015) and central estimates of 80 gCO₂ kWh⁻¹ (Hou et al. 2016), 50 gCO₂ kWh⁻¹
13 (Nugent and Sovacool 2014), and 20 gCO₂ kWh⁻¹ (Louwen et al. 2016). These recent values are an
14 order of magnitude lower than coal and natural gas and further decarbonization of the energy system
15 will make them lower still. Thin films and organics produce half the life-cycle emissions of silicon
16 wafer PV, mainly because they use less material (Lizin et al. 2013; Hou et al. 2016). Novel materials
17 promise even lower environmental impacts, especially with improvements to their performance ratios
18 and reliability (Gong et al. 2015; Muteri et al. 2020). Higher efficiencies, longer lifetimes, sunny
19 locations, less carbon intensive manufacturing inputs, and shifting to thin films could reduce future life-
20 cycle impacts.

21 Another environmental concern with large PV power plants is the conversion of land to collect solar
22 energy (Hernandez et al. 2015). Approximately 2 hectares of land are needed for 1 MW of solar
23 electricity capacity (Kabir et al. 2018; Perpiña Castillo et al. 2016); at 20% efficiency, a square of PV
24 panels of 550 km by 550 km, comprising 0.2% of Earth's land area, could meet global energy demand.
25 Land conversion can have local impacts, especially near cities and where land used for solar competes
26 with alternative uses, such as agriculture. Large installations can also adversely impact biodiversity
27 (Hernandez et al. 2014), especially where the above ground vegetation is cleared and soils are typically
28 graded. Landscape fragmentation creates barriers to the movement of species. However, a variety of
29 means have emerged to mitigate land use issues. Substitution among renewables can reduce land
30 conversion (Tröndle and Tröndle 2020). Solar can be integrated with other uses through 'agrivoltaics'
31 (the use of land for both agriculture and solar production) (Dupraz et al. 2011) by, for example, using
32 shade-tolerant crops (Dinesh and Pearce 2016). Combining solar and agriculture can also create income
33 diversification, reduced drought stress, higher solar output due to radiative cooling, and other benefits
34 (Elamri et al. 2018; Hassanpour Adeh et al. 2018; Barron-Gafford et al. 2019). PV installations floating
35 on water also avoid land-use conflicts (Sahu et al. 2016; Lee et al. 2020), as does dual-use infrastructure,
36 such as landfills (Jäger-Waldau 2020) and reservoirs where evaporation can also be reduced (Farfan
37 and Breyer 2018).

38 Material demand for PV will likely increase substantially to limit warming to well below 2°C, but PV
39 materials are widely available, have possible substitutes, and can be recycled (*medium confidence*) (Box
40 6.4). The primary materials for PV are silicon, copper, glass, aluminium, and silver, the costliest being
41 silicon and glass being the most essential by mass, at 70%. None of these materials is considered to be
42 either critical or potentially scarce (IEA 2020e). Thin-film cells, such as amorphous silicon, cadmium
43 telluride and copper indium gallium diselenide (CIGS), use far less material (though they use more
44 glass), but account for less than 10% of the global solar market. Other thin-films, such as those based
45 on perovskites, organic solar cells, or earth-abundant, non-toxic materials such as kesterites, either on
46 their own, or layered on silicon, could further reduce material use per energy produced. (Box 6.4)

47 After a typical lifetime of 30 years of use, PV modules can be recycled to prevent environmental
48 contamination from the toxic materials within them, reusing valuable materials and avoiding waste

1 accumulation. Recycling allows the reuse of nearly all - 83% in one study - of the components of PV
2 modules, other than plastics (Ardente et al. 2019) and would add less than 1% to lifecycle GHG
3 emissions (Latunussa et al. 2016). Glass accounts for 70% of the mass of a solar cell and is relatively
4 easy to recycle. Recycling technology is advancing, but the scale and share of recycling is still small
5 (Li et al. 2020d). By 2050, however, end-of-life PV could total 80 MT and comprise 10% of global
6 electronic waste (Stolz and Frischknecht 2017), although most of it is glass. IEA runs a program to
7 enable PV recycling by sharing best practices to minimise recycling life cycle impacts. Ensuring that a
8 substantial amount of panels are recycled at end of life will likely require policy incentives, as the
9 market value of the recovered materials, aside from aluminium and copper, is likely to be too low to
10 justify recycling on its own (Deng et al. 2019). A near-term priority is maximizing the recovery of
11 silver, silicon, and aluminium, the most valuable PV material components (Heath et al. 2020).

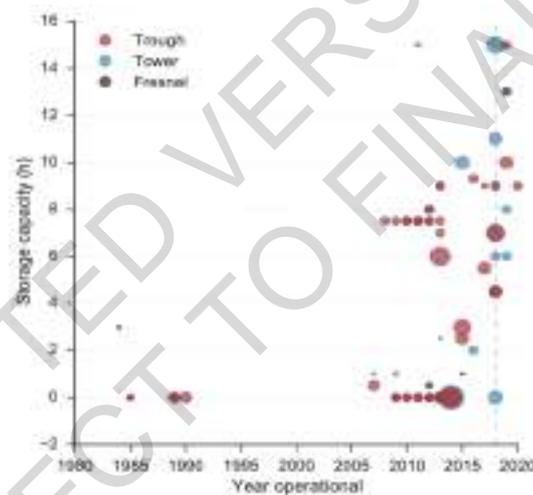

12 Many alternative PV materials are improving in efficiency and stability, providing longer-term
13 pathways for continued PV costs reductions and better performance (*high confidence*). While solar PV
14 based on semi-conductors constructed from wafers of silicon still captures 90% of the market, new
15 designs and materials have the potential to reduce costs further, increase efficiency, reduce resource
16 use, and open new applications. The most significant technological advance within silicon PV in the
17 past ten years has been the widespread adoption of the passivated emitter and rear cell (PERC) design
18 (Green 2015), which now accounts for the majority of production. This advance boosts efficiency over
19 traditional aluminium backing by increasing reflectivity within the cell and reducing electron hole
20 recombination (Blakers 2019). Bifacial modules increase efficiency by using reflected light from the
21 ground or roof on the backside of modules (Guerrero-Lemus et al. 2016). Integrating PV into buildings
22 can reduce overall costs and improve building energy performance (Shukla et al. 2016). Concentrating
23 PV uses lenses or mirrors that collect and concentrate light onto high efficiency PV cells (Li et al.
24 2020a). Beyond crystalline silicon, thin films of amorphous silicon, cadmium telluride, and copper
25 indium gallium selenide (among others) have the potential for much lower costs while their efficiencies
26 have increased (Green et al. 2019). Perovskites, inexpensive and easy to produce crystalline structures,
27 have increased in efficiency by a factor of six in the past decade; the biggest challenge is light-induced
28 degradation as well as finding lead-free efficient compounds or establish lead recycling at the end of
29 the life cycle of the device (Petrus et al. 2017; Chang et al. 2018; Wang et al. 2019b; Zhu et al. 2020).
30 Organic solar cells are made of carbon-based semiconductors like the ones found in the displays made
31 from organic light emitting diodes (OLEDs) and can be processed in thin films on large areas with
32 scalable and fast coating processes on plastic substrates. The main challenges are raising the efficiency
33 and improving their lifetime (Ma et al. 2020; Riede et al. 2021). Quantum dots, spherical semi-
34 conductor nano-crystals, can be tuned to absorb specific wavelengths of sunlight giving them the
35 potential for high efficiency with very little material use (Kramer et al. 2015). A common challenge for
36 all emerging solar cell technologies is developing the corresponding production equipment. Hybrids of
37 silicon with layers of quantum dots and perovskites have the potential to take advantage of the benefits
38 of all three, although those designs require that these new technologies have stability and scale that
39 match those of silicon (Palmstrom et al. 2019; Chang et al. 2017). This broad array of alternatives to
40 making PV from crystalline silicon offer realistic potential for lower costs, reduced material use, and
41 higher efficiencies in future years (Victoria et al. 2021).

42 Besides PV, alternative solar technologies exist, including CSP, which can provide special services in
43 high-temperature heat and diurnal storage, even if it is more costly than PV and its potential for
44 deployment is limited. CSP uses reflective surfaces, such as parabolic mirrors, to focus sunlight on a
45 receiver to heat a working fluid, which is subsequently transformed into electricity (Islam et al. 2018).
46 Solar heating and cooling are also well established technologies, and solar energy can be utilized
47 directly for domestic or commercial applications such as drying, heating, cooling, and cooking (Ge et
48 al. 2018). Solar chimneys, still purely conceptual, heat air using large transparent greenhouse-like
49 structures and channel the warm air to turbines in tall chimneys (Kasaeian et al. 2017). Solar energy

1 can also be used to produce solar fuels, for example, hydrogen or synthetic gas (syngas) (Nocera 2017;
 2 Montoya et al. 2016; Detz et al. 2018). In addition, research proceeds on space-based solar PV, which
 3 takes advantage of high insolation and a continuous solar resource (Kelzenberg et al. 2018), but faces
 4 the formidable obstacle of developing safe, efficient, and inexpensive microwave or laser transmission
 5 to the Earth's surface (Yang et al. 2016). CSP is the most widely adopted of these alternative solar
 6 technologies.

7 Like PV, CSP facilities can deliver large amounts of power (up to 200 MW per unit) and maintain
 8 substantial thermal storage, which is valuable for load balancing over the diurnal cycle (McPherson et
 9 al. 2020). However, unlike PV, CSP can only use direct sunlight, constraining its cost-effectiveness to
 10 North Africa, the Middle East, Southern Africa, Australia, the Western U.S., parts of South America
 11 (Peru, Chile), the Western part of China, and Australia (Deng et al. 2015; Dupont et al. 2020). Parabolic
 12 troughs, central towers and parabolic dishes are the three leading solar thermal technologies (Wang et
 13 al. 2017d). Parabolic troughs represented approximately 70% of new capacity in 2018 with the balance
 14 made up by central tower plants (Islam et al. 2018). Especially promising research directions are on
 15 tower-based designs that can achieve high temperatures, useful for industrial heat and energy storage
 16 (Mehos et al. 2017), and direct steam generation designs (Islam et al. 2018). Costs of CSP have fallen
 17 by nearly half since AR5 (Figure 6.8) albeit at a slower rate than PV. Since AR5, almost all new CSP
 18 plants have storage (Figure 6.9)(Thonig 2020).

19

20

21 **Figure 6.9 CSP plants by storage capacity in hours (vertical), year of installation (horizontal), and size of**
 22 **plant in MW (circle size). Since AR5, almost all new CSP plants have storage (Thonig 2020). Data**
 23 **source: <https://csp.guru/metadata.html>.**

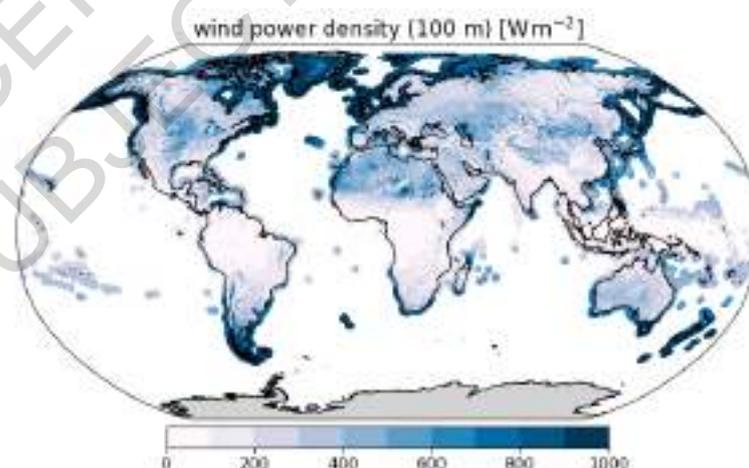

24 Solar energy elicits favourable public responses in most countries (*high confidence*) (Bessette and Arvai
 25 2018; Hanger et al. 2016; Jobin and Siegrist 2018; Ma et al. 2015; McGowan and Sauter 2005; Hazboun
 26 and Boudet 2020; Roddis et al. 2019). Solar energy is perceived as clean and environmentally friendly
 27 with few downsides (Faiers and Neame 2006; Whitmarsh et al. 2011b). Key motivations for
 28 homeowners to adopt photovoltaic systems are expected financial gains, environmental benefits, the
 29 desire to become more self-sufficient, and peer expectations (Korcaj et al. 2015; Palm 2017; Vasseur
 30 and Kemp 2015). Hence, the observability of photovoltaic systems can facilitate adoption (Boudet
 31 2019). The main barriers to the adoption of solar PV by households are its high upfront costs, aesthetics,
 32 landlord-tenant incentives, and concerns about performance and reliability (Whitmarsh et al. 2011b;
 33 Vasseur and Kemp 2015; Faiers and Neame 2006).

1 6.4.2.2 Wind Energy

2 Wind power is increasingly competitive with other forms of electricity generation and is the low-cost
3 option in many applications (*high confidence*). Costs have declined by 18% and 40% on land and
4 offshore since 2015 (*high confidence*), and further reductions can be expected by 2030 (*medium*
5 *confidence*). Critical areas for continued improvement are technology advancements and economies of
6 scale (*high confidence*). Global future potential is primarily limited by onshore land availability in wind
7 power-rich areas, lack of supporting infrastructure, grid integration, and access to finance (especially in
8 developing countries) (*high confidence*).

9 Energy from wind is abundant, and the estimated technical potentials surpass the total amount of energy
10 needed to limit warming to well below 2°C (*high confidence*). Recent global estimates of potentially
11 exploitable wind energy resource are in the range of 557–717 PWh yr⁻¹ (2005–2580 EJ yr⁻¹) (Eurek et
12 al. 2017; Bosch et al. 2017, 2018; McKenna et al. 2022), or 20–30 times the 2017 global electricity
13 demand. Studies have suggested that ‘bottom-up’ approaches may overestimate technical potentials
14 (Miller et al. 2015; Kleidon and Miller 2020). But even in the most conservative ‘top-down’ approaches,
15 the technical wind potential surpasses the amount needed to limit warming to well below 2°C (Bosch
16 et al. 2017; Eurek et al. 2017; Volker et al. 2017). The projected climate change mitigation from wind
17 energy by 2100 ranges from 0.3°C–0.8°C depending on the precise socio-economic pathway and wind
18 energy expansion scenario followed (Barthelmie and Pryor 2021). Wind resources are unevenly
19 distributed over the globe and by time of the year (Petersen and Troen 2012), but potential hotspots
20 exist on every continent (Figure 6.10) as expressed by the wind power density (a quantitative measure
21 of wind energy available at any location). Technical potentials for onshore wind power vary
22 considerably, often because of inconsistent assessments of suitability factors (McKenna et al. 2020).
23 The potential for offshore wind power is larger than for onshore because offshore wind is stronger and
24 less variable (Bosch et al. 2018). Offshore wind is more expensive, however, because of higher costs
25 for construction, maintenance, and transmission. Wind power varies at a range of time scales, from
26 annual to sub-seconds; the effects of local short-term variability can be offset by power plant control,
27 flexible grid integration, and storage (Barra et al. 2021) (section 6.4.3). In some regions, interannual
28 variations in wind energy resources could be important for optimal power system design (Wohland et
29 al. 2019a; Coker et al. 2020).

30

31

32 **Figure 6.10 Mean wind power density [W m⁻²] at 100 m above ground level over land and within 100 km**
33 **of the coastline. Source: Global Wind Atlas <https://globalwindatlas.info/>**

34 Wind power cost reductions (Figure 6.11) are driven mainly by larger capacity turbines, larger rotor
35 diameters and taller hub heights - larger swept areas increase the energy captured and the capacity

1 factors for a given wind speed; taller towers provide access to higher wind speeds (Beiter et al. 2021).
2 All major onshore wind markets have experienced rapid growth in both rotor diameter (from 81.2 m in
3 2010 to 120 m in 2020) (IRENA 2021b), and average power ratings (from 1.9 MW in 2010 to 3 MW
4 in 2020). The generation capacity of offshore wind turbines grew by a factor of 3.7 in less than two
5 decades, from 1.6 MW in 2000 to 6 MW in 2020 (Wiser et al. 2021). Floating foundations could
6 revolutionize offshore wind power by tapping into the abundant wind potential in deeper waters. This
7 technology is particularly important for regions where coastal waters are too deep for fixed-bottom
8 wind turbines. Floating wind farms potentially offer economic and environmental benefits compared
9 with fixed-bottom designs due to less-invasive activity on the seabed during installation, but the long-
10 term ecological effects are unknown and meteorological conditions further offshore and in deeper
11 waters are harsher on wind turbine components (IRENA 2019c). A radical new class of wind energy
12 converters has also been conceived under the name of Airborne Wind Energy Systems that can harvest
13 strong, high-altitude winds (typically between 200–800m), which are inaccessible by traditional wind
14 turbines (Cherubini et al. 2015). This technology has seen development and testing of small devices
15 (Watson et al. 2019).

16 Wind capacity factors have increased over the last decade (Figure 6.11). The capacity factor for onshore
17 wind farms increased from 27% in 2010 to 36% in 2020 (IRENA 2021a). The global average offshore
18 capacity factor has decreased from a peak of 45% in 2017. This has been driven by the increased share
19 of offshore development in China, where projects are often near-shore and use smaller wind turbines
20 than in Europe (IRENA 2021b). Improvements in capacity factors also come from increased
21 functionality of wind turbines and wind farms. Manufacturers can adapt the wind turbine generator to
22 the wind conditions. Turbines for windy sites have smaller generators and smaller specific capacity per
23 rotor area, and therefore operate more efficiently and reach full capacity for a longer time period (Rohrig
24 et al. 2019).

25 Electricity from onshore wind is less expensive than electricity generated from fossil fuels in a growing
26 number of markets (*high confidence*). The global average LCOE onshore declined by 38% from 2010
27 to 2020 (Figure 6.11), reaching USD 0.039 kWh⁻¹. However, the decrease in cost varies substantially
28 by region. Since 2014, wind costs have declined more rapidly than the majority of experts predicted
29 (Wiser et al. 2021). New modelling projects onshore wind LCOE of USD .037 kWh⁻¹ by 2030
30 (Junginger et al. 2020a), and additional reductions of 37–39% have been predicted by 2050 (Wiser et
31 al. 2021). The future cost of offshore wind is more uncertain because other aspects besides increases in
32 capacity factors influence the cost (Junginger et al. 2020b).

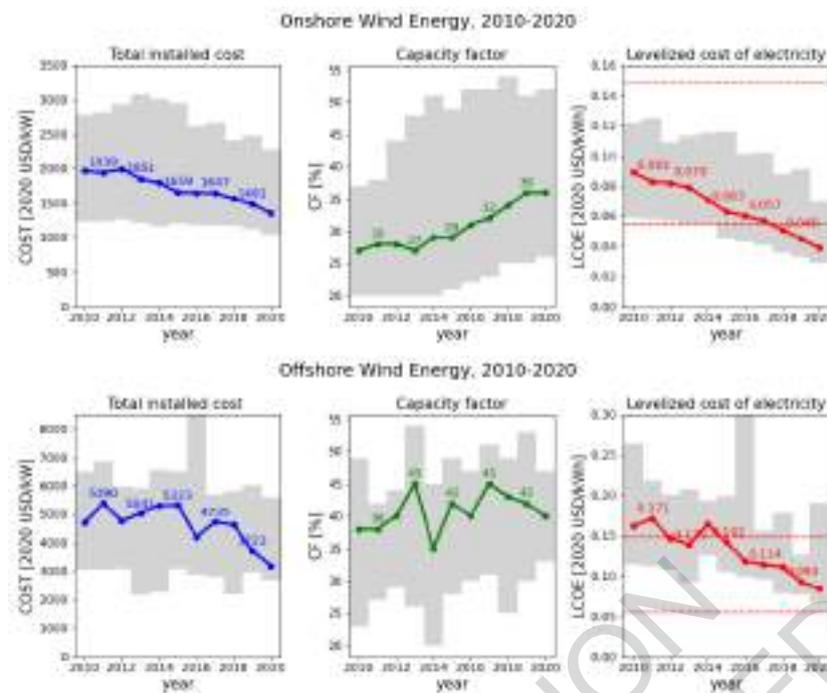

Figure 6.11 Global weighted average total installed costs, capacity factors, and LCOE for onshore (top) and offshore (bottom) wind power of existing power plants per year (2010-2020). The shaded area represents the 5th and 95th percentiles and the red dashed line represents the fossil fuel cost range.

Source: (IRENA 2021a)

The cost of the turbine (including the towers) makes up the largest component of wind's LCOE. Total installed costs for both onshore and offshore wind farms have decreased since 2015 (Figure 6.11), but the total installed costs for onshore wind projects are very site- and market-specific, as reflected in the range of LCOEs. China, India, and the U.S. have experienced the largest declines in total installed costs. In 2020, typical country-average total installed costs were around USD 1150 kW⁻¹ in China and India, and between USD 1403–2472 kW⁻¹ elsewhere (IRENA 2021b). Total installed costs of offshore wind farms declined by 12% between 2010 and 2020. But, because some of the new offshore wind projects have moved to deeper waters and further offshore, there are considerable year-to-year variations in their price (IRENA 2021b). Projects outside China in recent years have typically been built in deeper waters (10–55 m) and up to 120 km offshore, compared to around 10 m in 2001–2006, when distances rarely exceeded 20 km. With the shift to deeper waters and sites further from ports, the total installed costs of offshore wind farms rose, from an average of around USD 2500 kW⁻¹ in 2000 to around USD 5127 kW⁻¹ by 2011–2014, before falling to around USD 3185 kW⁻¹ in 2020 (IRENA 2020a). The full cost of wind power includes the transmission and system integration costs (Sections 6.4.3, 6.4.6. A new technology in development is the co-location of wind and solar PV power farms, also known as hybrid power plants. Co-locating wind, solar PV, and batteries can lead to synergies in electricity generation, infrastructure, and land usage, which may lower the overall plant cost compared to single technology systems (Lindberg et al. 2021).

Wind power plants pose relatively low environmental impact, but sometimes locally significant ecological effects (*high confidence*). The environmental impact of wind technologies, including CO₂ emissions, is concentrated in the manufacturing, transport, and building stage and in disposal as the end-of-life of wind turbines is reached (Liu and Barlow 2017; Mishnaevsky 2021). The operation of wind turbines produces no waste or pollutants. The LCA for wind turbines is strongly influenced by the operating lifetime, quality of wind resources, conversion efficiency, and size of the wind turbines

1 (Laurent et al. 2018; Kaldellis and Apostolou 2017). But, all wind power technologies repay their
2 carbon footprint in less than a year (Bonou et al. 2016).

3 Wind farms can cause local ecological impacts, including impacts on animal habitat and movements,
4 biological concerns, bird and bat fatalities from collisions with rotating blades, and health concerns
5 (Morrison and Sinclair 2004). The impacts on animal habitats and collisions can be resolved or reduced
6 by selectively stopping some wind turbines in high risk locations, often without affecting the
7 productivity of the wind farm (de Lucas et al. 2012). Many countries now require environmental studies
8 of impacts of wind turbines on wildlife prior to project development, and, in some regions, shutdowns
9 are required during active bird migration (de Lucas et al. 2012). Offshore wind farms can also impact
10 migratory birds and other sea species (Hooper et al. 2017). Floating foundations pose lower
11 environmental impacts at build stage (IRENA 2019c), but their cumulative long-term impacts are
12 unclear (Goodale and Milman 2016). Recent studies find weak associations between wind farm noise
13 and measures of long-term human health (Poulsen et al. 2018a,b, 2019a,b).

14 Public support for onshore and particularly offshore wind energy is generally high, although people
15 may oppose specific wind farm projects (*high confidence*) (e.g., Rand and Hoen 2017; Steg 2018; Bell
16 et al. 2005; Batel and Devine-Wright 2015). People generally believe that wind energy is associated
17 with environmental benefits and that it is relatively cheap. Yet, some people believe wind turbines can
18 cause noise and visual aesthetic pollution, threaten places of symbolic value (Russell et al. 2020;
19 Devine-Wright and Wiersma 2020), and have adverse effects on wildlife (Bates and Firestone 2015),
20 which challenges public acceptability (Rand and Hoen 2017). Support for local wind projects is higher
21 when people believe fair decision-making procedures have been implemented (Aitken 2010a; Dietz and
22 Stern 2008). Evidence is mixed whether distance from wind turbines or financial compensation
23 increases public acceptability of wind turbines (Hoen et al. 2019; Rand and Hoen 2017; Cass et al.
24 2010; Rudolph et al. 2018). Offshore wind farms projects have higher public support, but can also face
25 resistance (Rudolph et al. 2018; Bidwell 2017).

26 Common economic barriers to wind development are high initial cost of capital, long payback periods,
27 and inadequate access to capital. Optimal wind energy expansion is most likely to occur in the presence
28 of a political commitment to establish, maintain, and improve financial support instruments,
29 technological efforts to support a local supply chains, and grid investments integrate VRE electricity
30 (Diógenes et al. 2020).

31 [START BOX 6.4 HERE]

32 **Box 6.4 Critical strategic minerals and a low-carbon energy system transition**

33 The secure supply of many metals and minerals (e.g., cobalt, copper, lithium, and rare earth elements,
34 REEs) is critical to supporting a low-emissions energy system transition (Sovacool et al. 2020). A low-
35 carbon energy system transition will increase the demand for these minerals to be used in technologies
36 like wind turbines, PV cells, and batteries (World Bank 2020). Reliance on these minerals has raised
37 questions about possible constraints to a low-carbon energy system transition, including supply chain
38 disruptions (Chapter 10.6). Concerns have also been raised about mining for these materials, which
39 frequently results in severe environmental impacts (Sonter et al. 2020), and metal production itself is
40 energy-intensive and difficult to decarbonize (Sovacool et al. 2020).

41 Wind energy depends on two critical REEs - neodymium and dysprosium - used in magnets in high-
42 performance generators (Pavel et al. 2017; Li et al. 2020b). Silicon-wafer-based solar PV, which
43 accounted for 95% of PV production in 2020, does not use REEs but utilizes aluminium, copper, and
44 silver (IEA 2021a). Lithium, nickel, cobalt, and phosphorous are used in batteries. Many critical
45 minerals are used in EVs, including aluminium and copper in manufacturing the necessary EV charging
46 infrastructure, and neodymium in permanent magnet motors.

1 These strategic minerals are found in a limited number of countries, and concerns have been raised that
2 geopolitical factors could disrupt the supply chain necessary for a low-carbon energy system transition.
3 However, excluding cobalt and lithium, no single country holds more than a third of the world reserves.
4 The known supply of some strategic minerals is still close to 600 years at current levels of demand (BP
5 2020), but increased demand would cut more quickly into supplies.

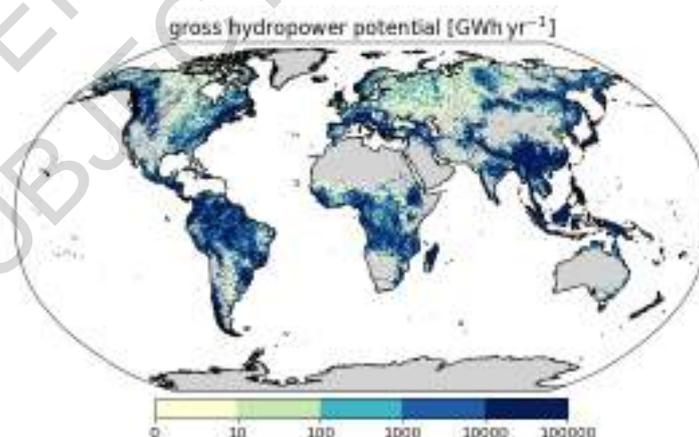

6 There are alternatives to the strategic minerals currently used to support a low-carbon transition. Wind
7 turbines can be manufactured without permanent magnets to reduce the need for strategic minerals, but
8 the production costs are higher, and their efficiency is reduced (Månberger and Stenqvist 2018).
9 Alternatives to silicon, such as thin films, could be used to produce PVs. Thin-films use much less
10 material than silicon-based PV, but they contain other potentially critical metals like tellurium,
11 cadmium, and gallium. Alternatives to lithium-ion batteries, such as sodium-ion batteries, are becoming
12 more practical and feasible (Sovacool et al. 2020).

13 **[END BOX 6.4HERE]**

14 **6.4.2.3 Hydroelectric Power**

15 Hydropower is technically mature, proved worldwide as a primary source of renewable electricity, and
16 may be used to balance electricity supply by providing flexibility and storage. The LCOE of
17 hydropower is lower than the cheapest new fossil fuel-fired option. However, the future mitigation
18 potential of hydropower depends on minimizing environmental and social impacts during the planning
19 stages, reducing the risks of dam failures, and modernising the aging hydropower fleet to increase
20 generation capacity and flexibility (*high confidence*).

21 Estimates of global gross theoretical available hydropower potential varies from 31–128 PWh yr⁻¹ (112–
22 460 EJ yr⁻¹), exceeding total electricity production in 2018 (Banerjee et al. 2017; IEA 2021d; BP 2020).
23 This potential is distributed over 11.8 million locations (Figure 6.12), but many of the locations cannot
24 be developed for (current) technical, economic, or political reasons. The estimated technical potential
25 of hydropower is 8–30 PWh yr⁻¹ (29–108 EJ yr⁻¹), and its estimated economic potential is 8–15 PWh
26 yr⁻¹ (29–54 EJ yr⁻¹) (van Vliet et al. 2016c; Zhou et al. 2015). Actual hydropower generation in 2019
27 was 4.2 PWh (15.3 EJ), providing about 16% of global electricity and 43% of global electricity from
28 renewables (BP 2020; Killingtveit 2020; IEA 2020f). Asia holds the largest hydropower potential
29 (48%), followed by S. America (19%) (Hoes et al. 2017).

30

31 **Figure 6.12 Global map of gross hydropower potential distribution [GWh yr⁻¹], Data: (Hoes et al. 2017)**

32 Hydropower is a mature technology with locally adapted solutions (*high confidence*) (Zhou et al. 2015;
33 Killingtveit 2020). The peak efficiency of hydroelectric plants is greater than 85%. Hydropower plants
34 without storage or with small storage typically produce a few kW to 10 MWs (examples of such plants
35 producing higher amounts do exist), and are useful for providing electricity at a scale from households

1 to small communities (El Bassam et al. 2013; Towler 2014). However, hydropower plants without or
2 with small storage may be susceptible to climate variability, especially droughts, when the amount of
3 water may not be sufficient to generate electricity (see Section 6.5, Premalatha et al. 2014).

4 Hydropower plants with storage may produce 10 GW, reaching over 100 TWh yr⁻¹ (0.36 EJ yr⁻¹), but
5 generally require large areas. Pumped storage hydropower stores energy by pumping water to higher
6 reservoirs during low-demand periods (Killingtveit 2020). The storage in hydropower systems provides
7 flexibility to compensate for rapid variations in electricity loads and supplies. The regulating
8 characteristics of the storage play an important role in assuring continuity of energy supply from
9 renewable sources (Yang et al. 2018b).

10 Hydropower is one of the lowest-cost electricity technologies (Mukheibir 2013; IRENA 2021b). Its
11 operation and maintenance costs are typically 2–2.5% of the investment costs per kW yr⁻¹ for a lifetime
12 of 40–80 years (Killingtveit 2020). Construction costs are site specific. The total cost for an installed
13 large hydropower project varies from USD 10,600–804,500 kW⁻¹ if the site is located far away from
14 transmission lines, roads, and infrastructure. Investment costs increase for small hydropower plants and
15 may be as high as USD 100,000 kW⁻¹ or more for the installation of plants of less than 1 MW - 20% to
16 80% more than for large hydropower plants (IRENA 2015). During the past 100 years, total installed
17 costs and LCOE have risen by a few percent, but the LCOE of hydropower remains lower than the
18 cheapest new fossil fuel-fired option (IRENA 2019b, 2021).

19 Hydroelectric power plants may pose serious environmental and societal impacts (*high confidence*)
20 (Mccartney 2009). Dams may lead to fragmentation of ecological habitats because they act as barriers
21 for migration of fish and other land and water-borne fauna, sediments, and water flow. These barriers
22 can be mitigated by sediment passes and fish migration aids, and with provision of environmental flows.
23 Below dams, there can be considerable alterations to vegetation, natural river flows, retention of
24 sediments and nutrients, and water quality and temperature. Construction of large reservoirs leads to
25 loss of land, which may result in social and environmental consequences. Minimizing societal and
26 environmental impacts requires taking into account local physical, environmental, climatological,
27 social, economic, and political aspects during the planning stage (Killingtveit 2020). Moreover, when
28 large areas of land are flooded by dam construction, they generate GHGs (Phyoe and Wang 2019;
29 Maavara et al. 2020; Prairie et al. 2018). On the other hand, hydropower provides flexible, competitive
30 low-emission electricity, local economic benefits (e.g., by increasing irrigation and electricity
31 production in developing countries), and ancillary services such as municipal water supply, irrigation
32 and drought management, navigation and recreation, and flood control (IRENA 2021b). However, the
33 long term economic benefits to communities affected by reservoirs are a subject of debate (de Faria et
34 al. 2017; Catolico et al. 2021).

35 Public support for hydroelectric energy is generally high (Steg 2018), and higher than support for coal,
36 gas, and nuclear. Yet, public support for hydro seems to differ for existing and new projects (*high*
37 *confidence*). Public support is generally high for small and medium scale hydropower in regions where
38 hydropower was historically used (Gormally et al. 2014). Additionally, there is high support for existing
39 large hydropower projects in Switzerland (Plum et al. 2019; Rudolf et al. 2014), Canada (Boyd et al.
40 2019), and Norway (Karlstrøm and Ryghaug 2014), where it is a trusted and common energy source.
41 Public support seems lower for new hydropower projects (Hazboun and Boudet 2020), and the
42 construction of new large hydropower plants has been met with strong resistance in some areas
43 (Bronfman et al., 2015; Vince, 2010). People generally perceive hydroelectric energy as clean and a
44 non-contributor to climate change and environmental pollution (Kaldellis et al. 2013). For example, in
45 Sweden, people believed that existing hydropower projects have as few negative environmental impacts
46 as solar, and even less than wind (Ek 2005). However, in areas where the construction of new large-
47 scale hydroelectric energy is met with resistance, people believe that electricity generation from hydro
48 can cause environmental, social, and personal risks (Bronfman et al., 2012; Kaldellis et al., 2013).

1 The construction time of hydroelectric power plants is longer than many other renewable technologies,
2 and that construction time may be extended by the additional time it takes to fill the reservoir. This
3 extended timeline can create uncertainty in the completion of the project. The uncertainty is due to
4 insecurity in year-to-year variations in precipitation and the water inflows required to fill reservoirs.
5 This is especially critical in the case of trans-boundary hydroelectric power plants, where filling up the
6 reservoirs can have large implications on downstream users in other nations. As a result of social and
7 environmental constraints, only a small fraction of potential economic hydropower projects can be
8 developed, especially in developed countries. Many developing countries have major undeveloped
9 hydropower potential, and there are opportunities to develop hydropower combined with other
10 economic activities such as irrigation (Lacombe et al. 2014). Competition for hydropower across
11 country borders can lead to conflict, which could be exacerbated if climate alters rainfall and streamflow
12 (Ito et al. 2016).

13 **6.4.2.4 Nuclear Energy**

14 Nuclear power can deliver low-carbon energy at scale (*high confidence*). Doing so will require
15 improvements in managing construction of reactor designs that hold the promise of lower costs and
16 broader use (*medium confidence*). At the same time, nuclear power continues to be affected by cost
17 overruns, high up-front investment needs, challenges with final disposal of radioactive waste, and
18 varying public acceptance and political support levels (*high confidence*).

19 There are sufficient resources for substantially increasing nuclear deployment (*medium confidence*).
20 Estimates for identified uranium resources have been increasing steadily over the years. Conventional
21 uranium resources have been estimated to be sufficient for over 130 years of supply at current levels of
22 use; 100 years were estimated in 2009 (Hahn 1983; NEA/IAEA 2021). In the case of future uranium
23 resource scarcity, thorium or recycling of spent fuel might be used as alternatives. Interest in these
24 alternatives has waned with better understanding of uranium deposits, their availability, and low prices
25 (OECD NEA 2015; IAEA 2005).

26 There are several possible nuclear technology options for the period from 2030 to 2050 (*medium*
27 *confidence*). In addition to electricity, nuclear can also be used to produce low-carbon hydrogen and
28 freshwater (Kayfeci et al. 2019; Kavvadias and Khamis 2014)

- 29 • **Large reactors.** The nuclear industry has entered a new phase of reactor construction, based on
30 evolutionary designs. These reactors achieve improvements over previous designs through small to
31 moderate modifications, including improved redundancy, increased application of passive safety
32 features, and significant improvements to containment design to reduce the risk of a major accident
33 (MIT 2018). Examples include European - EPR, Korean - APR1400, U.S. - AP1000, Chinese -
34 HPR1000 or Russian - VVER-1200.
- 35 • **Long-term operation (LTO) of the current fleet.** Continued production from nuclear power will
36 depend in part on life extensions of the existing fleet. By the end of 2020, two-thirds of nuclear
37 power reactors will have been operational for over 30 years. The design lifetime of most of existing
38 reactors is 30–40 years. Engineering assessments have established that reactors can operate safely
39 for longer if key replaceable components (e.g., steam generator, mechanical and electrical
40 equipment, instrumentation and control parts) are changed or refurbished (IAEA 2018). The first
41 lifetime extension considered in most of the countries typically is 10–20 years (OECD IEA NEA
42 2020).
- 43 • **Small Modular Reactors.** There are more than 70 SMR designs at different stages of consideration
44 and development, from the conceptual phase to licensing and construction of first-of-a-kind
45 facilities (IAEA 2020). Due to smaller unit sizes, the SMRs are expected to have lower total
46 investment costs, although the cost per unit of generation might be higher than conventional large
47 reactors (Mignacca and Locatelli 2020). Modularity and off-site pre-production may allow greater
48 efficiency in construction, shorter delivery times, and overall cost optimization (IEA 2019c). SMR

1 designs aim to offer an increased load-following capability that makes them suitable to operate in
2 smaller systems and in systems with increasing shares of VRE sources. Their market development
3 by the early 2030s will strongly depend on the successful deployment of prototypes during the
4 2020s.

5 Nuclear power costs vary substantially across countries (*high confidence*). First-of-a-kind projects
6 under construction in Northern America and Europe have been marked by delays and costs overruns
7 (Berthelemy and Rangel 2015). Construction times have exceeded 13–15 years and cost has surpassed
8 3–4 times initial budget estimates (OECD IEA NEA 2020). In contrast, most of the recent projects in
9 Eastern Asia (with construction starts from 2012) were implemented within 5–6 years (IAEA PRIS
10 2021). In addition to region-specific factors, future nuclear costs will depend on the ability to benefit
11 from the accumulated experience in controlling the main drivers of cost. These cost drivers fall into
12 four categories: design maturity, project management, regulatory stability and predictability, and multi-
13 unit and series effects (NEA 2020). With lessons learned from first-of-a-kind projects, the cost of
14 electricity for new builds are expected to be in the range of USD 42–102 MWh⁻¹ depending on the
15 region (OECD IEA NEA 2020).

16 Lifetime extensions are significantly cheaper than new builds and cost competitive with other low-
17 carbon technologies. The overnight cost of lifetime extensions is estimated in the range of USD 390–
18 630 kWe⁻¹ for Europe and North America, and the LCOE in the range of USD 30–36 MWh⁻¹ for
19 extensions of 10–20 years (OECD IEA NEA 2020).

20 Cost-cutting opportunities, such as design standardization and innovations in construction approaches,
21 are expected to make SMRs competitive against large reactors by 2040 (Rubio and Tricot 2016)
22 (*medium confidence*). As SMRs are under development, there is substantial uncertainty regarding the
23 construction costs. Vendors have estimated first-of-a-kind LCOEs at USD 131–190 MWh⁻¹. Effects of
24 learning for nth-of-a-kind SMR are anticipated to reduce the first-of-a-kind LCOE by 19–32%.

25 Despite low probabilities, the potential for major nuclear accidents exists, and the radiation exposure
26 impacts could be large and long-lasting (Steinhauser et al. 2014). However, new reactor designs with
27 passive and enhanced safety systems reduce the risk of such accidents significantly (*high confidence*).
28 The (normal) activity of a nuclear reactor results in low volumes of radioactive waste, which requires
29 strictly controlled and regulated disposal. On a global scale, roughly 421 kttons of spent nuclear fuel
30 have been produced since 1971 (IEA 2014). Out of this volume, 2–3% is high-level radioactive waste,
31 which presents challenges in terms of radiotoxicity and decay longevity, and ultimately entails
32 permanent disposal.

33 Nuclear energy is found to be favourable regarding land occupation (Cheng and Hammond 2017;
34 Luderer et al. 2019) and ecological impacts (Brook and Bradshaw 2015; Gibon et al. 2017). Similarly,
35 bulk material requirements per unit of energy produced are low (e.g. aluminum, copper, iron, rare earth
36 metals) (Vidal et al. 2013; Luderer et al. 2019). Water-intensive inland nuclear power plants may
37 contribute to localized water stress and competition for water uses. The choice of cooling systems
38 (closed-loop instead of once-through) can significantly moderate withdrawal rates of the freshwater (Jin
39 et al. 2019; Fricko et al. 2016; Mouratiadou et al. 2016; Meldrum et al. 2013). Reactors situated on the
40 seashore are not affected by water scarcity issues (JRC EU 2021). Life cycle assessment (LCA) studies
41 suggest that the overall impacts on human health (in terms of disability adjusted life years (DALYs))
42 from the normal operation of nuclear power plants are substantially lower than those caused by fossil
43 fuel technologies and are comparable to renewable energy sources (Treyer et al. 2014; Gibon et al.
44 2017).

45 Nuclear power continues to suffer from limited public and political support in some countries (*high*
46 *confidence*). Public support for nuclear energy is consistently lower than for renewable energy and
47 natural gas, and in many countries as low as support for energy from coal and oil (Hobman and

1 Ashworth 2013; Corner et al. 2011; Pampel 2011). The major nuclear accidents (i.e. Three Mile Island,
2 Chernobyl, and Fukushima) decreased public support (Poortinga et al. 2013; Bird et al. 2014). The
3 public remains concerned about the safety risks of nuclear power plants and radioactive materials
4 (TsujiKawa et al. 2016; Bird et al. 2014; Pampel 2011). At the same time, some groups see nuclear
5 energy as a reliable energy source, beneficial for the economy and helpful in climate change mitigation.
6 Public support for nuclear energy is higher when people are concerned about energy security, including
7 concerns about the availability of energy and high energy prices (Gupta et al. 2019b; Groot et al. 2013),
8 and when they expect local benefit (Wang et al. 2020c). Public support also increases when trust in
9 managing bodies is higher (de Groot and Steg 2011). Similarly, transparent and participative decision-
10 making processes enhance perceived procedural fairness and public support (Sjoberg 2004).

11 Because of the sheer scale of the investment required (individual projects can exceed USD 10 billion in
12 value), nearly 90% of nuclear power plants under construction are run by state-owned or controlled
13 companies with governments assuming significant part of the risks and costs. For countries that choose
14 nuclear power in their energy portfolio, stable political conditions and support, clear regulatory regimes,
15 and adequate financial framework are crucial for successful and efficient implementation.

16 Many countries have adopted technology-specific policies for low-carbon energy courses, and these
17 policies influence the competitiveness of nuclear power. For example, feed-in-tariffs and feed-in
18 premiums for renewables widely applied in the EU (Kitzing et al. 2012) or renewable portfolio
19 standards in the U.S. (Barbose et al. 2016) impact wholesale electricity price (leading occasionally to
20 low or even negative prices), which affects the revenues of existing nuclear and other plants (Bruninx
21 et al. 2013; Newbery et al. 2018; Lesser 2019).

22 Nuclear power's long-term viability may hinge on demonstrating to the public and investors that there
23 is a long-term solution to spent nuclear fuel. Evidence from countries steadily progressing towards first
24 final disposals - Finland, Sweden and France - suggests that broad political support, coherent nuclear
25 waste policies, and a well-managed, consensus-based decision-making process are critical for
26 accelerating this process (Metlay 2016). Proliferation concerns surrounding nuclear power are related
27 to fuel cycle (i.e., uranium enrichment and spent fuel processing). These processes are implemented in
28 a very limited number of countries following strict national and international norms and rules, such as
29 IAEA guidelines, treaties, and conventions. Most of the countries which might introduce nuclear power
30 in the future for their climate change mitigation benefits do not envision developing their own full fuel
31 cycle, significantly reducing any risks that might be linked to proliferation (IAEA 2014, 2019).

32 **6.4.2.5 Carbon Dioxide Capture, Utilization, and Storage**

33 Since AR5, there have been increased efforts to develop novel platforms that reduce the energy penalty
34 associated with CO₂ capture, develop CO₂ utilization pathways as a substitute to geologic storage, and
35 establish global policies to support CCS (*high confidence*). CCS can be used within electricity and other
36 sectors. While it increases the costs of electricity, CCS has the potential to contribute significantly to
37 low-carbon energy system transitions (IPCC 2018).

38 The theoretical global geologic storage potential is about 10,000 Gt-CO₂, with more than 80% of this
39 capacity existing in saline aquifers (*medium confidence*). Not all the storage capacity is usable because
40 geologic and engineering factors limit the actual storage capacity to an order of magnitude below the
41 theoretical potential, which is still more than the CO₂ storage requirement through 2100 to limit
42 temperature change to 1.5°C (Martin-Roberts et al. 2021) (*high confidence*). One of the key limiting
43 factors associated with geologic CO₂ storage is the global distribution of storage capacity (Table 6.2).
44 Most of the available storage capacity exists in saline aquifers. Capacity in oil and gas reservoirs and
45 coalbed methane fields is limited. Storage potential in the U.S. alone is >1,000 Gt-CO₂, which is more
46 than 10% of the world total (NETL 2015). The Middle East has more than 50% of global enhanced oil
47 recovery potential (Selosse and Ricci 2017). It is likely that oil and gas reservoirs will be developed

1 before saline aquifers because of existing infrastructure and extensive subsurface data (Alcalde et al.
2 2019; Hastings and Smith 2020). Notably, not all geologic storage is utilizable. In places with limited
3 geologic storage, international CCS chains are being considered, where sources and sinks of CO₂ are
4 located in two or more countries (Sharma and Xu 2021). For economic long-term storage, the desirable
5 conditions are a depth of 800-3000 m, thickness of greater than 50 m and permeability greater than 500
6 mD (Singh et al. 2020; Chadwick et al. 2008). Even in reservoirs with large storage potential, the rate
7 of injection might be limited by the subsurface pressure of the reservoir (Baik et al. 2018a). It is
8 estimated that geologic sequestration is safe with overall leakage rates at <0.001% yr⁻¹ (Alcalde et al.
9 2018). In many cases, geological storage resources are not located close to CO₂ sources, increasing
10 costs and reduces viability (Garg et al. 2017a).

11 **Table 6.2 Geologic storage potential across underground formations globally. These represent order-of-**
12 **magnitude estimates. Data: (Selosse and Ricci 2017)**

Reservoir Type	Africa	Australia	Canada	China	CSA	EEU	FSU	India	MEA	Mexico	ODA	USA	WEU

14 Other Asia (except China and India), WEU: Western Europe.

15 CO₂ utilization (CCU) - instead of geologic storage - could present an alternative method of
16 decarbonization (*high confidence*). The global CO₂ utilization potential, however, is currently limited
17 to 1–2 GtCO₂ yr⁻¹ for use of CO₂ as a feedstock (Hepburn et al. 2019; Kätelhön et al. 2019) but could
18 increase to 20 GtCO₂ by the mid-century (*medium confidence*). CCU involves using CO₂ as a feedstock
19 to synthesize products of economic value and as substitute to fossil feedstock. However, several CO₂
20 utilization avenues might be limited by energy availability. Depending on the utilization pathway, the
21 CO₂ may be considered sequestered for centuries (e.g., cement curing, aggregates), decades (plastics),
22 or only a few days or months (e.g. fuels) (Hepburn et al. 2019). Moreover, when carbon-rich fuel end-
23 products are combusted, CO₂ is emitted back into the atmosphere. Because of presence of several
24 industrial clusters (regions with high density of industrial infrastructure) globally, a number of regions
25 demonstrate locations where CO₂ utilization potential could be matched with large point sources of CO₂
26 (Wei et al. 2020).

27 The technological development for several CO₂ utilization pathways is still in the laboratory, prototype,
28 and pilot phases, while others have been fully commercialized (such as urea manufacturing).
29 Technology development in some end-uses is limited by purity requirements for CO₂ as a feedstock.
30 The efficacy of CCU processes depends on additional technological constraints such as CO₂ purity and
31 pressure requirements. For instance, urea production requires CO₂ pressurized to 122 bar and purified
32 to 99.9%. While most utilization pathways require purity levels of 95-99%, algae production may be
33 carried out with atmospheric CO₂ (Ho et al. 2019; Voldsund et al. 2016).

34 Existing post-combustion approaches relying on absorption are technologically ready for full-scale
35 deployment (*high confidence*). More novel approaches using membranes and chemical looping that
36 might reduce the energy penalty associated with absorption are in different stages of development -
37 ranging from laboratory phase to prototype phase (Abanades et al. 2015) (*high confidence*). There has
38 been significant progress in post-combustion capture technologies that used absorption in solvents such
39 as monoethanol amine (MEA). There are commercial-scale application of solvent-based absorption at
40 two facilities – Boundary Dam since 2015 and Petra Nova (temporarily suspended) since 2017, with
41 capacities of 1 and 1.6 MtCO₂ yr⁻¹ respectively (Mantripragada et al. 2019; Giannaris et al. 2020a).

Several 2nd and 3rd generation capture technologies are being developed with the aim of not just lowering costs but also enhancing other performance characteristics such as improved ramp-up and lower water consumption. These include processes such as chemical looping, which also has the advantage of being capable of co-firing with biomass (Bhave et al. 2017; Yang et al. 2019). Another important technological development is the Allam cycle, which utilizes CO₂ as a working fluid and operates based on oxy-combustion capture. Applications using the Allam Cycle can deliver net energy efficiency greater than 50% and 100% CO₂ capture, but they are quite sensitive to oxygen and CO₂ purity needs (Scaccabarozzi et al. 2016; Ferrari et al. 2017).

CO₂ capture costs present a key challenge, remaining higher than USD 50 tCO₂⁻¹ for most technologies and regions; novel technologies could help reduce some costs (*high confidence*). The capital cost of a coal or gas electricity generation facility with CCS is almost double one without CCS (Zhai and Rubin 2016; Rubin et al. 2015; Bui et al. 2018). Additionally, the energy penalty increases the fuel requirement for electricity generation by 13–44%, leading to further cost increases (Table 6.3).

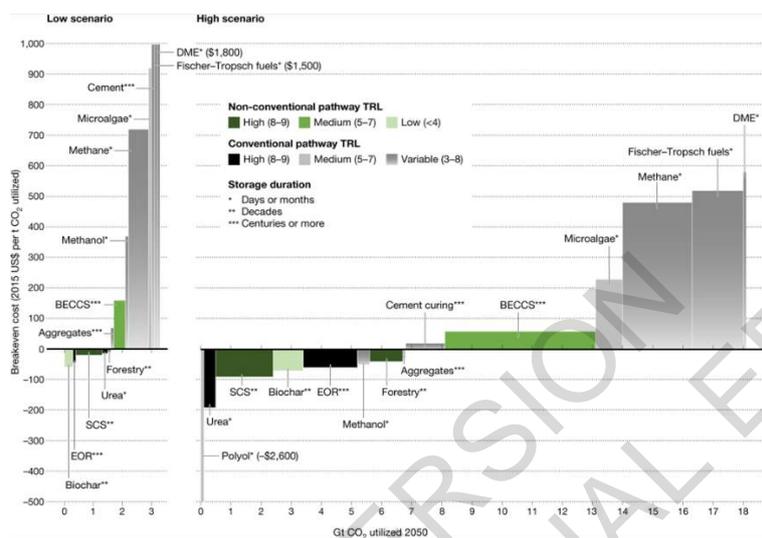

Table 6.3 Costs and efficiency parameters of CCS in electric power plants. Data: (Muratori et al. 2017a)

	Capital Cost [USD kW ⁻¹]	Efficiency [%]	CO ₂ Capture Cost [USD ton-CO ₂ ⁻¹]	CO ₂ Avoided Cost [USD ton-CO ₂ ⁻¹]
Coal (steam plant) + CCS	5800	28%	63	88
Coal (IGCC) + CCS	6600	32%	61	106
Natural Gas (CC) + CCS	2100	42%	91	33
Oil (CC) + CCS	2600	39%	105	95
Biomass (steam plant) + CCS	7700	18%	72	244
Biomass (IGCC) + CCS	8850	25%	66	242

In addition to reductions in capture costs, other approaches to reduce CCS costs rely on utilizing the revenues from co-products such as oil, gas, or methanol, and on clustering of large-point sources to reduce infrastructure costs. The potential for such reductions is limited in several regions due to low sink availability, but it could jumpstart initial investments (*medium confidence*). Injecting CO₂ into hydrocarbon formations for enhanced oil or gas recovery can produce revenues and lower costs (Edwards and Celia 2018). While enhanced oil recovery potential is <5% of the actual CCS needs, they can enable early pilot and demonstration projects (Núñez-López and Moskal 2019; Núñez-López et al. 2019). Substantial portions of CO₂ are effectively stored during enhanced oil recovery (Sminchak et al. 2020; Menefee and Ellis 2020). By clustering together of several CO₂ sources, overall costs may be reduced by USD 10 tCO₂⁻¹ (Abotalib et al. 2016; Garg et al. 2017a), but geographical circumstances determine the prospects of these cost reductions via economies-of-scale. The major pathways for methanol, methane, liquid fuel production, and cement curing have costs greater than USD 500 tCO₂⁻¹ (Hepburn et al. 2019). The success of these pathways therefore depends on the value of such fuels and on the values of other alternatives.

The public is largely unfamiliar with carbon capture, utilization, and storage technologies (Tcvetkov et al. 2019; L'Orange Seigo et al. 2014) (*high confidence*), and many people may not have formed stable attitudes and risk perceptions regarding these technologies (Daamen et al. 2006; Jones et al. 2015; Van Heek et al. 2017) (*medium confidence*). In general, low support has been reported for CCS technologies (Allen and Chatterton 2013; Demski et al. 2017). When presented with neutral information on CCS, people favour other mitigation options such as renewable energy and energy efficiency (de Best-Waldhober et al. 2009; Scheer et al. 2013; Karlstrøm and Ryghaug 2014). Although few totally reject CCS, specific CCS projects have faced strong local resistance, which has contributed to the cancellation of CCS projects (Terwel et al. 2012; L'Orange Seigo et al. 2014). Communities may also consider CCU to be lower-risk and view it more favourably than CCS (Arning et al. 2019).

1 CCS requires considerable increases in some resources and chemicals, most notably water. Power plants
 2 with CCS could shutdown periodically due to water scarcity. In several cases, water withdrawals for
 3 CCS are 25–200% higher than plants without CCS (Yang et al. 2020; Rosa et al. 2020b) due to energy
 4 penalty and cooling duty. The increase is slightly lower for non-absorption technologies. In regions
 5 prone to water scarcity such as the Southwestern U.S. or Southeast Asia, this may limit deployment and
 6 result in power plant shutdowns during summer months (Liu et al. 2019b; Wang et al. 2019c). The water
 7 use could be managed by changing heat integration strategies and implementing reuse of wastewater
 8 (Magneschi et al. 2017; Giannaris et al. 2020b).

9
 10 **Figure 6.13 Costs and potential for different CO₂ utilization pathways** (Hepburn et al. 2019)

11 Because CCS always adds cost, policy instruments are required for it to be widely deployed (*high*
 12 *confidence*). Relevant policy instruments include financial instruments such as emission certification
 13 and trading, legally enforced emission restraints, and carbon pricing (Haszeldine 2016; Kang et al.
 14 2020). There are some recent examples of policy instruments specifically focused on promoting CCS.
 15 The recent U.S. 45Q tax credits offers nationwide tax credits for CO₂ capture projects above USD 35–
 16 50 tCO₂⁻¹ which offset CO₂ capture costs at some efficient plants (Esposito et al. 2019). Similarly,
 17 California’s low-carbon fuel standard offers benefits for CO₂ capture at some industrial facilities such
 18 as biorefineries and refineries (Von Wald et al. 2020).

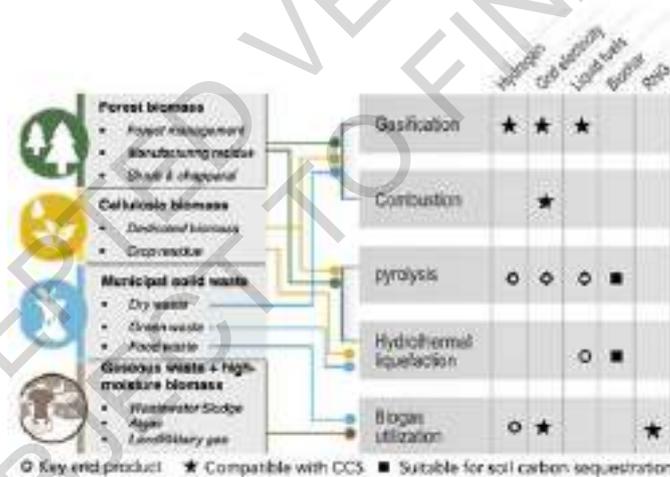

19 **6.4.2.6 Bioenergy**

20 Bioenergy has the potential to be a high-value and large-scale mitigation option to support many
 21 different parts of the energy system. Bioenergy could be particularly valuable for sectors with limited
 22 alternatives to fossil fuels (e.g., aviation, heavy industry), production of chemicals and products, and,
 23 potentially, in carbon dioxide removal (CDR) via BECCS or biochar. While traditional biomass and
 24 first-generation biofuels are widely used today, the technology for large-scale production from
 25 advanced processes is not competitive, and growing dedicated bioenergy crops raises a broad set of
 26 sustainability concerns. Its long-term role in low-carbon energy systems is therefore uncertain (*high*
 27 *confidence*). [Note that this section focuses on the key technological developments for deployment of
 28 commercial bioenergy.]

29 Bioenergy is versatile: technology pathways exist to produce multiple energy carriers from biomass -
 30 electricity, liquid fuels, gaseous fuels, hydrogen, and solid fuels - as well as other value-added products
 31 (*high confidence*). Different chemical and biological conversion pathways exist to convert diverse
 32 biomass feedstocks into multiple final energy carriers (Figure 6.14). Currently, biomass is mostly used
 33 to produce heat or for cooking purposes (traditional biomass), electricity, or first-generation sugar-based

1 biofuels (e.g., ethanol produced via fermentation), as well as biodiesel produced from vegetable oils
 2 and animal fats. Electricity generated from biomass contributes about 3% of global generation. Tens of
 3 billions of gallons of first-generation biofuels are produced per year. The processing requirements
 4 (drying, dewatering, pelletizing) of different feedstocks for producing electricity from biomass are
 5 energy-intensive, and when utilizing current power plants, the efficiency is around 22%, with an
 6 increase up to 28% with advanced technologies (Zhang et al. 2020).

7 Scaling up bioenergy use will require advanced technologies such as gasification, Fischer-Tropsch
 8 processing, hydrothermal liquefaction (HTL), and pyrolysis. These pathways could deliver several final
 9 energy carriers starting from multiple feedstocks, including forest biomass, dedicated cellulosic
 10 feedstocks, crop residues, and wastes (Figure 6.14). While potentially cost-competitive in the future,
 11 pyrolysis, Fischer-Tropsch, and HTL are not currently cost-competitive (IEA 2018c; Molino et al. 2018;
 12 Prussi et al. 2019), and scaling-up these processes will require robust business strategies and optimized
 13 use of co-products (Lee and Lavoie 2013). Advanced biofuels production processes are at the pilot or
 14 demonstration stage and will require substantial breakthroughs or market changes to become
 15 competitive. Moreover, fuels produced from these processes require upgrading to reach “drop-in”
 16 conditions – that is, conditions in which they may be used directly consistent with current standards in
 17 existing technologies (van Dyk et al. 2019). Additional opportunities exist to co-optimize second
 18 generation biofuels and engines (Ostadi et al. 2019; Salman et al. 2020). In addition, gaseous wastes,
 19 or high-moisture biomass, such as dairy manure, wastewater sludge and organic MSW could be utilized
 20 to produce renewable natural gas. Technologies for producing biogas (e.g. digestion) tend to be less
 21 efficient than thermochemical approaches and often produce large amounts of CO₂, requiring the
 22 produced fuels to undergo significant upgrading (Melara et al. 2020).

23
 24 **Figure 6.14 Range of advanced bioenergy conversion pathways (excluding traditional biomass, direct heat**
 25 **generation, first-generation biofuels, and non-energy products) based on feedstock, targeted end product,**
 26 **and compatibility with CDR via CCS and soil carbon sequestration (Modified from Baker et al, 2020)**

27 A major scale-up of bioenergy production will require dedicated production of advanced biofuels. First
 28 generation biofuels produced directly from food crops or animal fats both have limited potential and
 29 lower yield per land area than advanced biofuels. Wastes and residues (e.g., from agricultural, forestry,
 30 animal manure processing) or biomass grown on degraded, surplus, and marginal land can provide
 31 opportunities for cost-effective and sustainable bioenergy at significant but limited scale (Saha and
 32 Eckelman 2018; Fajardy and Mac Dowell 2020; Spagnolo et al. 2020; Morris et al. 2013). Assessing
 33 the potential for a major scale-up of purpose-grown bioenergy is challenging due to its far-reaching
 34 linkages to issues beyond the energy sector, including competition with land for food production and
 35 forestry, water use, impacts on ecosystems, and land-use change (IPCC 2020; Chapter 12; (Roe et al.
 36 2021)). These factors, rather than geophysical characteristics, largely define the potential for bioenergy

1 and explain the difference in estimates of potential in the literature. Biomass resources are not always
 2 in close proximity to energy demand, necessitating additional infrastructure or means to transport
 3 biomass or final bioenergy over larger distances and incur additional energy use (Baik et al. 2018b;
 4 Singh et al. 2020).

5 An important feature of bioenergy is that it can be used to remove carbon from the atmosphere by
 6 capturing CO₂ in different parts of the conversion process and then permanently storing the CO₂
 7 (BECCS or biochar) (Chapter 3, Chapter 7; Chapter 12.5; Smith et al. 2016; Fuss et al. 2018). Some
 8 early opportunities for low-cost BECCS are being utilized in the ethanol sector but these are applicable
 9 only in the near-term at the scale of $\leq 100 \text{ Mt-CO}_2 \text{ yr}^{-1}$ (Sanchez et al. 2018). Several technological and
 10 institutional barriers exist for large-scale BECCS implementation, including large energy requirements
 11 for CCS, limit and cost of biomass supply and geologic sinks for CO₂ in several regions, and cost of
 12 CO₂ capture technologies (*high confidence*). Besides BECCS, biofuels production through pyrolysis
 13 and hydrothermal liquefaction creates biochar, which could also be used to store carbon as 80% of the
 14 carbon sequestered in biochar will remain in the biochar permanently (Chapter 7). In addition to its
 15 ability to sequester carbon, biochar can be used as a soil amendment (Wang et al. 2014b).

16 First-generation bioenergy is currently competitive in some markets, though on average its costs are
 17 higher than other forms of final energy. Bioenergy from waste and residues from forestry and
 18 agriculture is also currently competitive, but the supply is limited (Aguilar et al. 2020). These costs are
 19 context-dependent, and regions having large waste resources are already producing low-cost bioenergy
 20 (Jin and Sutherland 2018). In the future, technology costs are anticipated to decrease, but bioenergy
 21 produced through cellulosic feedstocks may remain more expensive than fossil alternatives. Large-scale
 22 deployment of early opportunities especially in the liquid fuel sector may reduce the technological costs
 23 associated with biomass conversion (IEA 2020g). At the same time, the cost of feedstocks may rise as
 24 bioenergy requirements increase, especially in scenarios with large bioenergy deployment (Muratori et
 25 al. 2020). The costs of bioenergy production pathways are highly uncertain (Table 6.4).

26
 27 **Table 6.4 The costs of electricity generation, hydrogen production, and second-generation liquid fuels**
 28 **production from biomass in 2020.** These costs are adapted from (Daioglou et al. 2020), (Bhave et al. 2017),
 29 (NREL 2020a), (Lepage et al. 2021), (Witcover and Williams 2020), (NREL 2020b)

	Unit	Low	Median	High
Bioelectricity with CCS	USD/MWh	74	86	160
Bioelectricity without CCS	USD/MWh	66	84	112
Biohydrogen with CCS*	USD/kg	1.63	2.37	2.41
Biohydrogen without CCS*	USD/kg	1.59	1.79	2.37
Liquid biofuels with CCS	USD/gge	1.34	4.20	7.85
Liquid biofuels without CCS	USD/gge	1.15	4.00	7.60

30 * Using cellulosic feedstocks

- 31
- 32 • Electricity. The costs of baseload electricity production with biomass are higher than corresponding
 33 fossil electricity production with and without CCS, and are likely to remain as such without carbon
 34 pricing (Bhave et al. 2017). The additional cost associated with CO₂ capture are high for
 35 conventional solvent-based technologies. However, upcoming technologies such as chemical
 36 looping are well-suited to biomass and could reduce CCS costs.
 - 37 • Hydrogen. The costs of hydrogen production from biomass are somewhat higher than, but
 38 comparable, to that produced by natural gas reforming with CCS. Further, the incremental costs for
 incorporating CCS in this process are less than 5% of the levelized costs in some cases, since the

1 gasification route creates a high-purity stream of CO₂ (Muratori et al. 2017a; Sunny et al. 2020).
2 While these processes have fewer ongoing prototypes/demonstrations, the costs of biomass-based
3 hydrogen (with or without CCS) are substantially cheaper than that produced from electrolysis
4 utilizing solar/wind resources (Kayfeci et al. 2019; Newborough and Cooley 2020), even though
5 electrolysis costs are dropping.

- 6 • Liquid Biofuels. First-generation sugar-based biofuels (e.g., ethanol produced via fermentation) or
7 biodiesel produced from vegetable oils and animal fats are produced in several countries at large
8 scale and costs competitive with fossil fuels. However, supply is limited. The costs for second
9 generation processes (Fischer-Tropsch and cellulosic ethanol) are higher in most regions (Li et al.
10 2019). Technological learning is projected to reduce these costs by half (IEA 2020g).

11 Large-scale bioenergy production will require more than wastes/residues and cultivation on marginal
12 lands, which may raise conflicts with SDGs relevant to environmental and societal priorities (Gerten et
13 al. 2020; Heck et al. 2018) (Chapter 12). These include competition with food crops, implications for
14 biodiversity, potential deforestation to support bioenergy crop production, energy security implications
15 from bioenergy trade, point-of-use emissions and associated effects on air quality, and water use and
16 fertilizer use (Fajardy and Mac Dowell 2018; Tanzer and Ramírez 2019; Fuss et al. 2018; Brack and
17 King 2020). Overall, the environmental impact of bioenergy production at scale remains uncertain and
18 varies by region and application.

19 Alleviating these issues would require some combination of increasing crop yields, improving
20 conversion efficiencies, and developing advanced biotechnologies for increasing the fuel yield per
21 tonne of feedstock (Henry et al. 2018). Policy structures would be necessary to retain biodiversity,
22 manage water use, limit deforestation and land-use change emissions, and ultimately optimally integrate
23 bioenergy with transforming ecosystems. Large-scale international trade of biomass might be required
24 to support a global bioeconomy, raising questions about infrastructure, logistics, financing options, and
25 global standards for bioenergy production and trade (Box 6.10). Additional institutional and economic
26 barriers are associated with accounting of carbon dioxide removal, including BECCS (Fuss et al. 2014;
27 Muratori et al. 2016; Fridahl and Lehtveer 2018).

28 Life-cycle emissions impacts from bioenergy are subject to large uncertainties and could be
29 incompatible with net zero emissions in some contexts. Due to the potentially large energy conversion
30 requirements and associated GHG emissions (Chapter 7, Chapter 12), bioenergy systems may fail to
31 deliver near-zero emissions depending on operating conditions and regional contexts (Staples et al.
32 2017; Lade et al. 2020; Daioglou et al. 2017; Hanssen et al. 2020; Elshout et al. 2015). As a result,
33 bioenergy carbon neutrality is debated and depends on factors such as the source of biomass, conversion
34 pathways and energy used for production and transport of biomass, and land use changes, as well as
35 assumed analysis boundary and considered timescale (Fan et al. 2021; Wiloso et al. 2016; Zanchi et al.
36 2012; Booth 2018). Similarly, the lifecycle emissions of BECCS remain uncertain and will depend on
37 how effectively bioenergy conversion processes are optimized (Fajardy and Mac Dowell 2017; Tanzer
38 and Ramírez 2019).

39 Acceptability of bioenergy is relatively low compared to other renewable energy sources like solar and
40 wind (Poortinga et al. 2013; EPCC 2017; Peterson et al. 2015; Ma et al. 2015) and comparable to
41 natural gas (Scheer et al. 2013). People also know relatively little about bioenergy compared to other
42 energy sources (Whitmarsh et al. 2011a; EPCC 2017) and tend to be more ambivalent towards
43 bioenergy compared to other mitigation options (Allen and Chatterton 2013). People evaluate biomass
44 from waste products (e.g., food waste) more favourably than grown-for-purpose energy crops, which
45 are more controversial (Demski et al. 2015; Plate et al. 2010). The most pressing concerns for use of
46 woody biomass are air pollution and loss of local forests (Plate et al. 2010). Various types of bioenergy
47 additionally raise concerns about landscape impacts (Whitmarsh et al. 2011a) and biodiversity

1 (Immerzeel et al. 2014). Moreover, many people do not see biomass as a renewable energy source,
2 possibly because it involves burning of material.

3 **START BOX 6.5 HERE**

4 **Box 6.5 Methane mitigation options for coal, oil, and gas**

5 Methane emissions mainly from coal, oil, and gas currently represent in 2019 about 18% of energy
6 supply sector GHG emissions and 90% of global energy supply non-CO₂ emissions in 2019 (Minx et
7 al. 2021b). While approximately 80% of the life-cycle methane emissions in the coal sector occur during
8 underground mining, oil and gas emissions are spread throughout upstream, midstream, and
9 downstream stages (IPCC, 2019) (Alvarez et al. 2018). For this reason, methane reductions from coal
10 mining can be accomplished through coal mine methane recovery (where methane and coal are
11 recovered simultaneously) and from the ventilation air, which can reduce methane emissions by 50–
12 75% (Singh and Hajra 2018; Zhou et al. 2016). Governments incentivize such operations through a
13 number of emissions trading and offset programs (Haya et al. 2020). Methane emissions in the oil and
14 gas sector can be reduced by leak detection and repair, relevant across varying time scales (hours to
15 decades) and regional scopes (component/facility level to continental) (Fox et al. 2019). Around 50%
16 of the methane emitted from oil and gas infrastructure can be mitigated at net-negative costs; that is,
17 the market price of the recovered methane is higher than the mitigation costs (IEA 2021e). As CO₂
18 emissions are reduced and fossil fuel consumption decreases, methane emissions associated with these
19 supply chains are anticipated to decline (section 6.7). That said, substantial ‘legacy’ methane emissions
20 – methane leaks after abandonment – will remain even if a complete fossil fuel phase-out takes place.
21 These legacy emissions are estimated to be less than 1–4% of overall methane emissions across all
22 fossil fuel sources (Kholod et al. 2020; Williams et al. 2021b). Even without a complete phase-out, 50–
23 80% of methane emissions from coal, oil and gas could be avoided with currently available technologies
24 at less than USD 50 tCO₂-eq⁻¹ (Höglund-Isaksson et al. 2020; Harmsen et al. 2019). Methane recovery
25 from abandoned coal mines could offset most project costs (Singh and Sahu 2018). For abandoned oil
26 and gas wells, low plugging costs could be offset through methane recovery, while high plugging costs
27 would likely require some market or policy support (Kang et al. 2019).

28 **[END BOX 6.5 HERE]**

29 **6.4.2.7. Fossil Energy**

30 Fossil fuels could play a role in climate change mitigation if strategically deployed with CCS (*high*
31 *confidence*). On the one hand, the primary mechanism for reducing emissions is to eliminate the
32 unabated fossil fuel use. On the other hand, fossil energy combined with CCS provides a means of
33 producing low-carbon energy while still utilizing the available base of fossil energy worldwide and
34 limiting stranded assets. While Section 6.4.2.5 discusses the important aspects of CCS with fossil fuels,
35 this section aims to elucidate the feasibility criteria around these fuels itself.

36 Fossil fuel reserves have continued to rise because of advanced exploration and utilization techniques
37 (*high confidence*). A fraction of these available reserves can be used consistent with mitigation goals
38 when paired with CCS opportunities in close geographical proximity (*high confidence*). Based on
39 continued exploration, the fossil fuel resource base has increased significantly; for example, a 9%
40 increase in gas reserves and 12% in oil reserves was observed in the U.S. between 2017 and 2018. This
41 increase is a result of advanced exploration techniques, which are often subsidized (Lazarus and van
42 Asselt 2018; MA et al. 2018). Fossil reserves are distributed unevenly throughout the globe. Coal
43 represents the largest remaining resource (close to 500 ZJ). Conventional oil and gas resources are an
44 order of magnitude smaller (15–20 ZJ each). Technological advances have increased the reserves of
45 unconventional fossil in the last decade. Discovered ultimate recoverable resources of unconventional
46 oil and gas are comparable to conventional oil and gas (Fizaine et al. 2017).

1 It is unlikely that resource constraints will lead to a phaseout of fossil fuels, and instead, such a phase-
2 out would require policy action. Around 80% of coal, 50% of gas, and 20% of oil reserves are likely to
3 remain unextractable under 2°C constraints (McGlade and Ekins 2015; Pellegrini et al. 2020). Reserves
4 are more likely to be utilized in a low-carbon transition if they can be paired with CCS. Availability of
5 CCS technology not only allows continued use of fossil fuels as a capital resource for countries but also
6 paves the way for CDR through BECCS (Pye et al. 2020; Haszeldine 2016). While the theoretical
7 geologic CO₂ sequestration potential is vast, there are limits on how much resource base could be
8 utilized based on geologic, engineering, and source-sink mapping criteria (Budinis et al. 2017).

9 Technological changes have continued to drive down fossil fuel extraction costs. Significant
10 decarbonization potential also exists via diversification of the fossil fuel uses beyond combustion (high
11 evidence). The costs of extracting oil and gas globally have gone down by utilizing hydraulic fracturing
12 and directional drilling for resources in unconventional reservoirs (Wachtmeister and Höök 2020).
13 Although the extraction of these resources is still more expensive than those derived from conventional
14 reservoirs, the large availability of unconventional resources has significantly reduced global prices.
15 The emergence of liquefied natural gas (LNG) markets has also provided opportunities to export natural
16 gas significant distances from the place of production (Avraam et al. 2020). The increase in availability
17 of natural gas has been accompanied by an increase in the production of natural gas liquids as a co-
18 product to oil and gas. Over the period from 2014 to 2019, exports of natural gas liquids increased by
19 160%. Natural gas liquids could potentially be a lower-carbon alternative to liquid fuels and
20 hydrocarbons. On the demand side, natural gas can be used to produce hydrogen using steam methane
21 reforming, which is a technologically mature process (Sections 6.4.4, 6.4.5). When combined with 90%
22 CO₂ capture, the costs of producing hydrogen are around USD 1.5–2 kg(H₂)⁻¹ (Newborough and Cooley
23 2020; Collodi et al. 2017), considerably less than hydrogen produced via electrolysis.

24 Significant potential exists for gasifying deep-seated coal deposits *in situ* to produce hydrogen. Doing
25 so reduces fugitive methane emissions from underground coal mining. The integration costs of this
26 process with CCS are less than with natural gas reforming. The extent to which coal gasification could
27 be compatible with low-carbon energy would depend on the rate of CO₂ capture and the ultimate use of
28 the gas (Verma and Kumar 2015). Similarly, for ongoing underground mining projects, coal mine
29 methane recovery can be economic for major coal producers such as China and India. Coal mine
30 methane and ventilation air methane recovery can reduce the fugitive methane emissions by 50–75%
31 (Zhou et al. 2016; Singh and Sahu 2018).

32 The cost of producing electricity from fossil sources has remained roughly the same with some regional
33 exceptions while the costs of transport fuels has gone down significantly (*high confidence*). The cost of
34 producing electricity from fossil fuels has remained largely static, with the exception of some regional
35 changes, for example, a 40% cost reduction in the U.S. for natural gas (Rai et al. 2019), where the gas
36 wellhead price has declined by almost two-thirds due to large reserves. Similarly, the global price of
37 crude oil has declined from almost USD 100–55 bbl⁻¹ in the last five years.

38 The energy return of investment (EROI) is a useful indicator of full fossil lifecycle costs. Fossil fuels
39 create significantly more energy per unit energy invested – or in other words have much larger EROI –
40 than most cleaner fuels such as biomass or electrolysis-derived hydrogen, where intensive processing
41 reduces EROI (Hall et al. 2014). That said, recent years have seen a decrease in fossil EROI, especially
42 as underground coal mining has continued in China. Exploitation of unconventional gas reservoirs is
43 also energy intensive and has led to a reduction in EROI. The primary energy EROI of fossil fuels has
44 converged at about 30, which represents a 20-point decrease from the 1995 value for coal (Brockway
45 et al. 2019). When processing and refining stages are considered, these EROI values further decrease.

46 Several countries have large reserves of fossil fuels. Owing to climate constraints, these may become
47 stranded causing considerable economic impacts (6.7.3, 6.7.4, Box 6.13) (*high confidence*). While
48 global fossil energy resources are greater than 600 ZJ, more than half of these resources would likely

1 be unburnable even in the presence of CCS (Pye et al. 2020; McGlade and Ekins 2015). This would
2 entail a significant capital loss for the countries with large reserves. The total amount of stranded assets
3 in such a case would amount to USD 1–4 trillion at present value (Box 6.13).

4 Apart from CO₂ emissions and air pollutants from fossil fuel combustion, other environmental impacts
5 include fugitive methane leakages and implications to water systems. While the rate of methane leakage
6 from unconventional gas systems is uncertain, their overall GHG impact is less than coal (Deetjen and
7 Azevedo 2020; Tanaka et al. 2019). The stated rate of leakage in such systems ranges from 1-8%, and
8 reconciling different estimates requires a combination of top-down and bottom-up approaches (Grubert
9 and Brandt 2019; Zavala-Araiza et al. 2015). Similarly, for coal mining, fugitive methane emissions
10 have grown despite some regulations on the degree to which emission controls must be deployed.
11 Recent IPCC inventory guidance also notes considerable CO₂ emissions resulting from spontaneous
12 combustion of the coal surface, and accounting for these emissions will likely increase the overall life-
13 cycle emissions by 1–5% (Fiehn et al. 2020; Singh 2019; IPCC 2019).

14 Another key issue consistently noted with unconventional wells (both oil and gas, and coalbed methane)
15 is the large water requirements (Qin et al. 2018). The overall water footprint of unconventional
16 reservoirs is higher than conventional reservoirs because of higher lateral length and fracturing
17 requirements (Scanlon et al. 2017; Kondash et al. 2018). Moreover, produced water from such
18 formations is moderately to highly brackish, and treating such waters has large energy consumption
19 (Singh and Colosi 2019; Bartholomew and Mauter 2016).

20 Oil and coal consistently rank among the least preferred energy sources in many countries (*high*
21 *confidence*). The main perceived advantage of fossil energy is the relatively low costs, and emphasizing
22 these costs might increase acceptability somewhat (Pohjola et al. 2018; Hazboun and Boudet 2020;
23 Boyd et al. 2019). Acceptability of fossil fuels is on average similar to acceptability of nuclear energy,
24 although evaluations are less polarized. People evaluate natural gas as somewhat more acceptable than
25 other fossil fuels, although they generally oppose hydraulic fracturing (Clarke et al. 2016). Yet, natural
26 gas is evaluated as less acceptable than renewable energy sources, although evaluations of natural gas
27 and biogas are similar (Liebe and Dobers 2019; Plum et al. 2019). Acceptability of fossil energy tends
28 to be higher in countries and regions that strongly rely on them for their energy production (Boyd et al.
29 2019; Pohjola et al. 2018). Combining fossil fuels with CCS can increase their acceptability (Van
30 Rijnsoever et al. 2015; Bessette and Arvai 2018). Some people seem ambivalent about natural gas, as
31 they perceive both benefits (e.g., affordability, less carbon emissions than coal) and disadvantages (e.g.,
32 finite resource, contributing to climate change) (Blumer et al. 2018).

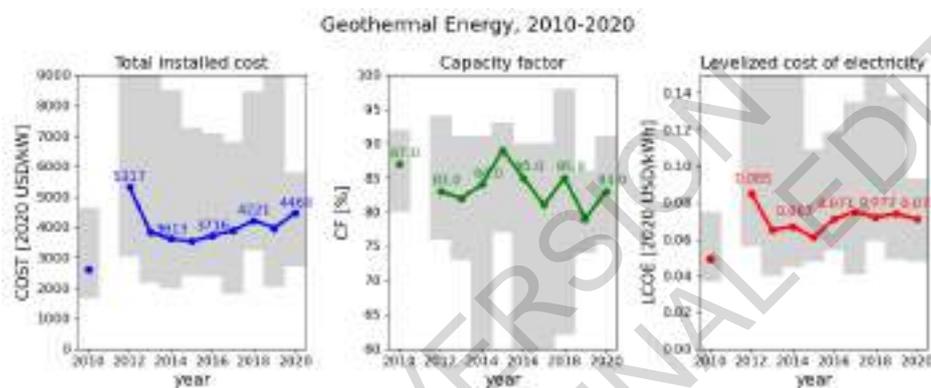

33 Fossil fuel subsidies have been valued of the order of USD 0.5–5 trillion annually by various estimates
34 which have the tendency to introduce economic inefficiency within systems (Merrill et al. 2015; Jakob
35 et al. 2015) (*high confidence*). Subsequent reforms have been suggested by different researchers who
36 have estimated reductions in CO₂ emissions may take place if these subsidies are removed (Mundaca
37 2017). Such reforms could create the necessary framework for enhanced investments in social welfare
38 – through sanitation, water, clean energy - with differentiating impacts (Edenhofer 2015).

39 **6.4.2.8 Geothermal Energy**

40 Geothermal energy is heat stored in the Earth's subsurface and is a renewable resource that can be
41 sustainably exploited. The geophysical potential of geothermal resources is 1.3 to 13 times the global
42 electricity demand in 2019 (*medium confidence*). Geothermal energy can be used directly for various
43 thermal applications, including space heating and industrial heat input, or converted to electricity
44 depending on the source temperature (Moya et al. 2018; REN21 2019; Limberger et al. 2018).

45 Suitable aquifers underlay 16% of the Earth's land surface and store an estimated 110,000–1,400,000
46 PWh (400,000–1,450,000 EJ) that could theoretically be used for direct heat applications. For electricity
47 generation, the technical potential of geothermal energy is estimated to be between 30 PWh yr⁻¹ (108

1 EJ yr⁻¹) (to 3 km depth) and 300 PWh yr⁻¹ (1080 EJ yr⁻¹) (to 10 km depth). For direct thermal uses, the
 2 technical potential is estimated to range from 2.7–86 PWh yr⁻¹ (9.7–310 EJ yr⁻¹) (IPCC 2011). Despite
 3 the potential, geothermal direct heat supplies only 0.15% of the annual global final energy consumption.
 4 The technical potential for electricity generation, depending on the depth, can meet one third to almost
 5 three times the global final consumption (based on IEA database for IPCC). The mismatch between
 6 potential and developed geothermal resources is caused by high up-front costs, decentralized
 7 geothermal heat production, lack of uniformity among geothermal projects, geological uncertainties,
 8 and geotechnical risks (IRENA 2017a; Limberger et al. 2018). A limited number of countries have a
 9 long history in geothermal. At least in two countries (Iceland and New Zealand), geothermal accounts
 10 for 20–25% of electricity generation (Spittler et al. 2020; Pan et al. 2019). Furthermore, in Iceland
 11 approximately 90% of the households are heated with geothermal energy. In Kenya, as of July 2019,
 12 geothermal accounted for 734 MW effective capacity spread over 10 power plants and approximately
 13 one third of the total installed capacity (Kahlen 2019).

14

15 **Figure 6.15 Global weighted average total installed costs, capacity factors and LCOE for geothermal**
 16 **power per year (2010-2020). The shaded area represents the 5% and 95% percentiles. Source: (IRENA**
 17 **2021a)**

18 There are two main types of geothermal resources: convective hydrothermal resources, in which the
 19 Earth's heat is carried by natural hot water or steam to the surface, and hot, dry rock resources, in which
 20 heat cannot be extracted using water or steam, and other methods must be developed. There are three
 21 basic types of geothermal power plants: (1) dry steam plants use steam directly from a geothermal
 22 reservoir to turn generator turbines; (2) flash steam plants take high-pressure hot water from deep inside
 23 the Earth and convert it to steam to drive generator turbines and (3) binary cycle power plants transfer
 24 the heat from geothermal hot water to another liquid. Many of the power plants in operation today are
 25 dry steam plants or flash plants (single, double and triple) harnessing temperatures of more than 180°C.

26 However, medium temperature fields are increasingly used for electricity generation or combined heat
 27 and power. The use of medium temperature fields has been enabled through the development of binary
 28 cycle technology, in which a geothermal fluid is used via heat exchangers. Increasing binary generation
 29 technologies are now being utilized instead of flash steam power plants. This will result in almost 100%
 30 injection and essentially zero GHG emissions, although GHG emissions from geothermal power
 31 production are generally small compared to traditional baseload thermal energy power generation
 32 facilities (Fridriksson et al. 2016).

33 Additionally, new technologies are being developed like Enhanced Geothermal Systems (EGS), which
 34 is in the demonstration stage (IRENA 2018), deep geothermal technology, which may increase the
 35 prospects for harnessing the geothermal potential in a large number of countries, or shallow-geothermal
 36 energy, which represents a promising supply source for heating and cooling buildings (Narsilio and Aye
 37 2018). Successful large-scale deployment of shallow geothermal energy will depend not only on site-
 38 specific economic performance but also on developing suitable governance frameworks (Bloemendal

1 et al. 2018; García-Gil et al. 2020). Technologies for direct uses like district heating, geothermal heat
2 pumps, greenhouses, and other applications are widely used and considered mature. Given the limited
3 number of plants commissioned, economic indicators (Figure 6.15) vary considerably depending on site
4 characteristics.

5 Public awareness and knowledge of geothermal energy is relatively low (*high confidence*). Geothermal
6 energy is evaluated as less acceptable than other renewable energy sources such as solar and wind, but
7 is preferred over fossil and nuclear energy, and in some studies, over hydroelectric energy (Karytsas et
8 al. 2019; Pellizzone et al. 2015; Steel et al. 2015; Hazboun and Boudet 2020) (*high confidence*). Some
9 people are concerned about the installation of geothermal facilities close to their homes, similar to solar
10 and wind projects (Pellizzone et al. 2015). The main concerns about geothermal energy, particularly for
11 large scale, high-temperature geothermal power generation plants, involve water usage, water scarcity,
12 and seismic risks of drilling (Dowd et al. 2011). Moreover, noise, smell and damages to the landscape
13 have been reasons for protests against specific projects (Walker 1995). However, with the
14 implementation of modern technologies, geothermal presents fewer adverse environmental impacts. At
15 the same time, people perceive geothermal energy as relatively environmentally friendly (Tampakis et
16 al. 2013).

17 **6.4.2.9 Marine Energy**

18 The ocean is a vast source of energy (Hoegh-Guldberg et al. 2019). Ocean energy can be extracted from
19 tides, waves, ocean thermal energy conversion (OTEC), currents, and salinity gradients (Bindoff et al.
20 2019). Their technical potentials, without considering possible exclusion zones, are explored below.
21 Tidal energy, which uses elevation differences between high and low tides, appears in two forms:
22 potential energy (rise and fall of the tide) and current energy (from tidal currents). The global technically
23 harvestable tidal power from areas close to the coast is estimated as $\sim 1.2 \text{ PWh yr}^{-1}$ (4.3 EJ yr^{-1}) (IRENA
24 2020b). The potential for tidal current energy is estimated to be larger than that for tidal range or barrage
25 (Melikoglu 2018). Ocean wave energy is abundant and predictable and can be extracted directly from
26 surface waves or pressure fluctuations below the surface (Melikoglu 2018). Its global theoretical
27 potential is 29.5 PWh yr^{-1} (106 EJ yr^{-1}), which means that wave energy alone could meet all global
28 energy demand (Mørk et al. 2010; IRENA 2020b). The temperature gradients in the ocean can be
29 exploited to produce energy, and its total estimated available resource could be up to 44.0 PWh yr^{-1}
30 (158 EJ yr^{-1}) (Rajagopalan and Nihous 2013). Salinity gradient energy, also known as osmotic power,
31 has a global theoretical potential of over 1.6 PWh yr^{-1} (6.0 EJ yr^{-1}) (IRENA 2020b). The greatest
32 advantage of most marine energy, excluding wave energy, is that their sources are highly regular and
33 predictable, and energy can be furthermore generated both day and night. An additional use of sea water
34 is to develop lower-cost district cooling systems near the sea (Hunt et al. 2019). The greatest barrier to
35 most marine technology advances is the relatively high upfront costs, uncertainty on environmental
36 regulation and impact, need for investments and insufficient infrastructure (Kempener and Neumann
37 2014a,b). There are also concerns about technology maturity and performance; thus, not all have the
38 potential to become economically viable (IRENA 2020b).

39 **6.4.2.10 Waste-to-Energy**

40 Waste-to-energy (WTE) is a strategy to recover energy from waste in a form of consumable heat,
41 electricity, or fuel (Zhao et al. 2016). Thermal (incineration, gasification, and pyrolysis) and biological
42 (anaerobic digestion and landfill gas to energy) technologies are commonly used (Ahmad et al.
43 2020). When WTE technologies are equipped with proper air pollution reduction facilities they can
44 contribute to clean electricity production and reduction of GHG emissions. However, if not properly
45 operated, they can exacerbate air quality issues.

46 In 2019, there were more than 1,200 WTE incineration facilities worldwide, with estimated capacity of
47 310 million tons per year (UNECE 2020). It is estimated that treatment of a minimum of 261 million

1 tons/year of waste could produce 283 TWh (1 EJ) of power and heat by 2022 (Awasthi et al., 2019).
2 Incineration plants can reduce the mass of waste by 70%-80% and the volume of waste by 80%-90%
3 (Haraguchi et al. 2019). Incineration technology can reduce water and soil pollution (Gu et al., 2019).
4 However, if not properly handled, dust, and gases such as SO₂, HCL, HF, NO₂, and dioxins in the flue
5 gases can harm the environment (Mutz et al. 2017). Anaerobic digestion technology has a positive
6 environmental impact and the ability to reduce GHG emissions (Ayodele et al. 2018; Cudjoe et al.
7 2020). The by-product of the anaerobic digestion process could be used as a nutrient-rich fertilizer for
8 enhancing soil richness for agricultural purposes (Wainaina et al. 2020). Due to the potential negative
9 impacts on domestic environment and residents' health, WTE projects such as incineration encounter
10 substantial opposition from the local communities in which they are located (Ren et al., 2016; Baxter
11 et al., 2016). Therefore, for WTE to be deployed more widely, policies would need to be tailored with
12 specific guidelines focused on mitigating emissions, which may have adverse effect on the environment.

13 Depending on the origin of the waste used, the integration of WTE and carbon capture and storage
14 (CCS) could enable waste to be a net zero or even net negative emissions energy source (Kearns 2019;
15 Wienchol et al. 2020). For example, in Europe only, the integration of CCS with WTE facilities has the
16 potential to capture about 60 to 70 million tons of carbon dioxide annually (Tota et al. 2021).

17 Waste-to-energy is an expensive process compared to other energy sources such as fossil fuels and
18 natural gas (Mohammadi and Harjunkoski 2020). However, the environmental and economic benefits
19 make its high financial costs justifiable. In 2019, the global WTE market size was valued at USD 31
20 billion, and it is predicted to experience 7.4% annual growth until 2027 (UNECE 2020).

21

22 **6.4.3 Energy System Integration**

23 Greenhouse gases are emitted across all economic activities. Therefore, cost-effective decarbonization
24 requires a “system of systems” approach that considers the interaction between different energy sectors
25 and systems. Flexibility technologies and advanced control of integrated energy systems (e.g.,
26 considering the interaction between electricity, heating/cooling, gas/hydrogen, transport sectors) could
27 reduce energy infrastructure investments substantially in future low-carbon energy systems (Strbac et
28 al. 2015b; Jacobson et al. 2019)

29 The electricity grid will serve as a backbone of future low-carbon energy systems. Integration of large
30 amounts of VRE generation (Hansen et al. 2019), particularly wind and solar generation (Perez et al.
31 2019; Bistline and Young 2019), presents economic and technical challenges to electricity system
32 management across different timescales from sub-seconds, hours, days, seasons, to multiple years.
33 Furthermore, electrification of segments of the transport and heat sectors could disproportionately
34 increase peak demand relative to supply (Bistline et al. 2021). Increases in peak demand may require
35 reinforcing network infrastructures and generation in the historical passive system operation paradigm
36 (Strbac et al. 2020).

37 These challenges to electricity system management can be addressed through system integration and a
38 digitalized control paradigm involving advanced information and communication technologies. Real-
39 time maintenance of supply-demand balance and sufficient flexibility technologies such as electricity
40 storage, flexible demand, and grid forming converters (Strbac et al. 2015a; López Prol and Schill 2021)
41 would be increasingly valuable for incorporating larger amounts of VRE generation. This flexibility
42 will be particularly important to deal with sudden losses of supply, for example, due to a failure of a
43 large generator or interconnector or a rapid increase in demand (Teng et al. 2017; Chamorro et al. 2020).

44 The transition to a digitalized-based electricity system control paradigm would facilitate radical changes
45 in the security of supply, moving from the traditional approach of redundancy in assets to a smart control

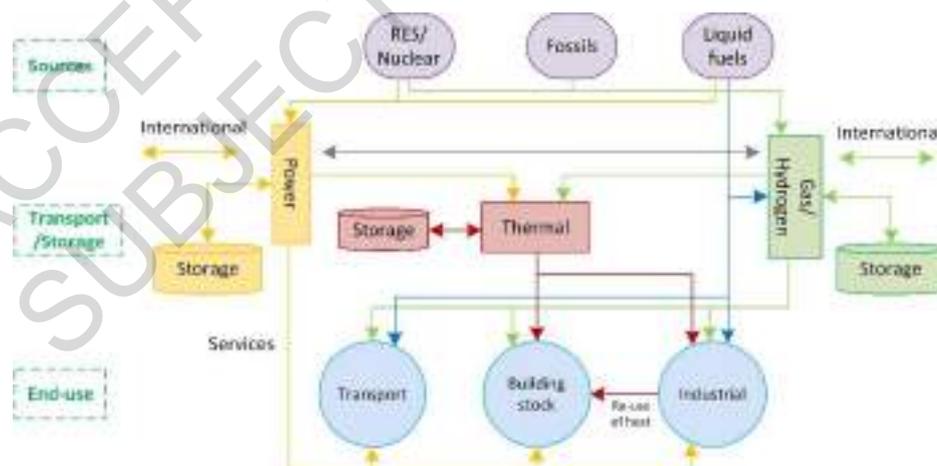

1 paradigm. Advanced control and communication systems can significantly reduce the electricity system
2 investment and operation costs (2020; Münster et al. 2020; Harper et al. 2018).

3 Importance of cross-sector coupling for cost-effective energy system decarbonization

4 Integrated whole-system approaches can reduce the costs of low-carbon energy system transitions (*high*
5 *confidence*). A lack of flexibility in the electricity system may limit the cost-effective integration of
6 technologies as part of broader net zero energy systems. At the same time, the enormous latent
7 flexibility hidden in heating and cooling, hydrogen, transport, gas systems, and other energy systems
8 provides opportunities to take advantage of synergies and to coordinate operations across systems
9 (Martinez Cesena and Mancarella 2019; Zhang et al. 2018; Bogdanov et al. 2021; Pavičević et al. 2020;
10 Martin et al. 2017) (Figure 6.16).

11 Sector coupling can significantly increase system flexibility, driven by the application of advanced
12 technologies (Bogdanov et al. 2019; Solomon et al. 2019; Clegg and Mancarella 2016; Zhang and
13 Fujimori 2020; Zhao et al. 2021; Heinen et al. 2016; Zhang et al. 2019b). For example, district heating
14 infrastructure can generate both heat and power. Cooling systems and electrified heating systems in
15 buildings can provide flexibility through preheating and precooling via thermal energy storage Li, G.
16 et al. 2017; Li, Z. et al. 2016).. System balancing services can be provided by electric vehicles (EVs)
17 based on vehicle-to-grid concepts and deferred charging through smart control of EV batteries without
18 compromising customers' requirements for transport (Aunedi and Strbac 2020).

19 Hydrogen production processes (power-to-gas and vice versa) and hydrogen storage can support short-
20 term and long-term balancing in the energy systems and enhance resilience (Stephen and Pierluigi 2016;
21 Strbac et al. 2020). However, the economic benefits of flexible power-to-gas plants, energy storage,
22 and other flexibility technological and options will depend on the locations of VRE sources, storage
23 sites, gas, hydrogen, and electricity networks (Jentsch et al. 2014; Heymann and Bessa 2015; Ameli
24 et al. 2020). Coordinated operation of gas and electricity systems can bring significant benefits in
25 supplying heat demands. For example, hybrid heating can eliminate investment in electricity
26 infrastructure reinforcement by switching to heat pumps in off-peak hours and gas boilers in peak hours
27 (Dengiz et al. 2019; Fischer et al. 2017; Bistline et al. 2021). The heat required by direct air carbon
28 capture and storage (DACCS) could be effectively supplied by inherent heat energy in nuclear plants,
29 enhancing overall system efficiency (Realmonte et al. 2019).

30

31 **Figure 6.16 Interaction between different energy sectors (extracted from Münster et al. 2020)**

32 Rather than incremental planning, strategic energy system planning can help minimize long-term
33 mitigation costs (*high confidence*). With a whole-system perspective, integrated planning can consider
34 both short-term operation and long-term investment decisions, covering infrastructure from local to
35 national and international, while meeting security of supply requirements and incorporating the

1 flexibility provided by different technologies and advanced control strategies (Zhang et al. 2018;
2 O'Malley et al. 2020; Strbac et al. 2020). Management of conflicts and synergies between local district
3 and national level energy system objectives, including strategic investment in local hydrogen and heat
4 infrastructure, can drive significant whole-system cost savings (Fu et al. 2020; Zhang et al. 2019b). For
5 example, long-term planning of the offshore grid infrastructure to support offshore wind development,
6 including interconnection between different countries and regions, can provide significant savings
7 compared to a short-term incremental approach in which every offshore wind farm is individually
8 connected to the onshore grid (E3G 2021).

9 **6.4.3.1 Role of flexibility technologies**

10 Flexibility technologies - including energy storage, demand-side response, flexible/dispatchable
11 generation, grid forming converters, and transmission interconnection - as well as advanced control
12 systems, can facilitate cost-effective and secure low-carbon energy systems (*high confidence*).
13 Flexibility technologies have already been implemented, but they can be enhanced and deployed more
14 widely. Due to their interdependencies and similarities, there can be both synergies and conflicts for
15 utilizing these flexibility options (Bistline et al. 2021). It will therefore be important to coordinate the
16 deployment of the potential flexibility technologies and smart control strategies. Important electricity
17 system flexibility options include the following:

- 18 • *Flexible/dispatchable generation*: Advances in generation technologies, for example, gas/hydrogen
19 plants and nuclear plants, can enable them to provide flexibility services. These technologies would
20 start more quickly, operate at lower power output, and make faster output changes, enabling more
21 secure and cost-effective integration of VRE generation and end-use electrification. There are
22 already important developments in increasing nuclear plants flexibility (e.g., in France (Office of
23 Nuclear Energy 2021)) and the development of small modular reactors, which could support system
24 balancing (FTI Consulting 2018).
- 25 • *Grid-forming converters (inverters)*: The transition from conventional electricity generation,
26 applying mainly synchronous machines to inverter-dominated renewable generation, creates
27 significant operating challenges. These challenges are mainly associated with reduced synchronous
28 inertia, system stability, and black start capability. Grid-forming converters will be a cornerstone
29 for the control of future electricity systems dominated by VRE generation. These converters will
30 address critical stability challenges, including the lack of system inertia, frequency and voltage
31 regulation, and black-start services while reducing or eliminating the need to operate conventional
32 generation (Tayyebi et al. 2019).
- 33 • *Interconnection*: Electricity interconnections between different regions can facilitate more cost-
34 effective renewable electricity deployment. Interconnection can enable large-scale sharing of
35 energy and provide balancing services. Back-up energy carriers beyond electricity, such as
36 ammonia, can be shared through gas/ammonia/hydrogen-based interconnections, strengthening
37 temporal coupling of multiple sectors in different regions (Bhagwat et al. 2017; Brown et al. 2018)
38 (Section 6.4.5).
- 39 • *Demand-side response*: Demand-side schemes – including, for example, smart appliances, EVs,
40 and building-based thermal energy storage (Heleno et al. 2014) – can provide flexibility services
41 across multiple time frames and systems. Through differentiation between essential and non-
42 essential needs during emergency conditions, smart control of demands can significantly enhance
43 system resilience (Chaffey 2016).
- 44 • *Energy storage*: Energy storage technologies (Section 6.4.4) can act as both demand and generation
45 sources. They can provide services such as system balancing, various ancillary services, and
46 network management. Long-duration energy storage can significantly enhance the utilization of
47 renewable energy sources and reduce the need for firm low-carbon generation (Sepulveda et al.
48 2021).

1 **6.4.3.2 Role of digitalization and advanced control systems**

2 A digitalized energy system can significantly reduce energy infrastructure investments while enhancing
3 supply security and resilience (*high confidence*) (Andoni et al. 2019; Strbac et al. 2020). Significant
4 progress has been made in the development of technologies essential for the transition to a digitalized
5 energy control paradigm, although the full implementation is still under development. Electrification
6 and the increased integration of the electricity system with other systems will fundamentally transform
7 the operational and planning paradigm of future energy infrastructure. A fully intelligent and
8 sophisticated coordination of the multiple systems through smart control will support this paradigm
9 shift. This shift will provide significant savings through better utilization of existing infrastructure
10 locally, regionally, nationally, and internationally. Supply system reliability will be enhanced through
11 advanced control of local infrastructure (Strbac et al. 2015a). Furthermore, this paradigm shift offers
12 the potential to increase energy efficiency through a combination of technologies that gather and analyse
13 data and consequently optimize energy use in real-time.

14 The transition to advanced data-driven control of energy system operations (Sun et al. 2019a; Cremer
15 et al. 2019) will require advanced information and communication technologies and infrastructure,
16 including the internet, wireless networks, computers, software, middleware, smart sensors, internet of
17 things components, and dedicated technological developments (Hossein Motlagh et al. 2020). The
18 transition will raise standardization and cybersecurity issues, given that digitalization can become a
19 single point of failure for the complete system (Unsal et al. 2021; Ustun and Hussain 2019).
20 Implementing peer-to-peer energy trading based on blockchain is expected to be one of the key elements
21 of next-generation electricity systems (Qiu et al. 2021). This trading will enable consumers to drive
22 system operation and future design, increasing overall system efficiency and security of supply while
23 reducing emissions without sacrificing users' privacy (Andoni et al. 2019; Ahl et al. 2020). When
24 deployed with smart contracts, this concept will be suitable for energy systems involving many
25 participants, where a prerequisite is digitalization (e.g., smart meters, end-use demand control systems)
26 (Teufel et al. 2019; Juhar and Khaled 2018).

27 **6.4.3.3 System benefits of flexibility technologies and advanced control systems**

28 New sources of flexibility and advanced control systems provide a significant opportunity to reduce
29 low-carbon energy system costs by enhancing operating efficiency and reducing energy infrastructure
30 and low-carbon generation investments, while continuing to meet security requirements (*high*
31 *confidence*). In the U.S, for example, one study found that flexibility in buildings alone could reduce
32 U.S. CO₂ emissions by 80 MT yr⁻¹ and save USD 18 bn yr⁻¹ in electricity system costs by 2030
33 (Satchwell et al. 2021). Key means for creating savings are associated with the following:

- 34 • *Efficient energy system operation*: Flexibility technologies such as storage, demand-side response,
35 interconnection, and cross-system control will enable more efficient, real-time demand and supply
36 balancing. This balancing has historically been provided by conventional fossil-fuel generation
37 (Nuytten et al. 2013).
- 38 • *Savings in investment in low carbon/renewable generation capacity*: System flexibility sources can
39 absorb or export surplus electricity, thus reducing or avoiding energy curtailment and reducing the
40 need for firm low-carbon capacity such as nuclear and fossil-fuel plants with CCS (Newbery et al.
41 2013; Solomon et al. 2019). For example, one study found that flexibility technologies and
42 advanced control systems could reduce the need for nuclear power by 14 GW and offshore wind by
43 20 GW in the UK's low-carbon transition (Strbac et al. 2015b).
- 44 • *Reduced need for backup capacity*: System flexibility can reduce energy demand peaks, reducing
45 the required generation capacity to maintain the security of supply, producing significant savings
46 in generation investments (Strbac et al. 2020).
- 47 • *Deferral or avoidance of electricity network reinforcement/addition*: Flexibility technologies
48 supported by advanced control systems can provide significant savings in investment in electricity

1 network reinforcement that might emerge from increased demand, for example, driven by
 2 electrification of transport and heat sectors. Historical network planning and operation standards
 3 are being revised considering alternative flexibility technologies, which would further support cost-
 4 effective integration of decarbonized transport and heat sectors (Strbac et al. 2020).

5 **6.4.4 Energy Storage for Low-Carbon Grids**

6 Energy storage technologies make low carbon electricity systems more cost-effective, allowing VRE
 7 technologies to replace more expensive firm low carbon generation technologies (Carbon Trust 2016)
 8 and reducing investment costs in backup generation, interconnection, transmission, and distribution
 9 network upgrades (*high confidence*). Energy system decarbonization relies on increased electrification
 10 (Section 6.6.2.3.). Meeting increasing demands with variable renewable sources presents challenges
 11 and could lead to costly infrastructure reinforcements. Energy storage enables electricity from variable
 12 renewables to be matched against evolving demands across both time and space, using short-, medium-
 13 and long-term storage of excess energy for delivery later or different location. In 2017, an estimated
 14 4.67 TWh (0.017 EJ) of electricity storage was in operation globally (IRENA 2017). If the integration
 15 of renewables is doubled from 2014 levels by 2030, the total capacity of global electricity storage could
 16 triple, reaching 11.89–15.27 TWh (0.043–0.055 EJ)(IRENA 2017b).

17

2 Energy storage technologies can provide a range of different grid services (Table 6.5). Energy storage
3 enhances security of supply by providing real time system regulation services (voltage support,
4 frequency regulation, fast reserve, and short-term reserve). A greater proportion of variable renewable
5 sources reduces system inertia, requiring more urgent responses to changes in system frequency, which
6 rapid response storage technologies can provide (stability requires responses within sub second
7 timescale for provision of frequency and voltage control services). Energy storage also provides
8 intermittent renewable sources with flexibility, allowing them to contribute a greater proportion of
9 electrical energy and avoiding curtailment (capacity firming). Investment costs in backup generation,
10 interconnection, transmission, and distribution network upgrades can thus be reduced (upgrade
11 deferral), meaning that less low carbon generation will need to be built while still reducing emissions.
12 In the event of an outage, energy storage reserves can keep critical services running (islanding) and
13 restart the grid (black start). The ability to store and release energy as required provides a range of
14 market opportunities for buying and selling of energy (arbitrage).

15 No single, sufficiently mature energy storage technology can provide all the required grid services - a
16 portfolio of complementary technologies working together can provide the optimum solution (*high*
17 *confidence*). Different energy storage technologies can provide these services and support cost-effective
18 energy system decarbonization (Carbon Trust 2016). To achieve very low carbon systems, significant
19 volumes of storage will be required (Strbac et al. 2015a; Section 0). There are few mature global supply
20 chains for many of the less-developed energy storage technologies. This means that although costs
21 today may be relatively high, there are significant opportunities for future cost reductions, both through
22 technology innovation and through manufacturing scale. Adding significant amounts of storage will
23 reduce the price variation and, therefore, the profitability of additional and existing storage, increasing
24 investment risk.

25 Energy storage extends beyond electricity storage and includes technologies that can store energy as
26 heat, cold, and both liquid and gaseous fuels. Energy storage is a conversion technology, enabling
27 energy to be converted from one form to another. This diversification improves the overall resilience
28 of energy systems, with each system being able to cover supply shortfalls in the others. For example,
29 storage can support the electrification of heating or cooling, as well as transport through electric
30 vehicles, powered by batteries or by fuel cells. Storage significantly reduces the need for costly
31 reinforcement of local distribution networks through smart charging schemes and the ability to flow
32 electricity back to the grid (e.g., through vehicle-to-grid). By capturing otherwise wasted energy
33 streams, such as heat or cold, energy storage improves the efficiency of many systems, such as
34 buildings, data centres and industrial processes.

35 **6.4.4.1 Energy Storage Technologies**

36 **Pumped Hydroelectric Storage (PHS).** PHS makes use of gravitational potential energy, using water as
37 the medium. Water is pumped into an elevated reservoir using off-peak electricity and stored for later
38 release when electricity is needed. These closed-loop hydropower plants have been in use for decades
39 and account for 97% of worldwide electricity storage capacity (IEA, 2018b; IRENA, 2017). PHS is best
40 suited to balancing daily energy needs at a large scale, and advances in the technology now allow both
41 rapid response and power regulation in both generating and pumping mode (Valavi and Nysveen 2018;
42 Kougias et al. 2019; Dong et al. 2019). The construction itself can cause disruption to the local
43 community and environment (Hayes et al. 2019), the initial investment is costly, and extended

1 construction periods delay return on investment (Section 6.4.2.3). In addition, locations for large-scale
2 PHS plants are limited.

3 Advanced pump-turbines are being developed, allowing both reversible and variable-speed operation,
4 supporting frequency control and grid stability with improved round-trip efficiencies (Ardizzon et al.
5 2014). New possibilities are being explored for small-scale PHS installations and expanding the
6 potential for siting (Kougiass et al. 2019). For example, in underwater PHS, the upper reservoir is the
7 sea, and the lower is a hollow deposit at the seabed. Seawater is pumped out of the deposit to store off-
8 peak energy and re-enters through turbines to recharge it (Kougiass et al. 2019). Using a similar concept,
9 underground siting in abandoned mines and caverns could be developed reasonably quickly (IEA
10 2020h). Storage of energy as gravitational potential can also be implemented using materials other than
11 water, such as rocks and sand. Pumped technology is a mature technology (Barbour et al. 2016; Rehman
12 et al. 2015) and can be important in supporting the transition to future low carbon electricity grids (IHA
13 2021).

14 **Batteries.** There are many types of batteries, all having unique features and suitability (c), but their key
15 feature is their rapid response times. A rechargeable battery cell is charged by using electricity to drive
16 ions from one electrode to another, with the reverse occurring on discharge, producing a usable electric
17 current (Crabtree et al. 2015). While lead-acid batteries (LABs) have been widely used for automotive
18 and grid applications for decades (May et al. 2018), li-ion batteries (LIBs) are increasingly being used
19 in grid-scale projects (Crabtree et al. 2015), displacing LABs. The rapid response time of batteries
20 makes them suitable for enhanced frequency regulation and voltage support, enabling the integration of
21 variable renewables into electricity grids (Strbac and Aunedi 2016). Batteries can provide almost all
22 electricity services, except for seasonal storage. Lithium-ion batteries, in particular, can store energy
23 and power in small volumes and with low weight, making them the default choice for EVs (Placke et
24 al. 2017). EV batteries are expected to form a distributed storage resource as this market grows, both
25 impacting and supporting the grid (Staffell and Rustomji 2016).

26

1

2 Drawbacks of batteries include relatively short lifespans and the use of hazardous or costly materials in
3 some variants. While LIB costs are decreasing (Schmidt et al. 2017; Vartiainen et al. 2020), the risk of
4 thermal runaway, which could ignite a fire (Gur 2018; Wang et al. 2019a), concerns about long-term
5 resource availability (Sun et al. 2017; Olivetti et al. 2017), and concerns about global cradle-to-grave
6 impacts (Peters et al. 2017; Kallitsis et al. 2020) need to be addressed.

7 The superior characteristics of LIBs will keep them the dominant choice for EV and grid applications
8 in the medium-term (*high confidence*). There are, however, several next-generation battery chemistries
9 (Placke et al. 2017), which show promise (*high confidence*). Cost reductions through economies of scale
10 are a key area for development. Extending the life of the battery can bring down overall costs and
11 mitigate the environmental impacts (Peters et al. 2017). Understanding and controlling battery
12 degradation is therefore important. The liquid, air-reactive electrolytes of conventional LIBs are the
13 main source of their safety issues (Gur 2018; Janek and Zeier 2016), so All-Solid-State Batteries, in
14 which the electrolyte is a solid, stable material, are being developed. They are expected to be safe, be
15 durable, and have higher energy densities (Janek and Zeier 2016). New chemistries and concepts are
16 being explored, such as lithium-sulfur batteries to achieve even higher energy densities (Van Noorden
17 2014; Blomgren 2017) and sodium chemistries because sodium is more abundant than lithium (Hwang
18 et al. 2017). Cost-effective recycling of batteries will address many sustainability issues and prevent
19 hazardous and wasteful disposal of used batteries (Harper et al. 2019). Post-LIB chemistries include
20 metal sulfur, metal-air, metal ion (besides Li) and All-Solid-State Batteries.

21 Compressed Air Energy Storage (CAES). With CAES, off-peak electricity is used to compress air in a
22 reservoir – either in salt caverns for large scale or in high-pressure tanks for smaller-scale installations.
23 The air is later released to generate electricity. While conventional CAES has used natural gas to power
24 compression, new low carbon CAES technologies, such as isothermal or adiabatic CAES, control
25 thermal losses during compression and expansion (Wang et al. 2017c). Fast responses and higher
26 efficiencies occur in small-scale CAES installations, scalable to suit the application as a distributed
27 energy store, offering a flexible, low maintenance alternative (Luo et al. 2014; Venkataramani et al.
28 2016).

29 CAES is a mature technology in use since the 1970s. Although CAES technologies have been
30 developed, there are not many installations at present (Blanc et al. 2020; Wang et al. 2017b). While the
31 opportunities for CAES are significant, with a global geological storage potential of about 6.5 PW
32 (Aghahosseini and Breyer 2018), a significant amount of initial investment is required. Higher
33 efficiencies and energy densities can be achieved by exploiting the hydrostatic pressure of deep water
34 to compress air within submersible reservoirs (Pimm et al. 2014). CAES is best suited to bulk diurnal
35 electricity storage for buffering VRE sources and services, which do not need a very rapid response. In
36 contrast to PHS, CAES has far more siting options and poses few environmental impacts.

37 Liquid Air Energy Storage (LAES). Liquid air energy storage uses electricity to liquefy air by cooling
38 it to -196°C and storing it in this condensed form (largely liquid nitrogen) in large, insulated tanks. To
39 release electricity, the ‘liquid air’ is evaporated through heating, expanding to drive gas turbines. Low-
40 grade waste heat can be utilized, providing opportunities for integrating with industrial processes to
41 increase system efficiency. There are clear, exploitable synergies with the existing liquid gas
42 infrastructure (Peters and Sievert 2016).

1 LAES provides bulk daily storage of electricity, with the additional advantage of being able to capture
2 waste heat from industrial processes. This technology is in the early commercial stage (Regen 2017;
3 Brandon et al. 2015). Advances in whole systems integration can be developed to integrate LAES with
4 industrial processes, making use of their waste heat streams. LAES uniquely removes contaminants in
5 the air and could potentially incorporate CO₂ capture (Taylor et al. 2012).

6 Thermal Energy Storage (TES). Thermal energy storage refers to a range of technologies exploiting the
7 ability of materials to absorb and store heat or cold, either within the same phase (sensible TES), through
8 phase changes (latent TES), or through reversible chemical reactions (thermochemical TES). Pumped
9 Thermal Energy Storage (PTES), a hybrid form of TES, is an air-driven electricity storage technology
10 storing both heat and cold in gravel beds, using a reversible heat-pump system to maintain the
11 temperature difference between the two beds and gas compression to generate and transfer heat (Regen
12 2017). TES technologies can store both heat and cold energy for long periods, for example in
13 underground water reservoirs for balancing between seasons (Tian et al. 2019; Dahash et al. 2019),
14 storing heat and cold to balance daily and seasonal temperatures in buildings and reducing heat build-
15 up in applications generating excessive waste heat, such as data centres and underground operations.

16 TES can be much cheaper than batteries and has the unique ability to capture and reuse waste heat and
17 cold, enabling the efficiency of many industrial, buildings, and domestic processes to be greatly
18 improved (*high confidence*). Integration of TES into energy systems is particularly important, as the
19 global demand for cooling is expected to grow (Peters and Sievert 2016; Elzinga et al. 2014). Sensible
20 TES is well developed and widely used; latent TES is less developed with few applications.
21 Thermochemical TES is the least developed, with no application yet (Prieto et al. 2016; Clark et al.
22 2020). The potential for high-density storage of industrial heat for long periods in thermochemical TES
23 (Brandon et al. 2015) is high, with energy densities comparable to that of batteries (Taylor et al. 2012),
24 but material costs are currently prohibitive, ranging from hundreds to thousands of dollars per tonne.

25 Flywheel Energy Storage (FES). Flywheels are charged by accelerating a rotor/flywheel. Energy is
26 stored in the spinning rotor's inertia which is only decelerated by friction (minimized by magnetic
27 bearings in a vacuum), or by contact with a mechanical, electric motor. They can reach full charge very
28 rapidly, their state of charge can be easily determined (Amiryar and Pullen 2017), and they operate over
29 a wide range of temperatures. While they are more expensive to install than batteries and
30 supercapacitors, they last a long time and are best suited to stationary grid storage, providing high power
31 for short periods (minutes). Flywheels can be used in vehicles, but not as the primary energy source.

32 Flywheels are a relatively mature storage technology but not widely used, despite their many advantages
33 over electrochemical storage (Dragoni 2017). Conventional flywheels require costly, high tensile
34 strength materials, but high-energy flywheels, using lightweight rotor materials, are being developed
35 (Amiryar and Pullen 2017; Hedlund et al. 2015).

36 Supercapacitors, aka Ultracapacitors or Double Layer Capacitors (Scap). Supercapacitors consist of a
37 porous separator sandwiched between two electrodes, immersed in a liquid electrolyte (Gur 2018).
38 When a voltage is applied across the electrodes, ions in the electrolyte form electric double layers at the
39 electrode surfaces, held by electrostatic forces. This structure forms a capacitor, storing electrical charge
40 (Lin et al. 2017; Brandon et al. 2015) and can operate from -40°C to 65°C.

41 Supercapacitors can supply high peaks of power very rapidly for short periods (seconds up to minutes)
42 and are able to fulfil the grid requirements for frequency regulation, but they would need to be
43 hybridized with batteries for automotive applications. Their commercial status is limited by costly
44 materials and additional power electronics required to stabilize their output (Brandon et al. 2015).
45 Progress in this area includes the development of high energy supercapacitors, LIB-supercapacitor
46 devices (Gonzalez et al. 2016), and cheaper materials (Wang et al. 2017a), all providing the potential

1 to improve the economic case for supercapacitors, either by reducing manufacturing costs or extending
2 their service portfolio.

3 Redox Flow Batteries (RFB). Redox flow batteries use two separate electrolyte solutions, usually
4 liquids, but solid or gaseous forms may also be involved, stored in separate tanks, and pumped over or
5 through electrode stacks during charge and discharge, with an ion-conducting membrane separating the
6 liquids. The larger the tank, the greater the energy storage capacity, whereas more and larger cells in
7 the stack increase the power of the flow battery. This decoupling of energy from power enables RFB
8 installations to be uniquely tailored to suit the requirements of any given application. There are two
9 commercially available types today: vanadium and zinc bromide, and both operate at near ambient
10 temperatures, incurring minimal operational costs.

11 RFBs respond rapidly and can perform all the same services as LIBs, except for onboard electricity for
12 EVs. Lower cost chemistries are emerging, to enable cost-effective bulk energy storage (Brandon et al.
13 2015). A new membrane-free design eliminates the need for a separator and also halves the system
14 requirements, as the chemical reactions can coexist in a single electrolyte solution (Navalpotro et al.
15 2017; Arenas et al. 2018).

16 Power to fuels (PtX). (see also Section 6.4.3.1) The process of using electricity to generate a gaseous
17 fuel, such as hydrogen or ammonia, is termed power-to-gas (PtG/P2G) (IEA 2020h). When injected
18 into the existing gas infrastructure (section 6.4.5), it has the added benefit of decarbonizing gas
19 (Brandon et al. 2015). Electricity can be used to generate hydrogen, which is then converted back into
20 electricity using combined-cycle gas turbines that have been converted to run on hydrogen. For greater
21 compatibility with existing gas systems and appliances, the hydrogen can be combined with captured
22 carbon dioxide to form methane and other synthetic fuels (Thema et al. 2019), however methane has
23 high global warming potential and its supply chain emissions have been found to be significant
24 (Balcombe et al. 2013).

25 PtX can provide all required grid services, depending on how it is integrated. However, a significant
26 amount of PtX is required for storage to produce electricity again (Bogdanov et al. 2019) due to the low
27 roundtrip efficiency of converting electricity to fuel and back again. However, portable fuels (hydrogen,
28 methane, ammonia, synthetic hydrocarbons) are useful in certain applications, for example in energy
29 systems lacking the potential for renewables, and the high energy density of chemical storage is
30 essential for more demanding applications, such as transporting heavy goods and heating or cooling
31 buildings (IEA 2020h). Research into more efficient and flexible electrolyzers which last longer and
32 cost less is needed (Brandon et al. 2015).

33 Hydrogen and Reversible Hydrogen Fuel Cells (H/RHFC). Hydrogen is a flexible fuel with diverse
34 uses, capable of providing electricity, heat, and long-term energy storage for grids, industry, and
35 transport, and has been widely used industrially for decades (Section 0). Hydrogen can be produced in
36 various ways and stored in significant quantities in geological formations at moderate pressures, often
37 for long periods, providing seasonal storage (Gabrielli et al. 2020). A core and emerging
38 implementation of PtX is hydrogen production through electrolyzers. Hydrogen is a carbon-free fuel
39 holding three times the energy held by an equivalent mass of gasoline but occupying a larger volume.
40 An electrolyzer uses excess electricity to split water into hydrogen and oxygen through the process of
41 electrolysis. A fuel cell performs the reverse process of recombining hydrogen and oxygen back into
42 water, converting chemical energy into electricity (Elzinga et al. 2014). Reversible hydrogen fuel cells
43 (RHFCs) can perform both functions in a single device, however they are still in the pre-commercial
44 stage, due to prohibitive production costs.

45 Hydrogen can play an important role in reducing emissions and has been shown to be the most cost-
46 effective option in some cases, as it builds on existing systems (Staffell et al. 2018). Fuel cell costs need
47 to be reduced and the harmonies between hydrogen and complementary technologies, such as batteries,

1 for specific applications need to be explored further. Hydrogen can provide long duration storage to
2 deal with prolonged extreme events, such as very low output of wind generation, to support resilience
3 of future low carbon energy systems. Research in this technology focuses on improving roundtrip
4 efficiencies, which can be as high as 80% with recycled waste heat and in high-pressure electrolyzers,
5 incorporating more efficient compression (Matos et al. 2019). Photo-electrolysis uses solar energy to
6 directly generate hydrogen from water (Amirante et al. 2017).

7 **6.4.4.2 Societal Dimensions of Energy Storage**

8 Public awareness knowledge about electricity storage technologies, their current state, and their
9 potential role in future energy systems is limited (Jones et al. 2018). For instance, people do not perceive
10 energy system flexibility and storage as a significant issue, or assume storage is already taking place.
11 Public perceptions differ across storage technologies. Hydrogen is considered a modern and clean
12 technology, but people also have safety concerns. Moreover, the public is uncertain about hydrogen
13 storage size and the possibility of storing hydrogen in or near residential areas (Eitan and Fischhendler
14 2021). Battery storage both on the household and community level was perceived as slightly positive
15 in one study in the UK (Ambrosio-Albala et al. 2020). However, financial costs are seen as a main
16 barrier. The potential of electric vehicle batteries to function as flexible storage is limited by the current
17 numbers of EV owners and concerns that one's car battery might not be fully loaded when needed.

18 **6.4.5 Energy Transport and Transmission**

19 The linkage between energy supply and distribution, on the one hand, and energy use on the other is
20 facilitated by various mechanisms for transporting energy. As the energy system evolves, the way that
21 energy is transported will also evolve.

22 **6.4.5.1 Hydrogen: Low-Carbon Energy Fuel**

23 Hydrogen is a promising energy carrier for a decarbonized world (Box 6.9). It can be utilized for
24 electricity, heat, transport, industrial demand, and energy storage (Abdin et al. 2020). In low-carbon
25 energy systems, hydrogen is expected to be utilized in applications that are not as amenable to
26 electrification, such as a fuel for heavy-duty road transport and shipping, or as a chemical feedstock
27 (Griffiths et al. 2021; Schemme et al. 2017). Hydrogen could also provide low-carbon heat for industrial
28 processes or be utilized for direct reduction of iron ore (Vogl et al. 2018). Hydrogen could replace
29 natural gas-based electricity generation (do Sacramento et al. 2013) in certain regions and support the
30 integration of variable renewables into electricity systems by providing a means of long-term electricity
31 storage. Hydrogen-based carriers, such as ammonia and synthetic hydrocarbons, can likewise be used
32 in energy-intensive industries and the transport sector (Schemme et al. 2017; IRENA 2019b) (e.g.,
33 synthetic fuels for aviation). These hydrogen-based energy carriers are easier to store than hydrogen.
34 At present hydrogen has limited applications – mainly being produced onsite for the creation of
35 methanol and ammonia (IEA 2019c), as well as in refineries.

36 Low- or zero-carbon produced hydrogen is not currently competitive for large-scale applications, but it
37 is likely to have a significant role in future energy systems, due to its wide-range of applications (*high*
38 *confidence*). Key challenges for hydrogen are: (a) cost-effective low/zero carbon production, (b)
39 delivery infrastructure cost, (c) land area (i.e., 'footprint') requirements of hydrogen pipelines,
40 compressor stations, and other infrastructure, (d) challenges in using existing pipeline infrastructure,
41 (e) maintaining hydrogen purity, (e) minimizing hydrogen leakage, and (f) the cost and performance of
42 end-uses. Furthermore, it is necessary to consider the public perception and social acceptance of
43 hydrogen technologies and their related infrastructure requirements (Scott and Powells 2020; Iribarren
44 et al. 2016)

45 *Hydrogen Production.* Low- or zero-carbon hydrogen can be produced from multiple sources. While
46 there is no consensus on the hydrogen production spectrum, "blue" hydrogen (Goldmann and

Dinkelacker 2018) generally refers to hydrogen produced from natural gas combined with CCS through processes such as steam methane reforming (SMR)(Sanusi and Mokheimer 2019) and advanced gas reforming (Zhou et al. 2020). Low-carbon hydrogen could also be produced from coal coupled with CCS (Hu et al. 2020) (Table 6.7). Current estimates are that adding CCS to produce hydrogen from SMR will add on average 50% on the capital cost, 10% to fuel, and 100% to operating costs. For coal gasification, CCS will add 5% to the capital and fuel costs and 130% to operating costs (IEA 2019d; Staffell et al. 2018). Further, biomass gasification could produce renewable hydrogen, and when joined with CCS could provide negative carbon emissions. “Green” hydrogen (Jaszczur et al. 2016) most often is referred to as hydrogen produced from zero-carbon electricity sources such as solar power and wind power (Schmidt et al. 2017) (Table 6.8). Nuclear power could also provide clean hydrogen, via electrolysis or thermochemical water splitting (EERE 2020). Hydrogen can even be produced pyrolysis of methane (Sánchez-Bastardo et al. 2020), sometimes called as “turquoise” hydrogen, solar thermochemical water splitting, biological hydrogen production (cyanobacteria) (Velazquez Abad and Dodds 2017), and microbes that use light to make hydrogen (under research)(EIA 2020).

Hydrogen energy carriers. Hydrogen can be both an energy carrier itself, be converted further for into other energy carriers (such as synthetic fuels) and be a means of transporting other sources of energy. For example, hydrogen could be transported in its native gaseous form or liquified. Hydrogen can also

1 be combined with carbon and transported as a synthetic hydrocarbons (Gumber and Gurumoorthy 2018)
2 (IRENA 2019d) as well as be transported via liquid organic hydrogen carriers (LOHCs) or ammonia
3 (IRENA 2019d). For synthetic hydrocarbons such as methane or methanol to be considered zero carbon,
4 the CO₂ used to produce them would need to come from the atmosphere either directly through DACCS
5 or indirectly through BECCS (IRENA 2019b). LOHCs are organic substances in liquid or semi-solid
6 states, which store hydrogen based on reversible catalytic hydrogenation and de-hydrogenation of
7 carbon double bounds (Rao and Yoon 2020; Niermann et al. 2019). Hydrogen produced from
8 electrolysis could also be seen as an electricity energy carrier. This is an example of the PtX processes
9 (section 6.4.4), entailing the conversion of electricity to other energy carriers for subsequent use.

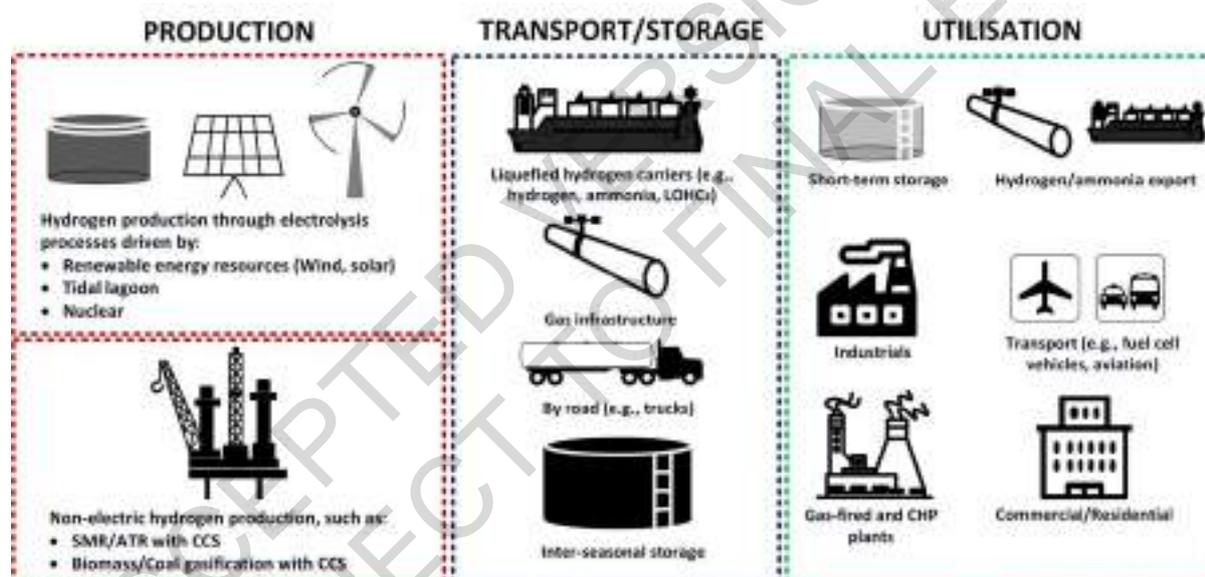

10 Ammonia is a promising cost-effective hydrogen carrier (Creutzig et al. 2019). Onsite generation of
11 hydrogen for the production of ammonia already occurs today, and the NH₃ could be subsequently
12 “cracked” (with a 15–25% energy loss) to reproduce hydrogen (Bell and Torrente-Murciano 2016;
13 Hansgen et al. 2010; Montoya et al. 2015). Because the energy density of ammonia is 38% higher than
14 liquid hydrogen (Osman and Sgouridis 2018), it is potentially a suitable energy carrier for long-distance
15 transport and storage (Salmon et al. 2021) Moreover, ammonia is more easily condensable (liquefied at
16 0.8 MPa, 20°C), which provides economically viable hydrogen storage and supply systems. Ammonia
17 production and transport are also established industrial processes (~180 MMT yr⁻¹ (Valera-Medina et
18 al. 2017), and hence ammonia is considered to be a scalable and cost-effective hydrogen-based energy
19 carrier. At present, most ammonia is used in fertilizers (~80%), followed by many industrial processes,
20 such as the manufacturing of mining explosives and petrochemicals (Jiao and Xu 2018). In contrast to
21 hydrogen, ammonia can be used directly as a fuel without any phase change for internal combustion
22 engines, gas turbines, and industrial furnaces (Kobayashi et al. 2019). Ammonia can also be used in
23 low and high temperature fuel cells (Lan and Tao 2014), whereby both electricity and hydrogen can be
24 produced without any NO_x emissions. Furthermore, ammonia provides the flexibility to be
25 dehydrogenated for hydrogen-use purposes. Ammonia is considered a carbon-free sustainable fuel for
26 electricity generation, since in a complete combustion, only water and nitrogen are produced (Valera-
27 Medina et al. 2017). Like hydrogen, ammonia could facilitate management of variable RES, due to its
28 cost-effective grid-scale energy storage capabilities. In this regard, production of ammonia via hydrogen
29 from low- or zero-carbon generation technologies along with ammonia energy recovery technologies
30 (Afif et al. 2016) could play a major role in forming a hydrogen and/or ammonia economy to support
31 decarbonization. However, there are serious concerns regarding the ability to safely use ammonia for
32 all these purposes, given its toxicity - whereas hydrogen is not considered toxic.

33 In general, challenges around hydrogen-based energy carriers - including safety issues around
34 flammability, toxicity, storage, and consumption - require new devices and techniques to facilitate their
35 large-scale use. Relatively high capital costs and large electricity requirements are also challenges for
36 technologies that produce hydrogen energy carriers. Yet, these energy carriers could become
37 economically viable through the availability of low-cost electricity generation and excess of renewable
38 energy production (Daiyan et al. 2020) A key challenge in use of ammonia is related to significant
39 amount of NO_x emissions, which is released from nitrogen and oxygen combustion, and unburned
40 ammonia. Both have substantial air pollution risks, which can result in lung and other injuries, and can
41 reduce visibility (EPA 2001). Due to the low flammability of hydrogen energy carriers such as liquified
42 hydrogen (Nilsson et al. 2016) and ammonia (Li et al. 2018), a stable combustion (Zengel et al. 2020;
43 Lamas and Rodriguez 2019) in the existing gas turbines is not currently feasible. In recent
44 developments, however, the proportion of hydrogen in gas turbines has been successfully increased,
45 and further development of gas turbines may enable them to operate on 100% hydrogen by 2030 (Pflug
46 et al. 2019)

47 *Long-Distance Hydrogen Transport.* Hydrogen can allow regional integration and better utilization of
48 low- or zero-carbon energy sources (Box 6.9 and Box 6.10). Hydrogen produced from renewables or

1 other low-carbon sources in one location could be transported for use elsewhere (Philibert 2017; Ameli
2 et al. 2020). Depending on the distance to the user and specific energy carrier utilized (e.g., gaseous
3 hydrogen or LOHC), various hydrogen transport infrastructures, distribution systems, and storage
4 facilities would be required (Hansen 2020; Schönauer and Glanz 2021) (Figure 6.17).

5 Hydrogen can be liquefied and transported at volume over the ocean without pressurization. This
6 requires a temperature of -253°C and is therefore energy-intensive and costly (Niermann et al. 2021).
7 Once it reaches its destination, the hydrogen needs to be re-gasified, adding further cost. A
8 demonstration project is under development exporting liquid hydrogen from Australia to Japan
9 (Yamashita et al. 2019). Hydrogen could also be transported as ammonia by ocean in liquid form.
10 Ammonia is advantageous because it is easier to store than hydrogen (Zamfirescu and Dincer 2008;
11 Nam et al. 2018; Soloveichik 2016). Liquid ammonia requires temperatures below -33°C and is
12 therefore more straightforward and less costly to transport than liquefied hydrogen and even liquefied
13 natural gas (Singh and Sahu 2018). A project exporting ammonia from Saudi Arabia to Japan is under
14 consideration (Nagashima 2018). LOHCs could also be used to transport hydrogen at ambient
15 temperature and pressure. This advantageous property of LOHCs makes them similar to oil products,
16 meaning they can be transported in existing oil infrastructure including oil tankers and tanks (Niermann
17 et al. 2019; IEA 2019). A project is under development to export hydrogen from Brunei to Japan using
18 LOHCs (Kurosaki 2018).

19
20 **Figure 6.17 Hydrogen value chain. Hydrogen can be produced by various means and input and fuel**
21 **sources. These processes have different emissions implications. Hydrogen can be transported by various**
22 **means and in various forms, and it can be stored in bulk for longer-term use. It also has multiple**
23 **potential end uses. CHP: Combined heat and power**

24 *Intra-Regional Hydrogen Transportation.* Within a country or region, hydrogen would likely be
25 pressurized and delivered as compressed gas. About three times as much compressed hydrogen by
26 volume is required to supply the same amount of energy as natural gas. Security of supply is therefore
27 more challenging in hydrogen networks than in natural gas networks. Storing hydrogen in pipelines
28 (linepack) would be important to maintaining security of supply (Ameli et al. 2019, 2017). Due to the
29 physics of hydrogen, in most cases existing gas infrastructure would need to be upgraded to transport
30 hydrogen. Transporting hydrogen in medium- or high-pressure networks most often would require
31 reinforcements in compressor stations and pipeline construction routes (Dohi et al. 2016). There are
32 several recent examples of efforts to transport hydrogen by pipeline. For example, in the Iron Mains
33 Replacement Programme in the UK, the existing low pressure gas distribution pipes are being converted

1 from iron to plastic (Committee on Climate Change 2018). In the Netherlands, an existing low-pressure
2 12 km natural gas pipeline has been used for transporting hydrogen (Dohi et al. 2016).

3 To bypass gas infrastructure in transporting hydrogen, methane can be transported using the existing
4 gas infrastructure, while hydrogen can be produced close to the demand centres. This approach will
5 only make sense if the methane is produced in a manner that captures carbon from the atmosphere
6 and/or if CCS is used when the methane is used to produce hydrogen.

7 *Bulk Hydrogen Storage.* Currently, hydrogen is stored in bulk in chemical processes such as metal and
8 chemical hydrides as well as in geologic caverns (Andersson and Grönkvist 2019; Caglayan et al. 2019)
9 (e.g., salt caverns operate in Sweden) (Elberry et al. 2021). There are still many challenges, however,
10 due to salt or hard rock geologies, large size, and minimum pressure requirements of the sites (IEA
11 2019c). Consequently, alternative carbon-free energy carriers, which store hydrogen, may become more
12 attractive (Kobayashi et al. 2019; Lan et al. 2012).

13 **6.4.5.2 Electricity Transmission**

14 Given the significant geographical variations in the efficiency of renewable resources across different
15 regions and continents, electricity transmission could facilitate cost effective deployment of renewable
16 generation, enhance resilience and security of supply, and increase operational efficiency (*high*
17 *confidence*). The diurnal and seasonal characteristics of different renewable energy sources such as
18 wind, solar, and hydropower can vary significantly by location. Through enhanced electricity
19 transmission infrastructure, more wind turbines can be deployed in areas with high wind potential and
20 more solar panels in areas with larger solar irradiation. Increases in electricity transmission and trade
21 can also enhance operational efficiency and reduce or defer the need for investment in peaking plants,
22 storage, or other load management techniques needed to meet security of supply requirements
23 associated with localized use of VRE sources. Increased interconnectivity of large-scale grids also
24 allows the aggregation of ‘smart grid’ solutions such as flexible heating and cooling devices for flexible
25 demand in industrial, commercial, and domestic sectors (Hakimi et al. 2020) and EVs (Li et al. 2021;
26 Muratori and Mai 2020). In general, interconnection is more cost-optimal for countries that are
27 geographically close to each other and can benefit from the diversity of their energy mixes and usage
28 (Schlachtberger et al. 2017). Such developments are not without price, however, and amongst other
29 concerns, raise issues surrounding land use, public acceptance, and resource acquisition for materials
30 necessary for renewable developments (Vakulchuk et al. 2020; Capellán-Pérez et al. 2017).

31 A number of studies have demonstrated the cost benefits of interconnected grids in a range of
32 geographical settings, including across the United States (Bloom et al. 2020), across Europe (2020;
33 Newbery et al. 2013; Cluet et al. 2020), between Australia and parts of Asia (Halawa et al. 2018), and
34 broader global regions, for example between the Middle East and Europe or North Africa and Europe
35 (Tsoutsos et al. 2015). While there is growing interest in interconnection among different regions or
36 continents, a broad range of geopolitical and socio-techno-economic challenges would need to be
37 overcome to support this level of international co-operation and large-scale network expansion (Bertsch
38 et al. 2017; Palle 2021).

39 *Status of electricity transmission technology.* Long-distance electricity transmission technologies are
40 already available. High voltage alternating current (HVAC), high-voltage direct current (HVDC), and
41 ultra HVDC (UHVDC) technologies are well-established and widely used for bulk electricity
42 transmission (Alassi et al. 2019). HVDC is used with underground cables or long-distance overhead
43 lines (typically voltages between 100–800 kV (Alassi et al. 2019) where HVAC is infeasible or not
44 economic. A ~USD 17 bn project development agreement was signed in January 2021 that would
45 connect 10 GW of PVs in the north of Australia via a 4500 km 3 GW HVDC cable to Singapore,
46 suggesting that this would be cost effective (Sun Cable 2021). In September 2019, the Changji-Guquan
47 ±1,100 kV ultra-high voltage direct current (UHVDC) transmission project built by State Grid

1 Corporation of China was officially completed and put into operation. The transmission line is able to
2 transmit up to 12 GW over 3341 km (Pei et al. 2020). This is the UHVDC transmission project with the
3 highest voltage level, the largest transmission capacity, and the longest transmission distance in the
4 world (Liu 2015).

5 Other technologies that could expand the size of transmission corridors and/or improve the operational
6 characteristics include low-frequency AC transmission (LFAC) (Xiang et al. 2021; Tang et al. 2021b)
7 and half-wave AC transmission (HWACT) (Song et al. 2018; Xu et al. 2019). LFAC is technically
8 feasible, but the circumstances in which it is the best economic choice compared to HVDC or HVAC
9 still needs to be established (Xiang et al. 2016). HWACT is restricted to very long distances, and it has
10 not been demonstrated in practice, so its feasibility is unproven. There are still a number of
11 technological challenges for long-distance transmission networks such as protection systems for DC or
12 hybrid AC-DC networks (Franck C. et al. 2017; Chaffey 2016), improvement in cabling technology,
13 and including the use of superconductors and nanocomposites (Ballarino et al. 2016; Doukas 2019),
14 which require advanced solutions.

15 *Challenges, barriers, and recommendations.* The main challenge to inter-regional transmission is the
16 absence of appropriate market designs and regulatory and policy frameworks. In addition, there are
17 commercial barriers for further enhancement of cross-border transmission. The differing impacts of
18 cross-border interconnections on costs and revenues for generation companies in different regions could
19 delay the development of these interconnectors. It is not yet clear how the investment cost of
20 interconnections should be allocated and recovered, although there is growing support for allocating
21 costs in accordance with the benefits delivered to the market participants. Increased cross-border
22 interconnection may also require new business models which provide incentives for investment and
23 efficient operation, manage risks and uncertainties, and facilitate coordinated planning and governance
24 (Poudineh and Rubino 2017).

25 Optimizing the design and operation of the interconnected transmission system, both onshore and
26 offshore grids, also requires more integrated economic and reliability approaches (Moreno et al. 2012)
27 to ensure the optimal balance between the economics and the provision of system security while
28 maximizing the benefits of smart network technologies.

29 A wide range of factors, including generation profiles, demand profiles circuit losses, reliability
30 characteristics, and maintenance, as well as the uncertainties around them will need to be considered in
31 designing and operating long-distance transmission systems if they are to be widely deployed (De Sa
32 and Al Zubaidy 2011; Du 2009; Djapic et al. 2008; E3G 2021). Public support for extending
33 transmission systems will also be crucial, and studies indicate that such support is frequently low
34 (Perlaviciute et al. 2018; Vince 2010).

35 **6.4.6 Demand Side Mitigation Options from an Energy Systems Perspective**

36 Demand-side measures are fundamental to an integrated approach to low carbon energy systems (*high*
37 *confidence*). Mitigation options, such as wind parks, CCS, and nuclear power plants, may not be
38 implemented when actors oppose these options. Further, end users, including consumers, governments,
39 businesses and industry, would need to adopt the relevant options, and then use these as intended; user
40 adoption can be a key driver to scale up markets for low carbon technologies. This section discusses
41 which factors shape the likelihood that end users engage in relevant mitigation actions, focusing on
42 consumers; strategies to promote mitigation actions are discussed in Section 6.7.6.1.

43 A wide range of actions of end users would reduce carbon emissions in energy systems (Abrahamse et
44 al. 2007; Dietz 2013; Creutzig et al. 2018; Hackmann et al. 2014; Grubler et al. 2018), including:

- 45 • use of low carbon energy sources and carriers. Actors can produce and use their own renewable
46 energy (e.g., install solar PV, solar water heaters, heat pumps), buy shares in a renewable energy
47 project (e.g., wind shares), or select a renewable energy provider.

- 1 • adoption of technologies that support flexibility in energy use and sector coupling, thereby
2 providing flexibility services by balancing demand and renewable energy supply. This would
3 reduce the need to use fossil fuels to meet demand when renewable energy production is low and
4 put less pressure on deployment of low-emission energy supply systems. Examples are technologies
5 to store energy (e.g., batteries and electric vehicles) or that automatically shift appliances on or off
6 (e.g., fridges, washing machines).
- 7 • adoption of energy-efficient appliances and systems and increase of resource efficiency of end uses
8 so that less energy is required to provide the same service. Examples are insulating buildings, and
9 passive or energy positive buildings.
- 10 • change behaviour to reduce overall energy demand or to match energy demand to available energy
11 supplies. Examples include adjusting indoor temperature settings, reducing showering time,
12 reducing car use or flying, and operating appliances when renewable energy production is high.
- 13 • purchase and use products and services that are associated with low GHG emissions during their
14 production (e.g., reduce dairy and meat consumption) or for transporting products (e.g., local
15 products). Also, end users can engage in behaviour supporting a circular economy, by reducing
16 waste (e.g., of food), sharing products (e.g., cars, equipment), and refurbishing products (e.g., repair
17 rather than buying new products) so that less new products are used.

18 Various factors shape whether such mitigation actions are feasible and considered by end users,
19 including contextual factors, individual abilities, and motivational factors. Mitigation actions can be
20 facilitated and encouraged by targeting relevant barriers and enablers (section 6.7.6.2).

21 Contextual factors, such as physical and climate conditions, infrastructure, available technology,
22 regulations, institutions, culture, and financial conditions define the costs and benefits of mitigation
23 options that enable or inhibit their adoption (*high confidence*). Geographic location and climate factors
24 may make some technologies, such as solar PV or solar water heaters, impractical (Chang et al. 2009).
25 Culture can inhibit efficient use of home heating or PV (Sovacool and Griffiths 2020), low carbon diets
26 (Dubois et al. 2019), and advanced fuel choices (Van Der Kroon et al. 2013). Also, favourable financial
27 conditions promote the uptake of PV (Wolske and Stern 2018), good facilities increase recycling
28 (Geiger et al. 2019), and vegetarian meal sales increase when more vegetarian options are offered..

29 Mitigation actions are more likely when individuals feel capable to adopt them (Pisano and Lubell 2017;
30 Geiger et al. 2019), which may depend on income and knowledge. Low-income groups may lack
31 resources to invest in refurbishments and energy-efficient technology with high upfront costs (Andrews-
32 Speed and Ma 2016; Chang et al. 2009; Wolske and Stern 2018). Yet, higher income groups can afford
33 more carbon-intensive lifestyles (Golley and Meng 2012; Namazkhan et al. 2019; Frederiks et al. 2015;
34 Santillán Vera and de la Vega Navarro 2019; Mi et al. 2020; Wiedenhofer et al. 2017). Knowledge of
35 the causes and consequences of climate change and of ways to reduce GHG emissions is not always
36 accurate, but lack of knowledge is not a main barrier of mitigation actions (Boudet 2019).

37 Motivation to engage in mitigation action, reflecting individuals' reasons for actions, depends on
38 general goals that people strive for in their life (i.e., values). People who strongly value protecting the
39 environment and other people are more likely to consider climate impacts and to engage in a wide range
40 of mitigation actions than those who strongly value individual consequences of actions, such as pleasure
41 and money (Taylor et al. 2014; Steg 2016). Values affect which types of costs and benefits people
42 consider and prioritize when making choices, including individual, affective, social, and environmental
43 costs and benefits (Gowdy 2008; Steg 2016).

44 First, people are more likely to engage in mitigation behaviour (i.e., energy savings, energy efficiency,
45 resource efficiency in buildings, low-carbon energy generation) when they believe such behaviour has
46 more individual benefits than costs (Harland et al. 1999; Steg and Vlek 2009; Kastner and Matthies
47 2016; Kastner and Stern 2015; Kardooni et al. 2016; Wolske et al. 2017; Korcaj et al. 2015), including
48 financial benefits, convenience, comfort, autonomy, and independence in energy supply (Wolske and

1 Stern 2018). Yet, financial consequences seem less important for decisions to invest in energy-
2 efficiency and renewable energy production than people indicate (Zhao et al. 2012).

3 Second, people are less likely to engage in mitigation behaviours that are unpleasurable or inconvenient
4 (Steg 2016), and more likely to do so when they expect to derive positive feelings from such actions
5 (Smith et al. 1994; Pelletier et al. 1998; Steg 2005; Carrus et al. 2008; Brosch et al. 2014; Taufik et al.
6 2016). Positive feelings may be elicited when behaviour is pleasurable, but also when it is perceived as
7 meaningful (Bolderdijk et al. 2013; Taufik et al. 2015).

8 Third, social costs and benefits can affect climate action (Farrow et al. 2017), although people do not
9 always recognize this (Nolan et al. 2008; Noppers et al. 2014). People engage more in mitigation actions
10 when they think others expect them to do so and when others act as well (Rai et al. 2016; Harland et al.
11 1999; Nolan et al. 2008). Being part of a group that advocates mitigation actions encourages such
12 actions (Biddau et al. 2016; Fielding and Hornsey 2016; Jans et al. 2018). Talking with peers can reduce
13 uncertainties and confirm benefits about adoption of renewable energy technology (Palm 2017), and
14 peers can provide social support (Wolske et al. 2017). People may engage in mitigation actions when
15 they think this would signal something positive about them (Griskevicius et al. 2010; Milinski et al.
16 2006; Kastner and Stern 2015; Noppers et al. 2014). Social influence can also originate from political
17 and business leaders (Bouman and Steg 2019); GHG emissions are lower when legislators have strong
18 environmental records (Jensen and Spoon 2011; Dietz et al. 2015).

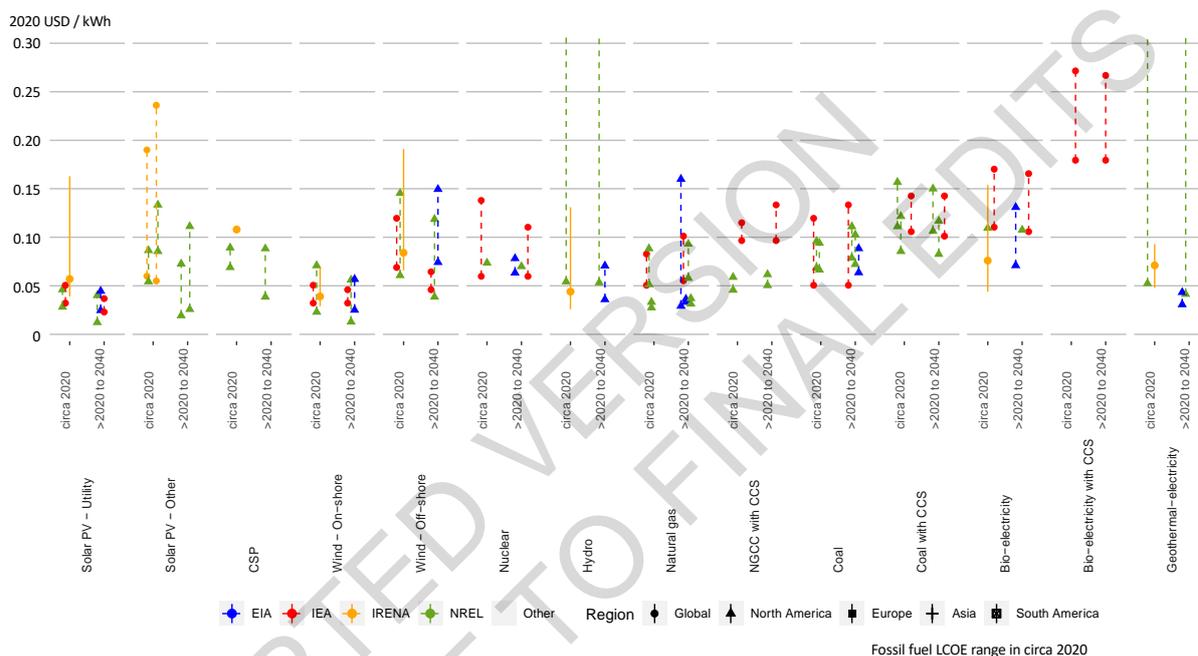

19 Fourth, mitigation actions, including saving energy and hot water, limiting meat consumption, and
20 investing in energy efficiency, resource efficiency in buildings, and renewable energy generation are
21 more likely when people more strongly care about others and the environment (Van Der Werff and Steg
22 2015; Steg et al. 2015; Wolske et al. 2017). People across the world generally strongly value the
23 environment (Bouman and Steg 2019; Steg 2016), suggesting that they are motivated to mitigate climate
24 change. The more individuals are aware of the climate impact of their behaviour, the more they think
25 their actions can help reduce such impacts, which strengthens their moral norms to act accordingly, and
26 promotes mitigation actions (Steg and de Groot 2010; Jakovcevic and Steg 2013; Chen 2015; Wolske
27 et al. 2017).

28 Initial mitigation actions can encourage engagement in other mitigation actions when people experience
29 that such actions are easy and effective (Lauren et al. 2016), and when initial actions make them realize
30 they are a pro-environmental person, motivating them to engage in more mitigation actions so as to be
31 consistent (van der Werff et al. 2014; Lacasse 2015, 2016; Peters et al. 2018). This implies it would be
32 important to create conditions that make it likely that initial mitigation actions motivate further actions.

33 **6.4.7 Summary of Mitigation Options**

34 Designing feasible, desirable, and cost-effective energy sector mitigation strategies requires comparison
35 between the different mitigation options. One such metric is the cost of delivering one unit of energy,
36 for example, the levelized cost, or USD MWh⁻¹, of electricity produced from different sources. LCOEs
37 are useful because they normalize the costs per unit of service provided. While useful in characterizing
38 options in broad strokes, it is important to acknowledge and understand several caveats associated with
39 these metrics, particularly when applied globally. They may be constructed with different discount
40 rates; they require information on energy input costs for options that require energy inputs (e.g., fossil
41 electricity generation, biofuels); they depend on local resource availability, for example solar insolation
42 for solar power, wind classes for wind power, and rainfall and streamflow for hydropower; and actual
43 implementation costs may include additional elements, for example, the costs of managing electricity
44 grids heavily dependent on VRE electricity sources. These complicating factors vary across regions,
45 some depend strongly on the policy environment in which mitigation options are deployed, and some
46 depend on how technologies are constructed and operated.

1 The literature provides multiple LCOE estimates for mitigation options today and in the future (see
 2 Table 6.9 for electricity generation options). LCOE ranges for low- and zero-carbon electricity
 3 technologies overlap with LCOE's of fossil generation without CCS. For example, LCOEs for utility
 4 solar and wind today and in the future overlap with those of new coal and gas without CCS (Figure
 5 6.18, NREL 2021; Lazard, 2020; IEA WEO 2020, IEA WEO 2020). Some of the overlap stems from
 6 differences in assumptions or regional conditions that apply to all technologies (e.g., variations in
 7 assumed discount rates), but the overlap also reflects the fact that low- and zero-carbon electricity
 8 generation options are, and will be, less expensive than emitting options in many regions. Future cost
 9 projections also illustrate that several technologies are anticipated to experience further cost declines
 10 over the coming decades, reinforcing the increasingly competitiveness of low- and zero-carbon
 11 electricity. For example, IEA's LCOEs estimates for offshore wind halve between 2020 and 2040 in
 12 several regions (IEA WEO 2020).

13
 14 **Figure 6.18 Range of LCOEs (in USD cents kWh⁻¹) from recent studies for different electricity generating**
 15 **technologies circa 2020 and in the future between 2020-2040. LCOEs are primarily taken from recent**
 16 **studies, because the costs of some technologies are changing rapidly. To make the figure more tractable**
 17 **across the studies, we highlight the data from IEA WEO 2020 STEPS scenario in red (EIA, 2020), the EIA**
 18 **AEO 2021 in blue (EIA, 2021), NREL ATB 2021 in green, (NREL, 2021), and IRENA Renewable Power**
 19 **Generation Costs in 2020 in yellow (IRENA, 2021). All other studies are shown in light grey markers.**
 20 **Marker shapes identify the regions included in the studies. Studies that included several regions are labelled**
 21 **as global. Only sources that provided LCOEs are included. Ranges for studies frequently reflect variations**
 22 **among regional estimates. Studies that are shown as a mid-point and a solid line represent studies that**
 23 **reported either a median or an average, and that had either a confidence interval or a minimum and a**
 24 **maximum reported. Dashed lines with markers at the end represent the range of values reported in studies**
 25 **that had several point estimates for either different regions or used different assumptions. All estimates**
 26 **were converted to 2020 USD. The publication year was used if no USD year was provided. Some studies**
 27 **included transmissions costs, and some the CCS studies included storage and sequestration costs, while**
 28 **others did not. Vertical axis is capped at USD₂₀₂₀ 0.30 kWh⁻¹, but some estimates for hydro, geothermal,**
 29 **natural gas and bioelectricity were higher than 0.30. The grey horizontal band denotes the range of fossil**
 30 **fuel electricity LCOEs in circa 2020.**

31 A more direct metric of mitigation options is the cost to reduce one tonne of CO₂ or equivalent GHGs,
 32 or USD tCO₂-eq⁻¹ avoided. In addition to the comparison challenges noted above, this metric must
 33 account for the costs and emissions of the emitting options that is being displaced by the low-carbon
 34 option. Assumptions about the displaced option can lead to very different mitigation cost estimates

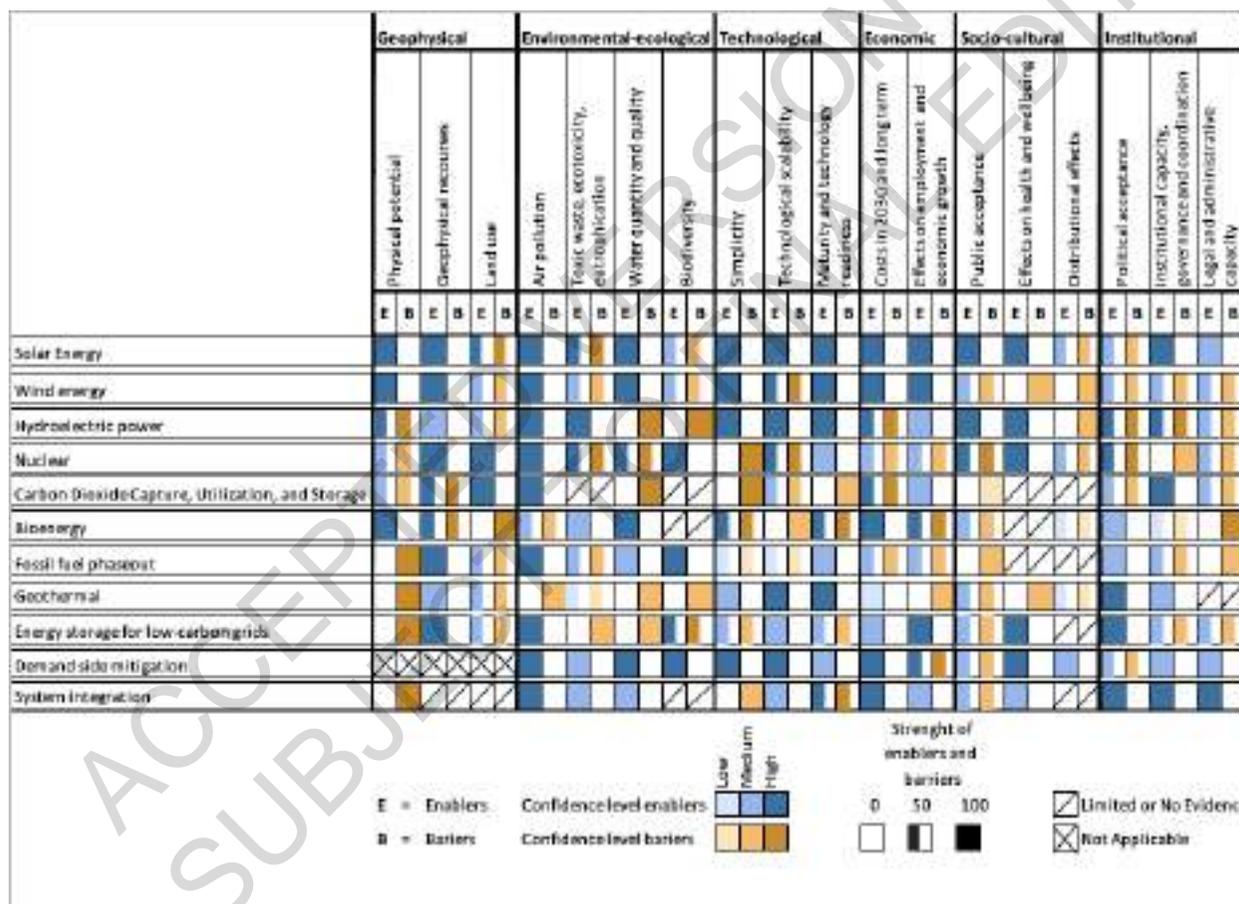

1 (Table 6.9). Despite these challenges, these metrics are useful for identifying broad trends and making
 2 broad comparisons, even from the global perspective in this assessment. But local information will
 3 always be critical to determine which options are most cost-effective in any specific applications.

4
 5 **Table 6.9 Examples of cost of mitigation for selected electricity options. Results represent variations in**
 6 **mitigation options and displaced fossil generation. LCOEs are illustrative, but consistent with recent**
 7 **estimates. Negative values mean that the mitigation option is cheaper than the displaced option,**
 8 **irrespective of emissions benefits.**

		Baseline			
		New coal	Existing coal	New NGCC	Existing NGCC
	Baseline emissions rate (tonCO ₂ MWh ⁻¹)	0.8	0.9	0.34	0.42
	LCOE (USD ₂₀₂₀ kWh ⁻¹)	0.065	0.041	0.044	0.028
Utility scale solar PV (poor resource site)	0.100	44 USD tCO ₂ -eq ⁻¹	66 USD tCO ₂ -eq ⁻¹	165 USD tCO ₂ -eq ⁻¹	171 USD tCO ₂ -eq ⁻¹
Utility scale solar PV (good resource site)	0.035	-38 USD tCO ₂ -eq ⁻¹	-7 USD tCO ₂ -eq ⁻¹	-26 USD tCO ₂ -eq ⁻¹	17 USD tCO ₂ -eq ⁻¹

9
 10 The feasibility and desirability of mitigation options extends well beyond the market economic costs of
 11 installation and operation (Section 6.4.1). Figure 6.19 summarizes the barriers and enablers for
 12 implementing different mitigation options in energy systems. The feasibility of different options can be
 13 enhanced by removing barriers and/or strengthening enablers of the implementation of the options. The
 14 feasibility of options may differ across context (e.g., region), time (e.g., 2030 versus 2050), scale (e.g.,
 15 small versus large) and the long-term warming goal (e.g., 1.5°C versus 2°C).

1 **Figure 6.19 Summary of the extent to which different factors would enable or inhibit the deployment of mitigation options in energy systems. Blue bars indicate the**
 2 **extent to which the indicator enables the implementation of the option (E) and orange bars indicate the extent to which an indicator is a barrier (B) to the**
 3 **deployment of the option, relative to the maximum possible barriers and enablers assessed. An X signifies the indicator is not applicable or does not affect the**
 4 **feasibility of the option, while a forward slash indicates that there is no or limited evidence whether the indicator affects the feasibility of the option. The shading**
 5 **indicates the level of confidence, with darker shading signifying higher levels of confidence. Appendix II provides an overview of the factors affecting the feasibility**
 6 **of options and how they differ across context (e.g., region), time (e.g., 2030 versus 2050), and scale (e.g., small versus large), and includes a line of sight on which the**
 7 **assessment is based. The assessment method is explained in Annex II.11.**

8

1 **6.5 Climate Change Impacts on the Energy System**

2 **6.5.1 Climate Impacts on the Energy System**

3 Many components of the energy system are affected by individual weather events and climate
4 conditions (Table 6.10). In addition, a range of compounding effects can be anticipated, as the complex,
5 interconnected climate and energy system are influenced by multiple weather and climate conditions.
6 This raises the question of whether the energy system transformation needed to limit warming will be
7 impacted by climate change.

8

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1 The impacts of *climate change* on the energy system can be divided into three areas: impacts on the
2 energy supply, impacts on energy consumption, and impacts on energy infrastructure. The rest of this
3 section focuses on how the *future changes* in climate drivers might affect the ability of the energy
4 system transformation needed to mitigate climate change. The discussion of energy infrastructure in
5 this section is limited to electric electricity system vulnerability.

6 **6.5.2 Impacts on Energy Supply**

7 The increased weather-dependency of future low-carbon electricity systems amplifies the possible
8 impacts of climate change (Staffell and Pfenninger 2018). However, *globally* climate change impacts
9 on electricity generation – including hydro, wind and solar power potentials – should not compromise
10 climate mitigation strategies (*high confidence*). Many of the changes in the climate system will be
11 geographically complex at the regional and local levels. Thus, *regionally* climate change impacts on
12 electricity generation could be significant. Climate change impacts on bioenergy potentials are more
13 uncertain because of uncertainties associated with the crop response to climate change, future water
14 availability and crop deployment. Climate change can reduce the efficiency of thermal power generation
15 and increase the risk of power plant shutdowns during droughts. The potential additional cooling water
16 needs of CCS can increase these risks.

17 **6.5.2.1 Hydropower**

18 The impacts of climate change on hydropower will vary by region. High latitudes in the northern
19 hemisphere are anticipated to experience increased runoff and hydropower potential. For other regions,
20 studies find both increasing and decreasing runoff and hydropower potential. Areas with decreased
21 runoff are anticipated to experience reduced hydropower production and increased water conflict among
22 different economic activities. (*high confidence*)

23 Hydropower production is directly related to the availability of water. Changes in runoff and its
24 seasonality and changes in temperature and precipitation intensity will influence hydro electricity
25 production (IHA 2019). In general, increased precipitation will increase water availability and
26 hydropower production. Increased precipitation intensity, however, may impact the integrity of dam
27 structures and affect power production by increasing debris accumulation and vegetation growth.
28 Additionally, increased precipitation intensity results in the silting of the reservoirs or increases the
29 amount of water spilt, resulting in erosion (Schaeffer et al. 2012; IHA 2019). Climate change will likely
30 lead to higher air temperatures, resulting in more surface evaporation, less water storage, and loss of
31 equipment efficiency (Ebinger and Vergara 2011; Fluixá-Sanmartín et al. 2018; Hock et al. 2019;
32 Mukheibir 2013). Climate change may alter the demands for water use by other sectors that often rely
33 on stored water in multi-purpose reservoirs and may therefore generate conflicts over water use. The
34 increased need for water for irrigation and/or industry can affect the availability of water for hydropower
35 generation (Solaun and Cerdá 2017; Spalding-Fecher et al. 2016). Higher temperatures increase glacier
36 melt, increasing water availability for hydropower while the glaciers exist. Changes in the timing of
37 snow and ice melt may require upgrading in storage capacity and adaptation of the hydropower plant
38 management for fully exploiting the increase in water availability.

Global Solar Atlas (ESMAP 2019)

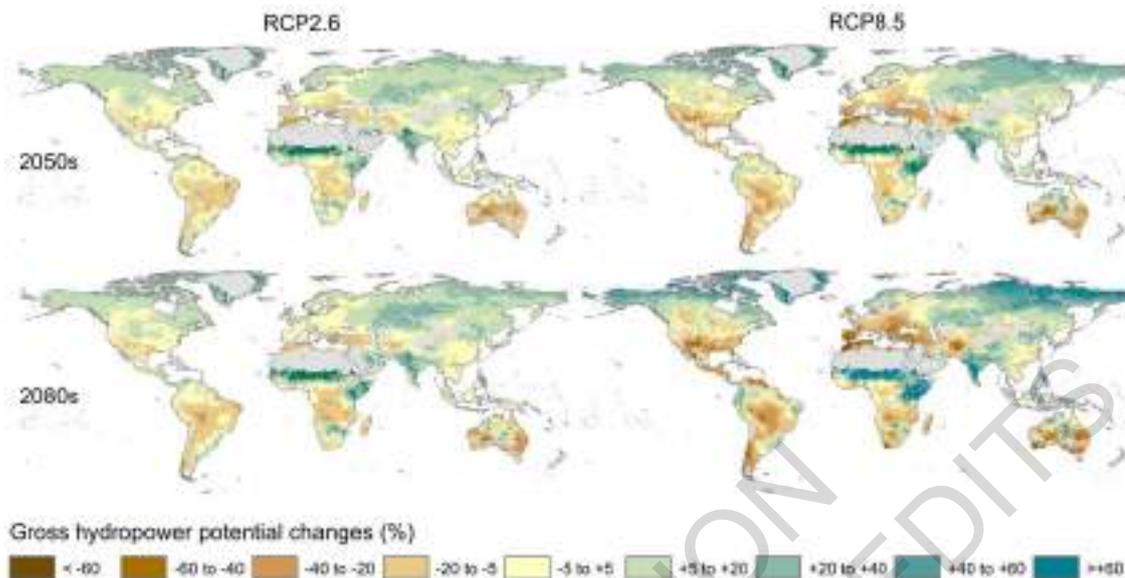

3
4

Figure 6.20 Global spatial patterns of changes in gross hydropower potential based on climate forcing from five climate models. Changes are shown for the 2050s (upper) and the 2080s (lower) for the low emission scenario (RCP2.6; left) and highest emission scenario (RCP8.5; right) scenarios relative to the control period (1971–2000). [Data source: (van Vliet et al. 2016a)].

9 The conclusions regarding climate change impacts on hydropower vary due to differences in modelling
10 assumptions and methodology, such as choice of the climate and hydrological models, choice of metrics
11 (e.g., projected production vs hydropower potential), level of modelling details between local and global
12 studies, reservoir operation assumptions. Also important is how hydropower production matches up
13 with other reservoir purposes, accounting for other water and energy users, and how the competing uses
14 are impacted by climate change (Turner et al. 2017; van Vliet et al. 2016b). Nonetheless, analyses
15 consistently demonstrate that the global impact of climate change on hydropower will be small, but the
16 regional impacts will be larger, and will be both positive and negative (Figure 6.20) Gross global
17 hydropower potential in the 2050s has been estimated to slightly decrease (Hamududu and Killingtveit
18 2012) between 0.4% (for the low emission scenario) and 6.1% (for the highest emission scenario) for
19 the 2080s compared to 1971–2000 (van Vliet et al. 2016a).

20 Regional changes in hydropower are estimated from 5–20% increases for most areas in high latitudes
21 (van Vliet et al. 2016b; Turner et al. 2017) to decreases of 5–20% in areas with increased drought
22 conditions (Cronin et al. 2018). Models show a consistent increase in streamflow and hydropower
23 production by 2080 in high latitudes of the northern hemisphere and parts of the tropics (Figure 6.20)
24 (e.g., central Africa and southern Asia) while decreasing in the U.S., southern and central Europe,
25 Southeast Asia and southern South America, Africa and Australia (van Vliet et al. 2016c,a). Decreases
26 in hydropower production are indicated for parts of North America, central and southern Europe, the
27 Middle East, central Asia and Southern South America. Studies disagree on the changes in hydropower
28 production in China, central South America, and partially in southern Africa (Solaun and Cerdá 2019;
29 Hamududu and Killingtveit 2012; van Vliet et al. 2016b; Fan et al. 2020).

1 **6.5.2.2 Wind Energy**

2 Climate change will not substantially impact future wind resources and will not compromise the ability
3 of wind energy to support low-carbon transitions (*high confidence*). Changing wind variability may
4 have a small to modest impact on backup energy and storage needs (*low confidence*); however, current
5 evidence is largely from studies focused on Europe.

6 Long-term global wind energy resources are not expected to substantially change in future climate
7 scenarios (Karnauskas et al. 2018; Yalew et al. 2020; Pryor et al. 2020). However, recent research has
8 indicated consistent shifts in the geographic position of atmospheric jets in the high emission scenarios
9 (Harvey et al. 2014), which would decrease wind power potentials across the Northern Hemisphere
10 mid-latitudes and increase wind potentials across the tropics and the Southern Hemisphere. However,
11 the climate models used to make these assessments differ in how well they can reproduce the historical
12 wind resources and wind extremes, which raises questions about the robustness of their predictions of
13 future wind resources (Pryor et al. 2020).

14 There are many regional studies on changes in wind resources from climate change. For Europe, there
15 is medium evidence and moderate agreement that wind resources are already increasing and will
16 continue to increase in Northern Europe and decrease in Southern Europe (Moemken et al. 2018;
17 Carvalho et al. 2017; Devis et al. 2018). For North America, the various studies have low agreement
18 for the changes in future wind resources in part because the year-to-year variations in wind resources
19 are often larger than the future change due to climate change (Johnson and Erhardt 2016; Wang et al.
20 2020b; Costoya et al. 2020; Chen 2020). Studies show increases in future wind resources in windy areas
21 in South America (Ruffato-Ferreira et al. 2017; de Jong et al. 2019). No robust future changes in wind
22 resources have been identified in China (Xiong et al. 2019). However, none of the global or regional
23 studies of the effects of climate change on wind resources considers the fine-scale dependence of wind
24 resources on the topography and wind direction (Sanz Rodrigo et al. 2016; Dörenkämper et al. 2020)
25 or the effect of expanding wind energy exploitation (Lundquist et al. 2019; Volker et al. 2017). There
26 is limited evidence that extreme wind speeds, which can damage wind turbines, will increase due to
27 climate change (Pes et al. 2017; Pryor et al. 2020). Nevertheless, projected changes in Europe and North
28 America – regions where the most extensive analysis has been undertaken – are expected to be within
29 the estimates embedded in the design standards of wind turbines (Pryor and Barthelmie 2013).

30 Future wind generation in Europe could decrease in summer and autumn, increasing in winter in
31 northern-central Europe but decreasing in southernmost Europe (Carvalho et al. 2017). Towards 2100,
32 intra-annual variations increase in most of Europe, except around the Mediterranean area (Reyers et al.
33 2016), but this may reflect natural multidecadal variability (Wohland et al. 2019b). Wind speeds may
34 become more homogeneous over large geographical regions in Europe due to climate change,
35 increasing the likelihood of large areas experiencing high or low wind speeds simultaneously (Wohland
36 et al. 2017). These changes could result in fewer benefits in the transmission of wind generation between
37 countries and increased system integration costs. Europe could require a modest increase (up to 7%) in
38 backup energy towards the end of the 21st century due to more homogeneous wind conditions over
39 Europe (Wohland et al. 2017; Weber et al. 2018). However, other studies report that impact of climate
40 change is substantially smaller than interannual variability, with no significant impact on the occurrence
41 of extreme low wind production events in Europe (Van Der Wiel et al. 2019). If European electricity
42 systems are designed to manage the effects of existing weather variability on wind power, they can
43 likely also cope with climate change impacts on wind power (Ravestein et al. 2018). Changes in wind
44 generation variability caused by climate change are also reported for North America (Haupt et al. 2016;
45 Losada Carreño et al. 2018), with modest impacts on electricity system operation (Craig et al. 2019).

1 **6.5.2.3 Solar Energy**

2 Climate change is not expected to substantially impact global solar insolation and will not compromise
3 the ability of solar energy to support low-carbon transitions (*high confidence*). Models show dimming
4 and brightening in certain regions, driven by cloud, aerosol and water vapour trends [WGI,ch12,p31].
5 The increase in surface temperature, which affects all regions, decreases solar power output by reducing
6 the PV panel efficiency. In some models and climate scenarios, the increases in solar insolation are
7 counterbalanced by reducing efficiency due to rising surface air temperatures, which increase
8 significantly in all models and scenarios (Jerez et al. 2015; Bartók et al. 2017; Emodi et al. 2019).
9 Increases in aerosols would reduce the solar resource available and add to maintenance costs
10 [AR6,WGI,ch12].

11 In many emission scenarios, the effect on solar PV from temperature-induced efficiency losses is
12 smaller than the effect expected from changes on solar insolation due to variations in water vapour and
13 clouds in most regions. Also, future PV technologies will likely have higher efficiency, which would
14 offset temperature-related declines (Müller et al. 2019). Cloud cover is projected to decrease in the
15 subtropics (around -0.05% per year), including parts of North America, vast parts of Europe and China,
16 South America, South Africa and Australia (medium agreement, medium evidence). Thus, models
17 project modest ($< 3\%$) increases in solar PV by the end of the century for southern Europe, northern
18 and southern Africa, Central America, and the Caribbean (Emodi et al. 2019). There are several studies
19 projecting decreasing solar production, but these are generally influenced by other factors, for example,
20 increasing air pollution (Ruosteenoja et al. 2019). The multi-model means for solar insolation in
21 regional models decrease 0.60 W m^{-2} per decade from 2006 to 2100 over most of Europe (Bartók et
22 al. 2017), with the most significant decreases in the Northern countries (Jerez et al. 2015).

23 **6.5.2.4 Bioenergy**

24 Climate change can affect biomass resource potential directly, via changes in the suitable range (i.e.,
25 the area where bioenergy crops can grow) and/or changes in yield, and indirectly, through changes in
26 land availability. Increases in CO_2 concentration increase biomass yield; climate changes (e.g.,
27 temperature, precipitation, etc.) can either increase or decrease the yield and suitable range.

28 Climate change will shift the suitable range for bioenergy towards higher latitudes, but the net change
29 in the total suitable area is uncertain (*high confidence*). Several studies show northward shifts in the
30 suitable range for bioenergy in the northern hemisphere (Tuck et al. 2006; Bellarby et al. 2010; Preston
31 et al. 2016; Barney and DiTomaso 2010; Hager et al. 2014; Conant et al. 2018; Cronin et al. 2018;
32 Wang et al. 2014a), but the net effect of climate change on total suitable area varies by region, species,
33 and climate model (Barney and DiTomaso 2010; Hager et al. 2014; Wang et al. 2014a).

34 The effect of climate change on bioenergy crop yields will vary across region and feedstock (*high*
35 *confidence*); however, in general, yields will decline in low latitudes (*medium confidence*) and increase
36 in high latitudes (*low confidence*) (Haberl et al. 2010; Cosentino et al. 2012; Mbow et al. 2019; Cronin
37 et al. 2018; Preston et al. 2016). However, the average change in yield varies significantly across studies,
38 depending on the feedstock, region, and other factors (Dolan et al. 2020; Kyle et al. 2014) Mbow et al.
39 (2019); Beringer et al. (2011). Only a few studies extend the modelling of climate change impacts on
40 bioenergy to quantify the effect on bioenergy deployment or its implications on the energy system
41 (Calvin et al. 2013, 2019; Thornton et al. 2017; Kyle et al. 2014). These studies find that changes in
42 deployment are of the same sign as changes in yield; that is, if yields increase, then deployment
43 increases.

44 Some of the uncertainty in the sign and magnitude of the impacts of climate change on bioenergy
45 potential is due to uncertainties in CO_2 fertilization (the increase in photosynthesis due to increases in
46 atmospheric CO_2 concentration) (Bonjean Stanton et al. 2016; Haberl et al. 2011; Cronin et al. 2018;
47 Solaun and Cerdá 2019; Yalaw et al. 2020). For example, earlier studies found that without CO_2

1 fertilization, climate change will reduce global bioenergy potential by about 16%; with CO₂
2 fertilization, however, climate change increases this potential by 45% (Haberl et al. 2011). However,
3 newer studies in the U.S. find little effect of CO₂ fertilization on switchgrass yield (Dolan et al. 2020).
4 There is also a considerable uncertainty across climate and crop models in estimating bioenergy
5 potential (Hager et al. 2014).

6 **6.5.2.5 Thermal power plants**

7 The operation of thermal power plants will be affected by climate change, deriving from changes in the
8 ambient conditions like temperature, humidity and water availability (Schaeffer et al. 2012) (*high*
9 *confidence*). Changes in ambient temperature have relatively small impacts on coal-fired and nuclear
10 power plants (Rankine cycle); however, gas-fired power plants (Brayton or combined-cycle) may have
11 their thermal efficiency and power output significantly decreased (De Sa and Al Zubaidy 2011;
12 Schaeffer et al. 2012). Droughts decrease potential cooling water for thermal power plants and increase
13 the probability of water outlet temperatures exceeding regulatory limits, leading to lower production or
14 even shutdowns. Thermal power utilization has been reported to be on average 3.8% lower during
15 drought years globally (van Vliet et al. 2016c). and further significant decreases in available thermal
16 power plant capacity due to climate change are projected (Koch et al. 2014; van Vliet et al. 2016b;
17 Yalew et al. 2020). An increase in climate-related nuclear power disruptions has been reported in the
18 past decades globally (Ahmad 2021).

19 Carbon capture may increase cooling water usage significantly, especially in retrofits, with up to 50%
20 increase in water usage for coal-fired power plants globally, depending on the CCS technology (Rosa
21 et al. 2020, Section 6.4). In Asia, planned coal capacity is expected to be vulnerable to droughts, sea
22 level rise, and rising air temperatures, and this may be exacerbated by incorporating carbon capture
23 (Wang et al. 2019c). Recently, however, studies have proposed designs of CCS with a minimal increase
24 in water requirements (Mikunda et al. 2021; Magneschi et al. 2017).

25 Older thermal power plants can be retrofitted to mitigate climate impacts by altering and redesigning
26 the cooling systems (Westlén 2018), although the costs for these solutions may be high. For example,
27 dry cooling may be used instead of once-through cooling; however, it lowers thermal efficiency and
28 would leave plants vulnerable to ambient temperature increase (Ahmad 2021). Closed-circuit cooling
29 is much less sensitive to water temperature than once-through cooling (Bonjean Stanton et al. 2016).
30 Modifying policies and regulation of water and heat emissions from power plants may also be used to
31 mitigate plant reliability problems induced by climate change (Eisenack 2016; Mu et al. 2020), albeit
32 with potential impacts for other water users and ecology. Improvements in water use and thermal
33 efficiencies and the use of transmission capabilities over large geographical regions to mitigate risks on
34 individual plants are also possible mitigation options (Miara et al. 2017).

35 **6.5.3 Impacts on Energy Consumption**

36 Heating demand will decrease, and cooling demand will increase in response to climate change. Peak
37 load may increase more than energy consumption, and the changing spatial and temporal load patterns
38 can impact transmission and needs for storage, demands-side management, and peak-generating
39 capacity. (*high confidence*)

40 Climate change will decrease heating demands, especially in cold regions, and it will increase cooling
41 demands, especially in warm regions (Yalew et al. 2020). Recent studies report significant net impacts,
42 with the commercial and industrial sectors and substantial air condition penetration driving an increase
43 in energy demand (De Cian and Sue Wing 2019; Levesque et al. 2018; van Ruijven et al. 2019; Davis
44 and Gertler 2015; Yalew et al. 2020). For example, globally, De Cian and Sue Wing (2019) found a 7–
45 17% increase in energy consumption due to climate change in 2050, with the range depending on the
46 climate change scenario. The overall effects of climate change on building energy consumption are

1 regionally dependent. For example, Zhang et al. (2019) find that reduced heating will outweigh
2 increased cooling in the residential buildings in Europe, but the reverse will be true in China.

3 While many studies have focused on energy consumption, climate extremes are expected to alter peak
4 energy demands, with the potential for blackouts, brownouts, and other short-term energy system
5 impacts (Yalew et al. 2020). For example, peak energy demand during heatwaves can coincide with
6 reduced transmission and distribution capacity at higher temperatures. In large cities, extreme heat
7 events increase cooling degree days significantly, with the urban heat island effect compounding the
8 impact (Morakinyo et al. 2019). One study found that total electricity consumption at the end of the
9 century in the U.S. could increase on average by 20% during summer months and decrease on average
10 by 6% in the winter (Ralston Fonseca et al. 2019). While the average increase in consumption is
11 modest, climate change is projected to have severe impacts on the frequency and intensity of peak
12 electricity loads. (Auffhammer et al. 2017). Bartos et al. (2016) find that peak per-capita summertime
13 load in the U.S. may rise by 4.2%–15% by mid-century. Efficient cooling technologies and other
14 demand side measures can limit cooling energy loads during periods of particularly high
15 demand (Dreyfus et al. 2020; International Energy Agency (IEA) 2018).

16 **[START BOX 6.6 HERE]**

17 **Box 6.6 Energy Resilience**

18 In February 2021, the state of Texas was hit by three major storms and suffered significant scale power
19 outages. More than 4.5 million homes and businesses on the Texas electric grid were left without
20 electricity for days, limiting the ability to heat homes during dangerously low temperatures and leading
21 to food and clean water shortages (Busby et al. 2021). The Texas and other events – e.g., during
22 Typhoon Haiyan that affected Southeast Asia in 2013; the Australian bush fires in 2019–2020 and forest
23 fires in 2018 in California; water shortages in Cape Town, South Africa in 2018 and the western United
24 States during 2021 – raise the question of whether future low-carbon energy systems will be more or
25 less resilient than those of today.

26 Some characteristics of low-carbon energy systems will make them less resilient. Droughts reduce
27 hydroelectric electricity generation (Gleick 2016; van Vliet et al. 2016c); wind farms do not produce
28 electricity in calm conditions or shut down in very strong winds (Petersen and Troen 2012); solar PV
29 generation is reduced by clouds and is less efficient under extreme heat, dust storms, and wildfires
30 (Perry and Troccoli 2015; Jackson and Gunda 2021). In addition, the electrification of heating will
31 increase the weather dependence of electricity consumption (Staffell and Pfenninger 2018; Gea-
32 Bermúdez et al. 2021). Non-renewable generation, for example from nuclear and fossil power plants,
33 are also vulnerable to high temperatures and droughts as they depend on water for cooling (Cronin et
34 al. 2018; Ahmad 2021).

35 But some aspects of low-carbon energy systems will make them more resilient. Wind and solar farms
36 are often spread geographically, which reduces the chances of being affected by the same extreme
37 weather event (Perera et al. 2020). The diversification of energy sources, in which each component has
38 different vulnerabilities, increases resilience. Less reliance on thermal electricity generation
39 technologies will reduce the risks of curtailment or efficiency losses from droughts and heat waves.
40 (Lohrmann et al. 2019). More generally, increased electricity system integration and flexibility (Section
41 6.4.3) and weatherization of generators increases electricity system resilience (Heffron et al. 2021;
42 Busby et al. 2021). Likewise, local district micro-grids with appropriate enabling technologies (e.g.,
43 distributed generation, energy storage, greater demand-side participation, electric vehicles) may ensure
44 access to electricity during major long-duration power outage events and radically enhance the
45 resilience of supply of essential demand (Stout et al. 2019).

46 **[END BOX 6.6 HERE]**

1

2 **6.5.4 Impacts on Electricity System Vulnerability**

3 While long-term trends are important for electricity system planning, short-term effects associated with
4 loss of power can be disruptive and lead to significant economic losses along with cascading impacts
5 on health and safety. Extreme weather and storms threaten the electricity system in different ways,
6 affecting system resilience, reliability, and adequacy (Moreno-Mateos et al. 2020). The implications of
7 climate change for electricity system vulnerability will depend on the degree to which climate change
8 alters the frequency and intensity of extreme weather events. The complex compounding effects of
9 simultaneous events (e.g., high winds and lightning occurring at the same time) are not well understood.

10 *High wind speeds* can shear lines through mechanical failure or cause lines to collide, causing transient
11 events (Panteli and Mancarella 2015; Yalew et al. 2020). Hurricane conditions can damage electricity
12 system infrastructures, including utility-scale wind and solar PV plants. Electricity systems may
13 experience high demand when lines are particularly at risk from mechanical failure from wind and
14 storm-related effects. However, except for medium evidence of increases in heavy precipitation
15 associated with tropical cyclones, there is limited evidence that extreme wind events will increase in
16 frequency or intensity in the future (Kumar et al. 2015; Pryor et al. 2020).

17 *Wildfires* pose a significant threat to electricity systems in dry conditions and arid regions (Dian et al.
18 2019). With climate change, wildfires will probably become more frequent (Flannigan et al. 2013) and
19 more difficult to address given that they frequently coincide with dry air and can be exacerbated by
20 high winds (Mitchell 2013).

21 *Lightning* can cause wildfires or common-mode faults on electricity systems associated with vegetation
22 falling on power substations or overhead lines but is more generally associated with flashovers and
23 overloads (Balijepalli et al. 2005). Climate change may change the probability of lightning-related
24 events (Romps et al. 2014).

25 *Snow and icing* can impact overhead power lines by weighing them down beyond their mechanical
26 limits, leading to collapse and cascading outages (Feng et al. 2015). Snow can also lead to flashovers
27 on lines due to wet snow accumulation on insulators (Croce et al. 2018; Yaji et al. 2014) and snow and
28 ice can impact wind turbines (Davis et al. 2016). Climate change will lower risk of snow and ice
29 conditions (McColl et al. 2012), but there is still an underlying risk of sporadic acute cold conditions
30 such as those associated with winter storms in Texas in 2021 (Box 6.).

31 *Flooding* poses a threat to the transmission and distribution systems by inundating low-lying substations
32 and underground cables. Coastal flooding also poses a threat to electricity system infrastructure. Rising
33 sea levels from climate change and associated storm surge may also pose a significant risk for coastal
34 electricity systems (Enriken and Lordan 2012).

35 *Temperature increases* influence electricity load profiles and electricity generation, as well as
36 potentially impact supporting information and communication infrastructure. Heat can pose direct
37 impacts to electricity system equipment such as transformers. Referred to as solar heat faults, they occur
38 under high temperatures and low wind speeds and can be exacerbated by the urban heat island effect
39 (McColl et al. 2012). Increasing temperatures affect system adequacy by reducing electric transmission
40 capacity, simultaneously increasing peak load due to increased air conditioning needs (Bartos et al.
41 2016).

42 **[START BOX 6.7 HERE]**

43 **Box 6.7 Impacts of Renewable Energy Production on Climate**

44 While climate change will affect energy systems (Section 6.5), the reverse is potentially also true:
45 increasing the use of renewable energy sources could affect local climate. Large solar PV arrays and

1 hydroelectric dams darken the land surface, and wind turbines extract the wind’s kinetic energy near
2 the Earth’s surface. Their environmental impacts of renewable energy production are mostly confined
3 to areas close to the production sources and have shown to be trivial compared to the mitigation benefits
4 of renewable energy (*high confidence*).

5 *Solar Energy.* Observations and model simulations have addressed whether large-scale solar PV power
6 plants can alter the local and regional climate. In rural areas at the local scale, large-scale solar PV farms
7 change the surface characteristics and affect air temperatures (Taha 2013). Measurements in rural
8 Arizona, U.S. show local nighttime temperatures 3–4°C warmer at the PV farm than surroundings
9 (Barron-Gafford et al. 2016). In contrast, measurements in urban settings show that solar PV panels on
10 roofs provide a cooling effect (Ma et al. 2017; Taha 2013). On the regional scale, modelling studies
11 suggest cooling in urban areas (0.11–0.53°C) and warming in rural areas (up to 0.27°C) (Millstein and
12 Menon 2011). Global climate model simulations show that solar panels induce regional cooling by
13 converting part of the incoming solar energy to electricity (Hu et al. 2016). However, converting the
14 generated electricity to heat in urban areas increases regional and local temperatures, compensating for
15 the cooling effect.

16 *Wind Energy.* Surface temperature changes in the vicinity of wind farms have been detected (Xia et al.
17 2019; Smith et al. 2013; Lee and Lundquist 2017; Takle et al. 2019) in the form of nighttime warming.
18 Data from field campaigns suggest that a “suppression of cooling” can explain the observed warming
19 (Takle et al. 2019). Regional and climate models have been used to describe the interactions between
20 turbines and the atmosphere and find minor impacts (Vautard et al. 2014). More sophisticated models
21 confirm the local warming effect of wind farms but report that the impact on the regional area is slight
22 and occasional (Wang et al. 2019d). Wind turbines alter the transport and dissipation of momentum
23 near the surface but do not directly impact the Earth’s energy balance (Fischereit et al. 2021). However,
24 the secondary modifications to the energy and water exchanges have added implications for the climate
25 system (Jacobson and Archer 2012).

26 *Hydropower.* The potential climate impacts of hydropower concentrate on the GHG emissions from
27 organic matter decomposition when the carbon cycle is altered by the flooding of the hydroelectric
28 power plant reservoir (Ocko and Hamburg 2019), but emissions from organic matter decomposition
29 decrease over time. The darker surface of the reservoir, compared to the lighter surrounding land may
30 counterbalance part of the reduced GHG emissions by hydropower production (Wohlfahrt et al. 2021).
31 However, these impacts vary significantly among facilities due to the surrounding land properties and
32 the area inundated by the reservoir.

33 **[END BOX 6.7 HERE]**

34

35

36 **6.6 Key Characteristics of Net Zero Energy Systems**

37 **6.6.1 What is a Net Zero Energy System?**

38 Limiting warming to well below 2°C requires that CO₂ emissions from the energy sector be reduced to
39 near zero or even below zero (Chapter 3, 6.7). Policies, technologies, behaviours, investments, and other
40 factors will determine the speed at which countries transition to net zero energy systems – those that
41 emit very little or no emissions. An understanding of these future energy systems can help to chart a
42 course toward them over the coming decades.

43 This section synthesizes current understanding of net zero energy systems. Discussions surrounding
44 efforts to limit warming are frequently communicated in terms of the point in time at which net
45 anthropogenic CO₂ emissions reach zero, accompanied by substantial reductions in non-CO₂ emissions

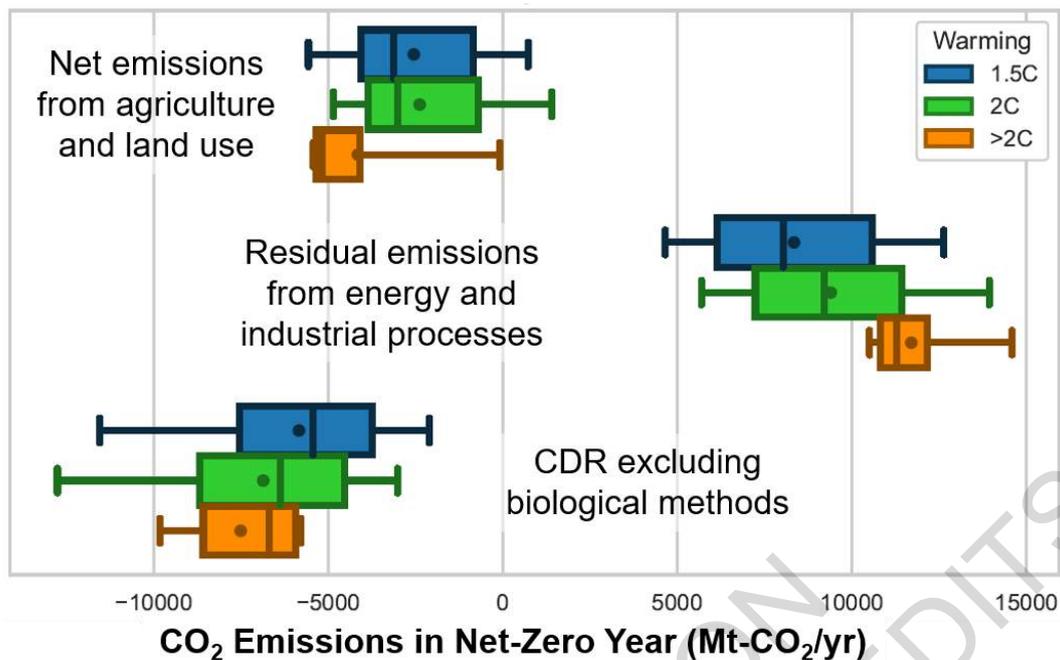

1 (IPCC 2018, Chapter 3). Net-zero GHG goals are also common, and they require net-negative CO₂
2 emissions to compensate for residual non-CO₂ emissions. Economy-wide CO₂ and GHG goals appear
3 in many government and corporate decarbonization strategies, and they are used in a variety of ways.
4 Most existing carbon-neutrality commitments from countries and subnational jurisdictions aim for
5 economies with very low emissions rather than zero emissions. Offsets, carbon dioxide removal (CDR)
6 methods, and/or land sink assumptions are used to achieve net zero goals (Kelly Levin et al. 2020).

7 Precisely describing a net zero energy system is complicated by the fact that different scenarios attribute
8 different future CO₂ emissions to the energy system, even under scenarios where economy-wide CO₂
9 emissions reach net zero. It is also complicated by the dependence of energy system configurations on
10 unknown future conditions like population and economic growth, and technological change. The energy
11 system is not the only source or sink of CO₂ emissions. Terrestrial systems may store or emit carbon,
12 and CDR options like BECCS or DACCS can be used to store CO₂, relieving pressure on the energy
13 system (Chapter 3). The location of such CDR options is ambiguous, as it might be deployed within or
14 outside of the energy sector (Figure 6.21), and many CDR options, such as DACCS, would be important
15 energy consumers (Bistline and Blanford 2021a, 6.6.2). If CDR methods are deployed outside of the
16 energy system (e.g., net negative agriculture, forestry, and land use CO₂ emissions), it is possible for
17 the energy system to still emit CO₂ but have economy-wide emissions of zero or below. When global
18 energy and industrial CO₂ emissions reach net zero, the space remaining for fossil energy emissions is
19 determined by deployment of CDR options (Figure 6.21).

20 This section focuses on energy systems that produce very little or no CO₂ emissions, referred to in this
21 chapter as net zero energy systems. While energy systems may not reach net zero concurrently with
22 economy-wide CO₂ or GHG emissions, they are a useful benchmark for planning a path to net zero.
23 Note that the focus here is on energy systems with net zero CO₂ emissions from fossil fuel combustion
24 and industrial processes, but the lessons will be broadly applicable to net zero GHG energy systems as
25 well. Net-zero GHG energy systems would incorporate the major efforts made to reduce non-CO₂
26 emissions (e.g., CH₄ from oil, gas and coal as discussed in Section 6.4) and would also need to
27 incorporate more CDR to compensate for remaining non-CO₂ GHG emissions. Energy sector emissions
28 in many countries may not reach net zero at the same time as global energy system emissions (Figure
29 6.25, Cross-Chapter Box 3 in Chapter 3).

7 **respectively.**

8 6.6.2 Configurations of Net-zero Energy Systems

9 Net-zero energy systems entail trade-offs across economic, environmental, and social dimensions
10 (Davis et al. 2018). Many socioeconomic, policy, and market uncertainties will also influence the
11 configuration of net zero energy systems (van Vuuren et al. 2018; Krey et al. 2019; Bistline et al. 2019;
12 Smith et al. 2015, Azevedo et al. 2021, Pye et al, 2021). There are reasons that countries might focus
13 on one system configuration versus another, including cost, resource endowments, related industrial
14 bases, existing infrastructure, geography, governance, public acceptance, and other policy priorities
15 (Section 6.6.4 and Chapter 18 of WGII).

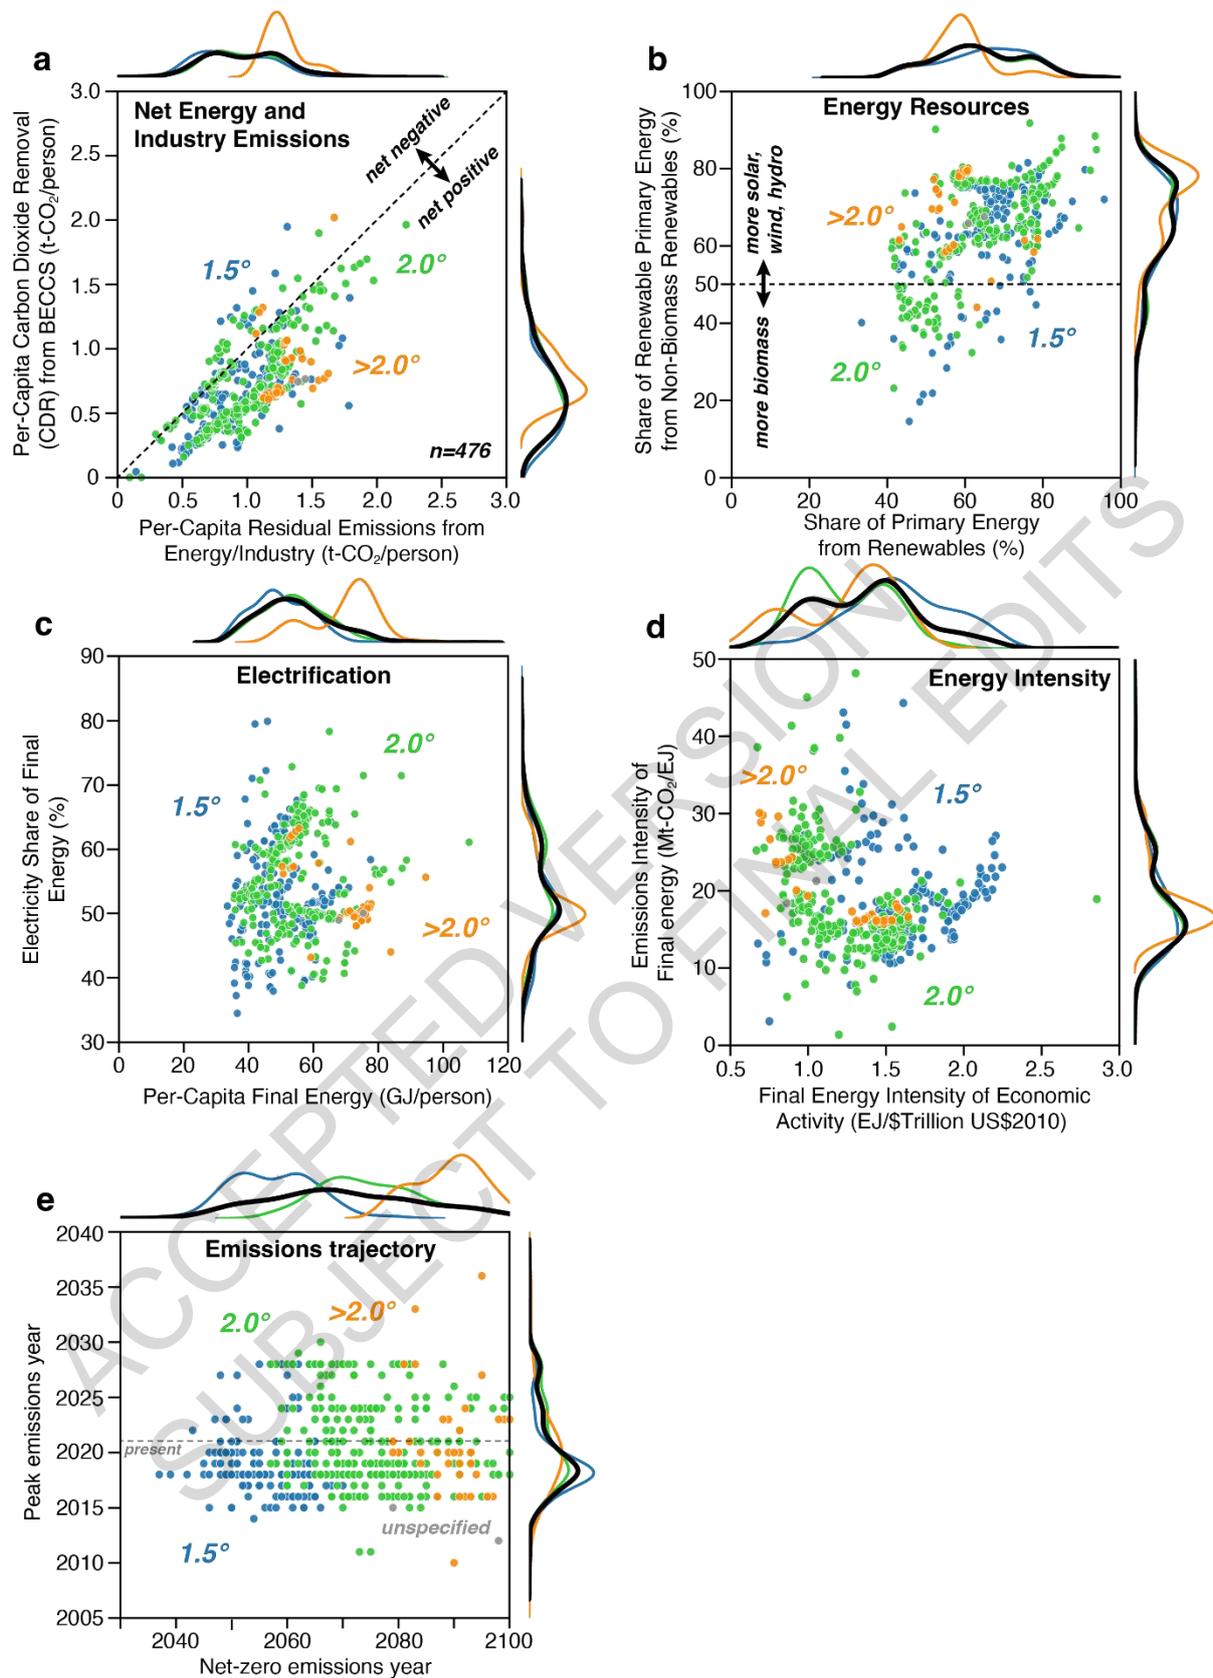

16 Explorations of net zero energy systems have been emerging in the detailed systems modelling literature
17 (Azevedo et al. 2021; Bistline 2021b). Reports associated with net zero economy-wide targets for
18 countries and subnational entities typically do not provide detailed roadmaps or modelling but discuss
19 high-level guiding principles, though more detailed studies are emerging at national levels (Williams et
20 al. 2021a; Duan et al. 2021; Capros et al. 2019; Wei et al. 2020). Most analysis has focused on
21 identifying potential decarbonization technologies and pathways for different sectors, enumerating
22 opportunities and barriers for each, their costs, highlighting robust insights, and characterizing key
23 uncertainties (Hepburn et al. 2019; Davis et al. 2018).

24 The literature on the configuration of net zero energy systems is limited in a few respects. On the one
25 hand, there is a robust integrated assessment literature that provides characterizations of these systems
26 in broad strokes (AR6 database), offering internally consistent global scenarios to link global warming
27 targets to regional/national goals. All integrated assessment scenarios that discuss net zero energy
28 system CO₂ emissions provide high-level characterizations of net zero systems. Because these
29 characterizations have less temporal, spatial, technological, regulatory, and societal detail, however,
30 they may not consider the complexities that could ultimately influence regional, national, or local

1 pathways. High-fidelity models and analyses are needed to assess the economic and environmental
2 characteristics and the feasibility of many aspects of net zero or net negative emissions energy systems
3 (*high confidence*) (Bistline and Blanford 2020; Blanford et al. 2018). For example, evaluating the
4 competitiveness of electricity sector technologies requires temporal, spatial, and technological detail to
5 accurately represent system investments and operations (Bistline 2021c; Victoria et al. 2021; Helistoe
6 et al. 2019; Collins et al. 2017; Santen et al. 2017).

7 Configurations of net zero energy systems will vary by region but are likely to share several common
8 characteristics (*high confidence*) (Figure 6.22). We focus on seven of those common characteristics in
9 the remainder of this subsection.

4

Figure 6.22 Characteristics of global net zero energy systems when global energy and industrial CO₂ emissions reach net zero. Scenarios reaching net zero emissions show differences in residual emissions

1 and carbon removal (a), energy resources (b), electrification (c), energy intensity (as measured here by
2 energy GDP⁻¹) (d), and emissions trajectory (e), particularly with respect to warming levels (blue =
3 <1.5°C, green = <2.0°C, orange = >2.0°C, gray = unspecified). Points represent individual scenarios, with
4 probability density distributions shown along each axis for each warming level (colours corresponding to
5 warming levels) and for all scenarios (black). Points represent different models and scenarios from the
6 AR6 database.

7 6.6.2.1 Limited and/or Targeted Use of Fossil Fuels

8 Net-zero energy systems will use far less fossil fuel than today (*high confidence*). The precise
9 quantity of fossil fuels will largely depend upon the relative costs of such fuels, electrification,
10 alternative fuels, and CDR (see Section 6.6.2.4) in the energy system (*high confidence*). All of these are
11 affected by regional differences in resources (McGlade and Ekins 2015), existing energy infrastructure
12 (Tong et al. 2019), demand for energy services, and climate and energy policies. Fossil fuel use may
13 persist, for example, if and where the costs of such fuels and the compensating carbon management
14 (e.g., CDR, CCS) are less than non-fossil energy. For most applications, however, it is likely that
15 electrification (McCullum et al. 2014; Madeddu et al. 2020; Zhang and Fujimori 2020) or use of non-
16 fossil alternative fuels (Zeman and Keith 2008; Graves et al. 2011; Hänggi et al. 2019; Ueckerdt et al.
17 2021) will prove to be the cheapest options. Most residual demand for fossil fuels is likely to
18 predominantly be petroleum and natural gas given their high energy density (Davis et al. 2018), while
19 demand for coal in net zero energy systems is likely to be very low (Luderer et al. 2018; Jakob et al.
20 2020, Section 6.7.4) (*high confidence*).

21 There is considerable flexibility regarding the overall quantity of liquid and gaseous fuels that will be
22 required in net zero energy systems (*high confidence*) (Figure 6.22, Section 6.7.4). This will be
23 determined by the relative value of such fuels as compared to systems which rely more or less heavily
24 on zero-emissions electricity. In turn, the share of any fuels that are fossil or fossil-derived is uncertain
25 and will depend on the feasibility of CCS and CDR technologies and long-term sequestration as
26 compared to alternative, carbon-neutral fuels. Moreover, to the extent that physical, biological, and/or
27 socio-political factors limit the availability of CDR (Smith et al. 2015; Field and Mach 2017), carbon
28 management efforts may prioritize residual emissions related to land use and other non-energy sources.

29 6.6.2.2 Zero or Negative CO₂ Emissions from Electricity

30 Net-zero energy systems will rely on decarbonized or net-negative CO₂ emissions electricity systems,
31 due to the many lower-cost options for producing zero-carbon electricity and the important role of end-
32 use electrification in decarbonizing other sectors (*high confidence*).

33 There are many possible configurations and technologies for zero- or net-negative-emissions electricity
34 systems (*high confidence*). These systems could entail a mix of variable renewables, dispatchable
35 renewables (e.g., biomass, hydropower), other firm, dispatchable (“on-demand”) low-carbon generation
36 (e.g., nuclear, CCS-equipped capacity), energy storage, transmission, carbon removal options (e.g.,
37 BECCS, DACCS), and demand management (Bistline and Blanford 2021b; Bistline et al. 2018; Jenkins
38 et al. 2018b; Luderer et al. 2017). The marginal cost of deploying electricity sector mitigation options
39 increases as electricity emissions approach zero; in addition, the most cost-effective mix of system
40 resources changes as emissions approach zero and, therefore, so do the implications of electricity sector
41 mitigation for sustainability and other societal goals (Cole et al. 2021; Jayadev et al. 2020; Bistline et
42 al. 2018; Mileva et al. 2016; Sepulveda et al. 2018). Key factors influencing the electricity mix include
43 relative costs and system benefits, local resource bases, infrastructure availability, regional integration
44 and trade, co-benefits, societal preferences and other policy priorities, all of which vary by country and
45 region (Section 6.6.4). Many of these factors depend on when the net zero point is reached (Figure
46 6.22).

1 Based on their increasing economic competitiveness, VRE technologies, especially wind and solar
2 power, will likely comprise large shares of many regional generation mixes (*high confidence*) (Figure
3 6.22). While wind and solar will likely be prominent electricity resources, this does not imply that 100%
4 renewable energy systems will be pursued under all circumstances, since economic and operational
5 challenges increase nonlinearly as shares approach 100% (Box 6.8) (Bistline and Blanford 2021a; Cole
6 et al. 2021; Shaner et al. 2018; Frew et al. 2016; Imelda et al. 2018b). Real-world experience planning
7 and operating regional electricity systems with high instantaneous and annual shares of renewable
8 generation is accumulating, but debates continue about how much wind and solar should be included in
9 different systems, and the cost-effectiveness of mechanisms for managing variability (Box 6.8). Either
10 firm, dispatchable generation (including nuclear, CCS-equipped capacity, dispatchable renewables such
11 as geothermal, and fossil units run with low capacity factors and CDR to balance emissions) or seasonal
12 energy storage (alongside other balancing resources discussed in Box 6.8) will be needed to ensure
13 reliability and resource adequacy with high percentages of wind and solar (Jenkins et al. 2018b;
14 Dowling et al. 2020; Denholm et al. 2021) though each option involves uncertainty about costs, timing,
15 and public acceptance (Albertus et al. 2020).

16 Electricity systems require a range of different functional roles – for example, providing energy,
17 capacity, or ancillary services. As a result, a range of different types of generation, energy storage, and
18 transmission resources may be deployed in these systems (Baik et al. 2021). There are many options
19 for each of these roles, each with their strengths and weaknesses (Sections 6.4.3 and 6.4.4), and
20 deployment of these options will be influenced by the evolution of technological costs, system benefits,
21 and local resources (Veers et al. 2019; Mai et al. 2018; Bistline et al. 2018; Hirth 2015; Fell and Linn
22 2013).

23 System management is critical for zero- or negative-emissions electricity systems. Maintaining
24 reliability will increasingly entail system planning and operations that account for characteristics of
25 supply- and demand-side resources (Hu et al. 2018). Coordinated planning and operations will likely
26 become more prevalent across portions of the electricity system (e.g., integrated generation,
27 transmission, and distribution planning), across sectors, and across geographies (Bistline and Young
28 2019; Chan et al. 2018; Konstantelos et al. 2017; EPRI 2017, Section 6.4.3).

29 Energy storage will be increasingly important in net zero energy systems, especially in systems with
30 shares of VRE (*high confidence*). Deployment of energy storage will vary based on the system benefits
31 and values of different options (Arbabzadeh et al. 2019; Denholm and Mai 2019). Diurnal storage
32 options like lithium-ion batteries have different value than storing and discharging electricity over
33 longer periods through long-duration energy storage with less frequent cycling, which require different
34 technologies, supporting policies, and business models (Sepulveda et al. 2021; Dowling et al. 2020;
35 Gallo et al. 2016; Albertus et al. 2020; Blanco and Faaij 2017) (Section 6.4.4). The value of energy
36 storage varies with the level of deployment and on the competitiveness of economic complements such
37 as VRE options (Bistline and Young 2020; Mileva et al. 2016) and substitutes such as flexible demand
38 (Brown et al. 2018; Merrick et al. 2018), transmission (Merrick et al. 2018; Brown et al. 2018;
39 Schlachtberger et al. 2017; Bistline and Young 2019), trade (Bistline et al. 2020b), dispatchable
40 generators (Hittinger and Lueken 2015; Gils et al. 2017; Arbabzadeh et al. 2019), DAC (Daggash et al.
41 2019), and efficiencies in system operations (Tuohy et al. 2015).

42 The approach to other sectors could impact electricity sector planning, and the role of some technologies
43 (e.g., hydrogen, batteries, CCS) could depend on deployment in other sectors. CCS offers opportunities
44 for CO₂ removal when fuelled with syngas or biomass containing carbon captured from the atmosphere
45 (Hepburn et al. 2019); however, concerns about lifecycle environmental impacts, uncertain costs, and
46 public acceptance are potential barriers to widespread deployment (Section 6.4.2). It is unclear whether
47 CDR options like BECCS will be included in the electricity mix to offset continued emissions in other
48 parts of the energy system or beyond (Mac Dowell et al. 2017; Luderer et al. 2018; Bauer et al. 2018a).

1 Some applications may also rely on PtX electricity conversion to create low-emissions synthetic fuels
2 (Sections 6.6.2.6, 6.4.4, and 6.4.5), which could impact electricity system planning and operations.
3 Additionally, if DAC technologies are used, electricity and heat requirements to operate DAC could
4 impact electricity system investments and operations (Bistline and Blanford 2021a; Realmonte et al.
5 2019).

6 **[START BOX 6.8 HERE]**

7 **Box 6.8 100% Renewables in Net Zero Energy Systems**

8 The decreasing cost and increasing performance of renewable energy has generated interest in the
9 feasibility of providing nearly all energy services with renewables. Renewable energy includes wind
10 power, solar power, hydroelectric power, bioenergy, geothermal energy, tidal power, and ocean power.
11 There are two primary frames around which 100% renewable energy systems are discussed: 100%
12 renewable electricity systems and 100% renewable energy systems, considering not only electricity but
13 all aspects of the energy system.

14 It is technically feasible to use very high renewable shares (e.g., above 75% of annual regional
15 generation) to meet hourly electricity demand under a range of conditions, especially when VRE
16 options, notably wind and solar, are complemented by other resources (*high confidence*). There are
17 currently many grids with high renewable shares and large anticipated roles for VRE sources, in
18 particular wind and solar (see Section 6.4), in future low-carbon electricity systems. An increasingly
19 large set of studies examines the feasibility of high renewable penetration and economic drivers under
20 different policy, technology, and market scenarios (Denholm et al. 2021; Blanford et al. 2021; Bistline
21 et al. 2019; Hansen et al. 2019; Jenkins et al. 2018b; Cochran et al. 2014; Dowling et al. 2020; Deason
22 2018). High wind and solar penetration involves technical and economic challenges due to their unique
23 characteristics such as spatial and temporal variability, short- and long-term uncertainty, and non-
24 synchronous generation (Cole et al. 2017). These challenges become increasingly important as
25 renewable shares approach 100% (Sections 6.6.2.2 and 6.4.3).

26 There are many balancing options in systems with very high renewables (Denholm et al. 2021; Bistline
27 2021a; Mai et al. 2018; Milligan et al. 2015; Jenkins et al. 2018b).

- 28 • **Energy storage:** Energy storage technologies like batteries, pumped hydro, and hydrogen can
29 provide a range of system services (Balducci et al. 2018; Bistline et al. 2020a; Section 6.4.4).
30 Lithium-ion batteries have received attention as costs fall and installations increase, but very high
31 renewable shares typically entail either dispatchable generation or long-duration storage in addition
32 to short-duration options (Schill 2020; Arbabzadeh et al. 2019; Jenkins et al. 2018b). Energy storage
33 technologies are part of a broad set of options (including synchronous condensers, demand-side
34 measures, and even inverter-based technologies themselves) for providing grid services (Castillo
35 and Gayme 2014; EPRI 2019a).
- 36 • **Transmission and trade:** To balance differences in resource availability, high renewable systems
37 will very likely entail investments in transmission capacity (Zappa et al. 2019; Pleßmann and
38 Blechinger 2017; Macdonald et al. 2016; Mai and Et al 2014; Section 6.4.5) and changes in trade
39 (Abrell and Rausch 2016; Bistline et al. 2019). These increases will likely be accompanied by
40 expanded balancing regions to take advantage of geographical smoothing.
- 41 • **Dispatchable (“on-demand”) generation:** Dispatchable generation could include flexible fossil
42 units or low-carbon fuels such as hydrogen with lower minimum load levels (Bistline 2019;
43 Denholm et al. 2018), renewables like hydropower, geothermal, or biomass (Hansen et al. 2019;
44 Hirth 2016), or flexible nuclear (Jenkins et al. 2018a). The composition depends on costs and other
45 policy goals, though in all cases, capacity factors are low for these resources (Mills et al. 2020).
- 46 • **Demand management:** Many low-emitting and high-renewables systems also utilize increased
47 load flexibility in the forms of energy efficiency, demand response, and demand flexibility, utilizing

1 newly electrified end uses such as electric vehicles to shape demand profiles to better match supply
2 (Bistline 2021a; Imelda et al. 2018a; Hale 2017; Brown et al. 2018; Ameli et al. 2017).

- 3 ● **Sector coupling:** Sector coupling includes increased end-use electrification and PtX electricity
4 conversion pathways, which may entail using electricity to create synthetic fuels such as hydrogen
5 (Ueckerdt et al. 2021; Davis et al. 2018) (see Sections 6.4.3, 6.4., 6.4.5, 6.6.4.3, and 6.6.4.6).

6 Deployment of integration options depends on their relative costs and value, regulations, and electricity
7 market design. There is considerable uncertainty about future technology costs, performance,
8 availability, scalability, and public acceptance (Kondziella and Bruckner 2016; Bistline et al. 2019).
9 Deploying balanced resources likely requires operational, market design, and other institutional
10 changes, as well as technological changes in some cases (Denholm et al. 2021; Cochran et al. 2014).
11 Mixes will differ based on resources, system size, flexibility, and whether grids are isolated or
12 interconnected.

13 Although there are no technical upper bounds on renewable electricity penetration, the economic value
14 of additional wind and solar capacity typically decreases as their penetration rises, creating economic
15 challenges at higher deployment levels (Denholm et al. 2021; Millstein et al. 2021; Cole et al. 2021;
16 Gowrisankaran et al. 2016; Hirth 2013). The integration options above, as well as changes to market
17 design, can mitigate these challenges but likely will not solve them, especially since these options can
18 exhibit declining value themselves (Denholm and Mai 2019; Bistline 2017; De Sisternes et al. 2016)
19 and may be complements or substitutes to each other.

20 Energy systems that are 100% renewable (including all parts of the energy sector, and not only
21 electricity generation) raise a range of technological, regulatory, market, and operational challenges that
22 make their competitiveness uncertain (*high confidence*). These systems require decarbonizing all
23 electricity, using this zero-carbon electricity broadly, and then utilizing zero-carbon energy carriers for
24 all end uses not served by electricity, for example, air travel, long-distance transport, and high-
25 temperature process heat. Broader questions emerge regarding the attractiveness of supplying all
26 energy, and not just electricity, with renewables (Figure 6.22). Integrated assessment and energy
27 systems research suggest large roles for renewables, but energy and electricity shares are far from 100%,
28 even with stringent emissions reductions targets and optimistic assumptions about future cost reductions
29 (Huntington et al. 2020; Jenkins et al. 2018b; Bauer et al. 2018; Bistline et al. 2018, Section 6.7.1).
30 Scenarios with 100% renewable energy systems are an emerging subset in the decarbonization
31 literature, especially at regional levels (Denholm et al. 2021; Hansen et al. 2019). Many 100%
32 renewables studies focus more heavily on electrification for decarbonizing end uses, and include less
33 biofuels and hydrogen than the broader literature on deep decarbonization (Bauer et al. 2018a). These
34 studies typically assume a constrained set of available technologies to demonstrate the technical
35 feasibility of very high renewable systems and do not optimize to find least-cost, technology-neutral
36 decarbonization pathways, and many 100% renewables studies focus on the electricity sector or a
37 limited number of sectors (Hansen et al. 2019; Jenkins et al. 2018a). In addition to renewables, studies
38 broadly agree that including additional low-carbon options – including not only low-carbon electricity
39 but also targeted use of fossil fuels with and without CCS (Section 6.6.2.1) and alternative fuels for
40 sectors that are difficult to electrify (Section 6.6.2.4) – can lower the cost of decarbonization even with
41 very high shares of renewables (Figure 6.22). However, there is disagreement about the magnitude of
42 cost savings from larger portfolios, which depend on context- and scenario-specific assumptions about
43 technologies, markets, and policies.

44 **[END BOX 6.8 HERE]**

45 **6.6.2.3 Widespread Electrification of End Uses**

46 Net-zero energy systems will rely more heavily on increased use of electricity (electrification) in end
47 uses (*high confidence*). The literature on net zero energy systems almost universally calls for increased

1 electrification (Williams et al. 2012; Sugiyama 2012; Williams et al. 2014; Rogelj et al. 2015a; Sachs
2 et al. 2016; Kriegler et al. 2014a; Sven et al. 2018; Luderer et al. 2018; Schreyer et al. 2020). At least
3 30% of the global final energy needs are expected to be served by electricity, with some estimates
4 suggesting upwards of 80% of total energy use being electrified (Figure 6.22, panel c). Increased
5 electrification is especially valuable in net zero energy systems in tandem with decarbonized electricity
6 generation or net-negative emissions electricity generation (Section 6.5.4.2). Flexible electric loads
7 (electric vehicles, smart appliances) can in turn facilitate incorporation of VRE electricity options,
8 increase system flexibility, and reduce needs for grid storage (Section 6.4.3) (Mathiesen et al. 2015);
9 Lund et al., 2018).

10 Several end-uses such as passenger transportation (light-duty electric vehicles, two and three wheelers,
11 buses, rail) as well as building energy uses (lighting, cooling) are likely to be electrified in net zero
12 energy systems (*high confidence*). Variations in projections of electrification largely result from
13 differences in expectations about the ability and cost-competitiveness of electricity to serve other end
14 uses such as non-rail freight transport, aviation, and heavy industry (McCollum et al. 2014; Breyer et
15 al. 2019; Bataille et al. 2016; EPRI 2018) (Section 6.5.4.4), especially relative to biofuels and hydrogen
16 ('low carbon fuels') (Sachs et al. 2016; Rockström et al. 2017; McCollum et al. 2014), the prospects for
17 which are still quite uncertain (Section 6.4). The emergence of CDR technologies and the extent to
18 which they allow for residual emissions as an alternative to electrification will also affect the overall
19 share of energy served by electricity (Section 6.6.2.7).

20 Regions endowed with cheap and plentiful low-carbon electricity resources (wind, solar, hydropower)
21 are likely to emphasize electrification, while those with substantial bioenergy resources or availability
22 of other liquid fuels might put less emphasis on electrification, particularly in hard-to-electrify end-uses
23 (*medium confidence*). For example, among a group of Latin American countries, relative assumptions
24 about liquid fuels and electricity result in an electrification range of 28–82% for achieving a net zero
25 energy system (Bataille et al. 2020). Similarly, the level of penetration of biofuels that can substitute
26 for electrification will depend on regional circumstances such as land-use constraints, competition with
27 food, and sustainability of biomass production (Section 6.6.2.4).

28 Electrification of most buildings services, with the possible exception of space heating in extreme
29 climates, is expected in net zero energy systems (*high confidence*) (Chapter 9). Space cooling and water
30 heating are expected to be largely electrified. Building electrification is expected to rely substantially
31 on heat pumps, which will help lower emissions both through reduced thermal requirements and higher
32 efficiencies (Mathiesen et al. 2015; Rissman et al.; Sven et al. 2018). The level of electrification for
33 heating will depend on the tradeoffs between building or household level heat pumps versus more
34 centralized district heating network options (Mathiesen et al. 2015; Brown et al. 2018), as well as the
35 cost and performance of heat pumps in more extreme climates and grid infrastructure (EPRI 2018;
36 Waite and Modi 2020).

37 A significant share of transportation, especially road transportation, is expected to be electrified in net
38 zero energy systems (*high confidence*). In road transportation, two-three wheelers, light-duty vehicles
39 (LDVs), and buses, are especially amenable to electrification, with more than half of passenger LDVs
40 expected to be electrified globally in net zero energy systems (*medium confidence*) (Bataille et al. 2020;
41 Sven et al. 2018; Khalili et al. 2019; Fulton et al. 2015). Long-haul trucks, large ships, and aircraft are
42 expected to be harder to electrify absent technological breakthroughs (Mathiesen et al. 2015; Fulton et
43 al. 2015), although continued improvements in battery technology may enable electrification of long-
44 haul trucks (Nykqvist and Olsson 2021; Chapter 10). Due to the relative ease of rail electrification, near
45 complete electrification of rail and a shift of air and truck freight to rail is expected in net zero energy
46 systems (Sven et al. 2018; Khalili et al. 2019; Rockström et al. 2017; Fulton et al. 2015). The degree of
47 modal shifts and electrification will depend on local factors such as infrastructure availability and
48 location accessibility. Due to the challenges associated with electrification of some transport modes,

1 net zero energy systems may include some residual emissions associated with the freight sector that are
2 offset through CDR technologies (Muratori et al. 2017b), or reliance on low and zero-carbon fuels
3 instead of electrification.

4 A non-trivial number of industry applications could be electrified as a part of a net zero energy system,
5 but direct electrification of heavy industry applications such as cement, primary steel manufacturing,
6 and chemical feedstocks is expected to be challenging (*medium confidence*) (Davis et al. 2018;
7 Madeddu et al. 2020; Philibert 2019; van Sluisveld et al. 2021). Process and boiler heating in industrial
8 facilities are anticipated to be electrified in net zero energy systems. Emissions intensity reductions for
9 cement and concrete production can be achieved through the use of electrified cement kilns, while
10 emissions associated with steel production can be reduced through the use of an electric arc furnace
11 (EAF) powered by decarbonized electricity (Rissman et al.). Electricity can also be used to replace
12 thermal heat such as resistive heating, electric arc furnaces, and laser sintering (Rissman et al.; Madeddu
13 et al. 2020). One study found that as much as 60% of the energy end-use in European industry could be
14 met with direct electrification using existing and emerging technologies (Madeddu et al. 2020). Industry
15 electrification for different regions will depend on the economics and availability of alternative
16 emissions mitigation strategies such as carbon neutral fuels and CCS (Davis et al. 2018; Madeddu et al.
17 2020).

18 **6.6.2.4 Alternative Fuels in Sectors not Amenable to Electrification**

19 Net-zero energy systems will need to rely on alternative fuels – notably hydrogen or biofuels – in several
20 sectors that are not amenable to electricity and otherwise hard to decarbonize (*medium confidence*).
21 Useful carbon-based fuels (e.g., methane, petroleum, methanol), hydrogen, ammonia, or alcohols can
22 be produced with net zero CO₂ emissions and without fossil fuel inputs (Sections 6.4.4 and 6.4.5). For
23 example, liquid hydrocarbons can be synthesized via hydrogenation of non-fossil carbon by processes
24 such as Fischer-Tropsch (Mac Dowell et al. 2017) or by conversion of biomass (Tilman et al. 2009).
25 The resulting energy-dense fuels can serve applications that are difficult to electrify, but it is not clear
26 if and when the combined costs of obtaining necessary feedstocks and producing these fuels without
27 fossil inputs will be less than continuing to use fossil fuels and managing the related carbon through,
28 for example, CCS or CDR (Ueckerdt et al. 2021)

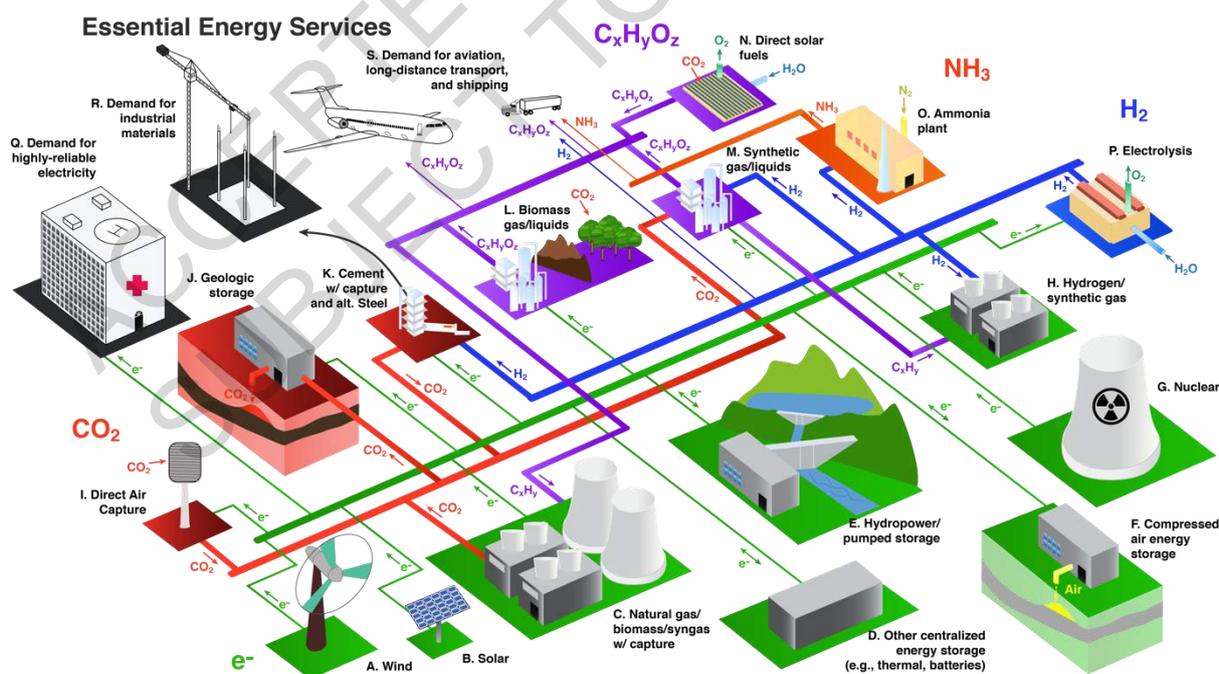

29 CO₂ emissions from some energy services are expected to be particularly difficult to cost-effectively
30 avoid, among them aviation; long-distance freight by ships; process emissions from cement and steel
31 production; high-temperature heat (e.g., >1000°C); and electricity reliability in systems with high
32 penetration of variable renewable energy sources (NAS; Davis et al. 2018; Luderer et al. 2018;
33 Chiamonti 2019; Sepulveda et al. 2018; Bataille 2020; Rissman et al.; Thiel and Stark 2021; Madeddu
34 et al. 2020). The literature focused on these services and sectors is growing, but remains limited, and
35 provides minimal guidance on the most promising or attractive technological options and systems for
36 avoiding these sectors' emissions. Technological solutions do exist, but those mentioned in the literature
37 are prohibitively expensive, exist only at an early stage, and/or are subject to much broader concerns
38 about sustainability (e.g., biofuels) (Davis et al. 2018).

39 Liquid biofuels today supply about 4% of transportation energy worldwide, mostly as ethanol from
40 grain and sugar cane and biodiesel from oil seeds and waste oils (Davis et al. 2018). These biofuels
41 could conceivably be targeted to difficult-to-electrify sectors, but face substantial challenges related to
42 their life-cycle carbon emissions, cost, and further scalability (Tilman et al. 2009; Staples et al. 2018),
43 (Section 6.4.2). The extent to which biomass will supply liquid fuels or high temperature heat for
44 industry in a future net zero energy system will thus depend on advances in conversion technology that
45 enable use of feedstocks such as woody crops, agricultural residues, algae, and wastes, as well as
46 competing demands for bioenergy and land, the feasibility of other sources of carbon-neutral fuels, and
47 integration of bioenergy production with other objectives, including CDR, economic development, food
48 security, ecological conservation, and air quality (Lynd 2017; Laurens 2017; Williams and Laurens

1 2010; Strefler et al. 2018; Bauer et al. 2018a; Fargione 2010; Creutzig et al. 2015; Bauer et al. 2018b;
2 Muratori et al. 2020b; Chatziaras et al. 2016; Fennell et al. 2021) (Section 6.4.2.6).

3 Costs are the main barrier to synthesis of net zero emissions fuels (*high confidence*), particularly costs
4 of hydrogen (a constituent of hydrocarbons, ammonia, and alcohols) (Section 6.4.5). Today, most
5 hydrogen is supplied by steam reformation of fossil methane (CH_4 into CO_2 and H_2) at a cost of 1.30-
6 1.50 USD kg^{-1} (Sherwin 2021). Non-fossil hydrogen can be obtained by electrolysis of water, at current
7 costs of 5-7 USD $\text{kg}^{-1} \text{H}_2^{-1}$ (assuming relatively low electricity costs and high utilization rates) (Graves
8 et al. 2011; Newborough and Cooley 2020; Peterson et al. 2020; DOE 2020a). At these costs for
9 electrolytic hydrogen, synthesized net zero emissions fuels would cost at least 1.6 USD per liter of
10 diesel equivalent (or 6 USD gallon $^{-1}$ and 46 USD GJ^{-1} , assuming non-fossil carbon feedstock costs of
11 100 USD per ton of CO_2 and low process costs of 0.05 USD liter $^{-1}$ or 1.5 USD GJ^{-1}). Similar calculations
12 suggest that synthetic hydrocarbon fuels could currently avoid CO_2 emissions at a cost of 936-1404
13 USD ton $^{-1}$ (Ueckerdt et al. 2021). However, economies of scale are expected to bring these costs down
14 substantially in the future (Ueckerdt et al. 2021; IRENA 2020c), and R&D efforts are targeting 60-80%
15 reductions in costs (to less than 2 USD $\text{kg}^{-1} (\text{H}_2)^{-1}$) possibly by use of less mature but promising
16 technologies such as high-temperature electrolysis and thermochemical water splitting (Schmidt et al.
17 2017; Pes et al. 2017; DOE 2018; Saba et al. 2018; Kuckshinrichs et al. 2017; DOE 2020b).
18 Technologies capable of producing hydrogen directly from water and sunlight (photoelectrochemical
19 cells or photocatalysts) are also under development, but still at an early stage (DOE 2020a; Nielander
20 et al. 2015). High hydrogen production efficiencies have been demonstrated, but costs, capacity factors,
21 and lifetimes need to be improved in order to make such technologies feasible for net zero emissions
22 fuel production at scale (DOE 2020a; Newborough and Cooley 2020; McKone et al. 2014).

23 The carbon contained in net zero emissions hydrocarbons must have been removed from the atmosphere
24 either through DAC, or, in the case of biofuels, by photosynthesis (which could include CO_2 captured
25 from the exhaust of biomass or biogas combustion) (Zeman and Keith 2008; Graves et al. 2011). A
26 number of different groups are now developing DAC technologies, targeting costs of 100 USD per ton
27 of CO_2 or less (Darton and Yang 2018; Keith et al. 2018; Fasihi et al. 2019).

28

29 **Figure 6.23 Schematic of net zero emissions energy system, including methods to address difficult-to-**
30 **electrify sectors. (Source: Davis et al. 2018)**

1 **[START BOX 6.9 HERE]**

2 **Box 6.9 The Hydrogen Economy**

3 The phrase “hydrogen economy” is often used to describe future energy systems in which hydrogen
4 plays a prominent role. These future energy systems would not use hydrogen for all end uses; they
5 would use hydrogen to complement other energy carriers, mainly electricity, where hydrogen might
6 have advantages. Hydrogen could provide long-term electricity storage to support high-penetration of
7 intermittent renewables and could enable trading and storage of electricity between different regions to
8 overcome seasonal or production capability differences (Dowling et al. 2020; Sepulveda et al. 2021). It
9 could also be used in lieu of natural gas for peaking generation, provide process heat for industrial
10 needs, or be used in the metal sector via direct reduction of iron ore (Chapter 11). Clean hydrogen could
11 be used as a feedstock in the production of various chemicals and synthetic hydrocarbons. Finally,
12 hydrogen-based fuel cells could power vehicles. Recent advances in battery storage make electric
13 vehicles the most attractive alternative for light-duty transport. However, fuel cell technology could
14 complement electric vehicles in supporting the decarbonisation of heavy-duty transport segments (e.g.,
15 trucks, buses, ships, and trains) (Chapter 10).

16 Hydrogen production costs have historically been prohibitive, but recent technological developments
17 are bringing costs down. These developments include improvements in hydrogen production
18 technologies in terms of efficiency and capital costs (e.g., SMR) (Alrashed and Zahid 2021; Boretti and
19 Banik 2021) and the emergence of alternative production technologies such as electrolyzers (Dawood
20 et al. 2020). These technological changes, along with decreasing costs of renewable power, are
21 increasing the viability of hydrogen. Other improvements in hydrogen-based technologies are also
22 emerging quickly. Gas turbines now run on blended fuels containing 5-95% hydrogen by volume (GE
23 2020) and could operate entirely on hydrogen by 2030 (Pflug et al. 2019). Fuel cell costs have decreased
24 by 80-95% since the early 2000s, while power density and durability have improved (Kurtz et al. 2019;
25 IEA 2019e; Jouin et al. 2016).

26 For hydrogen to support decarbonisation, it will need to be produced from zero-carbon or extremely
27 low-carbon energy sources. One such production category is “green hydrogen.” While there is no
28 unified definition for green hydrogen, it can be produced by the electrolysis of water using electricity
29 generated without carbon emissions (such as renewables). Hydrogen can also be produced through
30 biomass gasification with CCS (BECCS), leading to negative carbon emissions (del Pozo et al. 2021).
31 Additionally, “blue hydrogen” can be produced from natural gas through the process of auto-thermal
32 reforming (ATR) or steam methane reforming (SMR), combined with CCS technology that would
33 absorb most of the resulting CO₂ (80-90%).

34 However, the potential role of hydrogen in future energy systems depends on more than just production
35 methods and costs. For some applications, the competitiveness of hydrogen also depends on the
36 availability of the infrastructure needed to transport and deliver it at relevant scales (Lee et al. 2021).
37 Transporting hydrogen through existing gas pipelines is generally not feasible without changes to the
38 infrastructure itself (Muratori et al. 2018; Gumber and Gurumoorthy 2018). Existing physical barriers,
39 such as steel embrittlement and degradation of seals, reinforcements in compressor stations, and valves,
40 require retrofitting during the conversion to H₂ distribution or new H₂ dedicated pipelines to be
41 constructed (Dohi et al. 2016). The capacity to leverage and convert existing gas infrastructure to
42 transport hydrogen will vary regionally, but in many cases could be the most economically viable
43 pathway (Brändle et al. 2021; Cerniauskas et al. 2020; Brooks 2021; Wettengel 2021). Hydrogen could
44 also be transported as liquid gas or as liquid organic hydrogen carriers such as ammonia, for which
45 industry knowledge exists (Hong et al. 2021; Wulf et al. 2018; Demir et al. 2018). Additionally,
46 improvements in fuel cell technologies are needed to make hydrogen-based transport economically

1 viable. There are also safety concerns associated with the flammability (Nilsson et al. 2017) and storage
2 (Andersson and Grönkvist 2019; Caglayan et al. 2019) of hydrogen which will need to be considered.

3 **[END BOX 6.9 HERE]**

4 **6.6.2.5 Using Less Energy and Using It More Efficiently**

5 Demand-side or demand reduction strategies include technology efficiency improvements, strategies
6 that reduce energy consumption or demand for energy services (such as reducing the use of personal
7 transportation, often called “conservation”) (Creutzig et al. 2018), and strategies such as load
8 curtailment.

9 Net-zero energy systems will use energy more efficiently than those of today (*high confidence*). Energy
10 efficiency and energy use reduction strategies are generally identified as being flexible and cost-
11 effective, with the potential for large scale deployment (Chapters 5, 9, 10, and 11). For this reason,
12 existing studies find that energy efficiency and demand reduction strategies will be important
13 contributors to net zero energy systems (Creutzig et al. 2018; Davis et al. 2018; DeAngelo et al. 2021).
14 Lower demand reduces the need for low-carbon energy or alternative fuel sources.

15 Characterizing efficiency of net zero energy systems is problematic due to measurement challenges
16 (*high confidence*). Efficiency itself is difficult to define and measure across full economies (Saunders
17 et al. 2021). There is no single definition of energy efficiency and the definition understandably depends
18 on the context used (Patterson 1996), which ranges from device level efficiency all the way to the
19 efficient use of energy throughout an economy. Broadly, energy efficient strategies allow for the same
20 level of services or output while using less energy. At the level of the entire economy, measures such
21 as primary or final energy per capita or per GDP are often used as a proxy for energy efficiency, but
22 these measures reflect not only efficiency, but also many other factors such as industrial structure,
23 endowed natural resources, consumer preferences, policies, and regulations. Energy efficiency and
24 other demand-side strategies represent such a large set of technologies, strategies, policies, market and
25 consumers’ responses and policies that aggregate measures can be difficult to define (Saunders et al.
26 2021).

27 Measurement issues notwithstanding, virtually all studies that address net zero energy systems assume
28 improved energy intensity in the future (*high confidence*). The overall efficiency outcomes and the
29 access to such improvements across different nations, however, is not clear. Energy consumption will
30 increase over time despite energy efficiency improvements due to population growth and development
31 (DeAngelo et al. 2021).

32 A study (DeAngelo et al. 2021) reviewed 153 IAM scenarios that attain net zero energy sector CO₂
33 emissions and found that, under a scenario with net zero emissions: global final energy per capita lies
34 between 21–109 GJ per person (median: 57), in comparison to 2018 global final energy use of 55 GJ
35 per person; many countries use far more energy per capita than today as their incomes increase; global
36 final energy use per unit of economic output ranges from 0.7–2.2 EJ per trillion USD (median: 1.5), in
37 comparison to 5 EJ per trillion USD in 2018; and the median final energy consumption is 529 EJ. By
38 comparison, final energy consumption would be 550 EJ if current energy consumption per capita
39 continued under a future population of 10 billion people. Across all scenarios, total final energy
40 consumption is higher today than in the year in which net zero emissions are attained, and regionally,
41 only the OECD+EU and Eurasia have lower median total final energy than in 2010.

42 Net-zero energy systems will be characterized by greater efficiency and more efficient use of energy
43 across all sectors (*high confidence*). Road transportation efficiency improvements will require a shift
44 from liquid fuels (Chapters 5 and 10). Emissions reductions will come from a transition to electricity,
45 hydrogen, or synthetic fuels produced with low carbon energy sources or processes. Vehicle
46 automation, ride-hailing services, online shopping with door delivery services, and new solutions like

1 last mile delivery with drones may result in increased service share. Lighter vehicles, a shift to public
2 transit, and incorporation of 2- and 3-wheelers will be features of a net zero energy system (Chapter
3 10). Teleworking and automation of work may provide reductions in driving needs. Other sectors, such
4 as air travel and marine transportation may rely on alternative fuels such as biofuels, synthetic fuels,
5 ammonia, produced with zero carbon energy source (Section 6.6.2.4).

6 Under net zero energy systems, buildings would be characterized by improved construction materials,
7 an increase in multi-family dwellings, early retirement of inefficient buildings, smaller floor areas, and
8 smart controls to optimize energy use in the building, namely for heating, cooling, LED lighting, and
9 water heating (Chapter 9). End-uses would utilize electricity, or potentially hydrogen, produced from
10 zero carbon sources. The use of electricity for heating and cooking may often be a less efficient process
11 at converting primary energy to energy services than using natural gas, but using natural gas would
12 require CDR in order to be considered net zero emissions. Changes in behaviour may modestly lower
13 demand. Most economies would have buildings with more efficient technologies powered by zero
14 carbon electricity, and developing economies would shift from biomass to electricity, raising their
15 energy consumption as population and wealth increase under net zero energy systems.

16 Industry has seen major efficiency improvements in the past, but many processes are now close to their
17 thermodynamic limits. Electrification and breakthrough processes (such as producing steel with
18 electricity and H₂), using recycled materials, using heat more efficiently by improving thermal
19 insulation, and using waste heat for heat pumps, as well using advanced sensors, monitoring, and
20 visualization and communication technologies may provide further efficiency improvements. (Chapter
21 11)

22 **6.6.2.6 Greater Reliance on Integrated Energy System Approaches**

23 Energy systems integration refers to connected planning and operations across energy carriers,
24 including electricity, fuels, and thermal resources. Coordinated planning could be important in lowering
25 system costs, increasing reliability, minimizing environmental impacts, and ensuring that costs of R&D
26 and infrastructure account for not just current needs but also for those of future energy systems (Section
27 6.4.3). Integration includes not only the physical energy systems themselves but also simultaneous
28 societal objectives (e.g., sustainable development goals), innovation processes (e.g., coordinating R&D
29 to increase the likelihood of beneficial technological spillovers), and other institutional and
30 infrastructural transformations (Sachs et al. 2019). Given system variability and differences in regional
31 resources, there are economic and technical advantages to greater coordination of investments and
32 policies across jurisdictions, sectors, and levels of government (Schmalensee and Stavins 2017).
33 Coordinated planning and operations can improve system economics by sharing resources, increasing
34 the utilization of capital-intensive assets, enhancing the geographical diversity of resource bases, and
35 smoothing demand. But integration could require regulatory and market frameworks to facilitate and
36 appropriate price signals to align incentives and to coordinate investments and operations.

37 Carbon-neutral energy systems are likely to be more interconnected than those of today (*high*
38 *confidence*). The many possible feedstocks, energy carriers, and interconversion processes imply a
39 greater need for the integration of production, transport, storage, and consumption of different fuels
40 (Davis et al. 2018). For instance, electrification is expected to play an important role in decarbonizing
41 light-duty vehicles (Chapter 10, Section 6.4.3), yet the electricity and transport sectors have few direct
42 interactions today. Systems integration and sectoral coupling are increasingly relevant to ensure that net
43 zero energy systems are reliable, resilient, and affordable (EPRI 2017; O'Malley et al. 2020; Buttler
44 and Spliethoff 2018; Martin et al. 2017). Deep decarbonization offers new opportunities and challenges
45 for integrating different sectors as well as supply- and demand-side options. For instance, increasing
46 electrification will change daily and seasonal load shapes, and end-use flexibilities and constraints could
47 impact the desirability of different supply-side technologies (EPRI 2019b; Brown et al. 2018). The
48 feasibility of net zero energy system configurations could depend on demonstrating cross-sector

1 benefits like balancing VRE sources in the electricity sector, and on offering the flexibility to produce
2 multiple products. For instance, low-emissions synthetic fuels could help to bridge stationary and
3 mobile applications, since fuel markets have more flexibility than instantaneously balanced electricity
4 markets due to the comparative ease and cost of large-scale, long-term storage of chemical fuels (Davis
5 et al. 2018).

6 There are few detailed archetypes of integrated energy systems that provide services with zero- or net-
7 negative CO₂ emissions (such as (Jacobson et al. 2019)), so there is considerable uncertainty about
8 integration and interactions across parts of the system. Although alternate configurations, tradeoffs, and
9 pathways are still being identified, common elements include fuels and processes like zero- or negative-
10 CO₂ electricity generation and transmission, hydrogen production and transport, synthetic hydrocarbon
11 production and transport, ammonia production and transport, and carbon management, where linkages
12 across pathways could include the use of electricity to produce hydrogen via electrolysis (Davis et al.
13 2018; Jenkins et al. 2018b; van Vuuren et al. 2018; Shih et al. 2018; Moore 2017; Smith et al. 2016).
14 Linked analytical frameworks are increasing being used to understand the potential role for system
15 coupling with greater temporal resolution, spatial resolution, and heterogeneity of consumer and firm
16 decisions (Pye et al. 2021; Gerboni et al. 2017; Santen et al. 2017; Collins et al. 2017; Bistline and de
17 la Chesnaye 2017; Bohringer and Rutherford 2008).

18 Challenges associated with integrating net zero energy systems include rapid technological change, the
19 importance of behavioural dimensions in domains with limited experience and data, policy changes and
20 interactions, and path dependence. Technological cost and public acceptance will influence the degree
21 of integration. Sectoral pathways will likely be adaptive and adjust based on the resolution of
22 uncertainties over time, and the relative competitiveness will evolve as the technological frontier
23 evolves, which is a complex and path-dependent function of deployment, R&D, and inter-industry
24 spillovers. Supply-side options interact with demand-side measures in increasingly integrated energy
25 systems (van Vuuren et al. 2018; Sorrell 2015).

26 **6.6.2.7 Carbon Dioxide Removal**

27 While CDR is likely necessary for net zero energy systems, the scale and mix of strategies is unclear –
28 nonetheless some combination of BECCS and DACCS are likely to be part of net zero energy systems
29 (*high confidence*). Studies indicate that energy-sector CDR may potentially remove 5–12 GtCO₂
30 annually globally in net zero energy systems (Fuss et al. 2018) (Figure 6.22; Section 6.7; Chapter 12).
31 CDR is not intended as a replacement for emissions reduction, but rather as a complementary effort to
32 offset residual emissions from sectors that are not decarbonized and from other low-carbon technologies
33 such as fossil CCS (McLaren et al. 2019; Gaffney et al. 2020; Iyer et al. 2021).

34 CDR covers a broad set of methods and implementation options (Chapters 7 and 12). The two CDR
35 methods most relevant to the energy sector are BECCS, which is used to produce energy carriers, and
36 DACCS which is an energy user (Smith et al. 2016; Singh and Colosi 2021). BECCS has value as an
37 electricity generation technology, providing firm, dispatchable power to support electricity grids with
38 large amounts of VRE sources, and reducing the reliance on other means to manage these grids,
39 including electricity storage (Bistline and Blanford 2021a; Mac Dowell et al. 2017). BECCS may also
40 be used to produce liquid fuels or gaseous fuels, including hydrogen (Section 6.4.2.6) (Muratori et al.
41 2020b). For instance, CO₂ from bio-refineries could be captured at <45 USD tCO₂⁻¹ (Sanchez et al.
42 2018). Similarly, while CO₂ capture is expensive, its integration with hydrogen via biomass gasification
43 can be achieved at an incremental capital cost of 3-35% ((Muratori et al. 2020b); Section 6.4). As with
44 all uses of bioenergy, linkages to broad sustainability concerns may limit the viable development, as
45 will the presence of high-quality geologic sinks in close proximity (Melara et al. 2020).

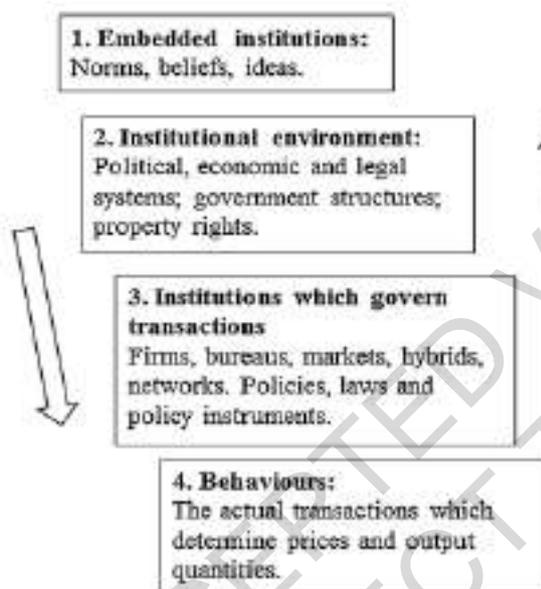

46 DACCS offers a modular approach to CDR (Creutzig et al. 2019), but it could be a significant consumer
47 of energy. DAC could also interact with other elements of the energy systems as the captured CO₂ could

1 be reused to produce low-carbon methanol and other fuels (Realmonte et al. 2019; Hoppe et al. 2018;
 2 Zhang and Fujimori 2020). DACCS might also offer an alternative for use of excess electricity produced
 3 by variable renewables (Wohland et al. 2018), though there are uncertainties about the economic
 4 performance of this integrated approach.

5

6 **6.6.3 The Institutional and Societal Characteristics of Net-zero Energy Systems**

7 The transition to net zero energy systems is not just technological; it requires shifts in institutions,
 8 organizations, and society more generally. As such, it involves institutional changes alongside changes
 9 in supply, technology, or markets (Andrews-Speed 2016, Pai et al. 2021). Institutional relationships
 10 between governments and energy sector actors (e.g., consumers, electricity companies) affect the nature
 11 of net zero systems, as these entities may collaborate on or dispute net zero goals and measures to
 12 achieve them. For example, following the Fukushima disaster, Japan placed emphasis on government-
 13 utility-public cooperation on use of nuclear power as a means of reducing carbon emissions (Sklarew
 14 2018). Institutions are instrumental in shaping net zero energy systems in multiple ways, complemented
 15 by and interacting with the behaviours of actors and policy regimes in these systems (Figure 6.24).

16

17 **Figure 6.24 A four-level framework for institutional change. The diagram depicts three levels of**
 18 **institutions (1-3) which collectively govern actor behaviours (4). Source: Andrews-Speed 2016**

19 One level of institutional interactions reflects embedded institutions, norms, beliefs, and ideas that
 20 would need to change to support net zero energy systems. This applies, for example, to the objectives
 21 of modern economies and the potentially contradictory dynamics embedded in the concept of “green
 22 growth” (Stegemann and Ossewaarde 2018; Stoknes and Rockström 2018). The institutional
 23 environment – the political and legal systems that govern exchanges and protect property rights – would
 24 also need to be different in net zero energy systems. In this setting, changing regulations or subsidies
 25 that continue to favour carbon-intensive systems over the technologies of a net zero energy system
 26 might prove difficult (Sovacool 2017). More generally, net zero energy systems will need new
 27 regulatory frameworks to undertake new challenges, from managing a more interconnected grid to
 28 adequately governing underground storage of CO₂. Institutions may also govern specific transactions,
 29 such as firms or networks that supply energy fuels or services. Current actors are typically resistant to
 30 disruptions, even if such disruptions may broadly benefit society (Kungl 2015, Mori 2018, Schmid et
 31 al. 2017).

1 For example, one energy system characterized by differentiated institutional interactions is the United
2 States, where delivery of liquid fuels is lightly regulated, while electricity delivery is closely regulated
3 (Dworkin et al. 2013). Reforming this two-pronged system for decarbonization would require four types
4 of institutional change: (1) changes to the control systems that coordinate generation and transmission
5 through a pyramidal architecture for the operational control, dispatch, and delivery of electricity with a
6 primary emphasis on reliability; (2) changes to the financing of central-station power plants through
7 long-term bonds, as valued by Wall Street ratings analysts; (3) changes to the structure of investor-
8 owned utilities that attract private investors who expected decades of technological stability to yield
9 long-term, low-risk revenues; and (4) changes to regulations to restructure and limit excessive returns
10 and easy entry of new retail competitors, all recognizing local and national concerns through state and
11 federal regulatory agencies. The example shows how decision-making and the infrastructures involved
12 are layered, and can create “nested hierarchies” where institutions fulfill multiple roles for energy
13 governance or regulation simultaneously (Stern et al. 2016b). Internationally and across different parts
14 of the energy system, institutional challenges such as these could become even more stark and complex
15 (Van de Graaf 2013).

16 **6.6.4 Regional Circumstances and Net-zero Energy Systems**

17 Countries have flexibility to pursue options that make the most sense for their national circumstances
18 (Figure 6.25). They may emphasize supply transformation over demand reduction; deploy different
19 resources; engage at different levels in international energy trade; support different energy industries;
20 focus on different energy carriers (e.g., electricity, hydrogen); or focus more on distributed or integrated
21 systems, among others. Many factors may influence the long-term net zero energy systems that are
22 appropriate for any country’s national circumstances, including the following.

23 *Future Technology.* Technological transitions have often been driven by the relative merits of different
24 technology options. Recent trends in the use of PV cells, wind power, and in batteries, for example,
25 have been spurred by their increasing economic competitiveness (Section 6.3). Yet future technology
26 cannot be fully predicted, so it provides only a partial guide today for charting a path toward future
27 systems.

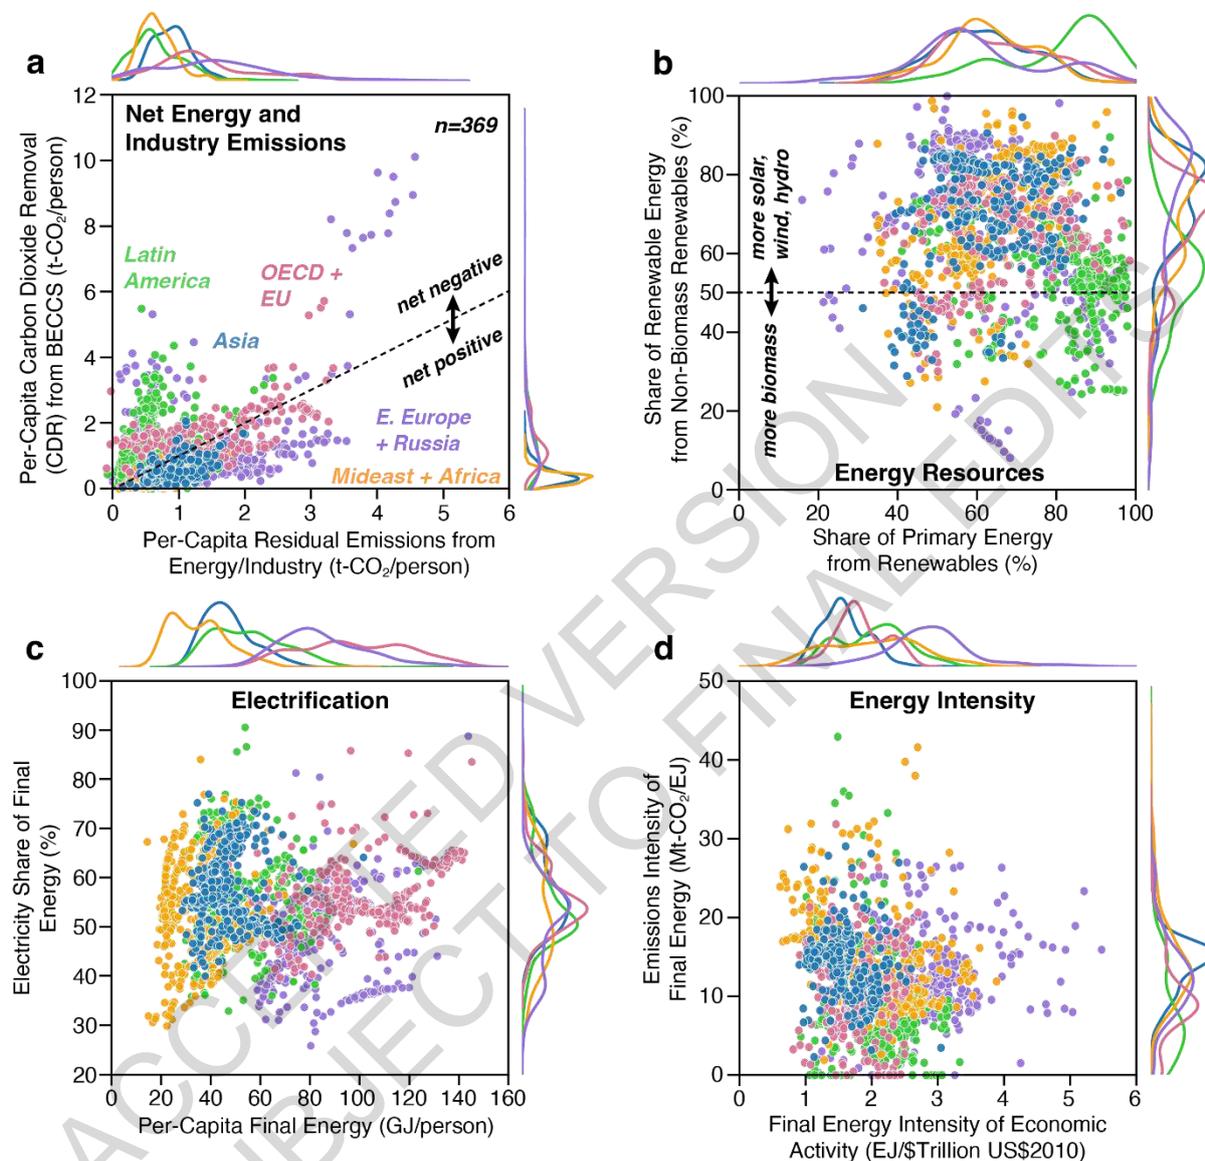

28 *Indigenous Energy Resources.* Countries may emphasize approaches that take advantage of indigenous
29 energy resources such as solar power, wind, hydroelectric resources, land for bioenergy crops, CO₂
30 storage capability, or fossil resources to be used with CCS. Countries with less abundant resources may
31 put greater emphasis on demand reductions and regional integration. Countries with resource bases that
32 are easily tradeable, like low-carbon electricity or bioenergy, may choose to trade those resources rather
33 than use them domestically (Box 6.10, Section 6.4.3, 6.4.5).

34 *Regional Climate.* Climate influences heating and cooling demand, both of which influence countries’
35 energy demands and energy infrastructure to meet those demands (Section 6.5). In addition to daily
36 demand profiles, heating and cooling are seasonal, influencing which energy sources may serve these
37 loads and the seasonal storage they require. Cooling is almost entirely served by electricity today, and
38 heating has commonly been served by non-electric fuels. In low-carbon energy systems, heating may
39 be increasingly served by electricity (Section 6.6.4), meaning that the influence of regional climate may
40 be strongest on countries’ electricity systems.

41 *Current Energy System Configuration.* Future sectoral energy demands and the potential for demand-
42 side transformation are partially determined by existing infrastructure (e.g., building stocks, transport
43 infrastructure). Countries with less developed or growing energy systems will have more flexibility to
44 create the systems that best match their long-term goals, but there may be substantial challenges in
45 transitioning directly to the most advanced low-carbon technology options, and countries may have
46 different capacities to absorb technology from other countries.

1 *Regional Integration.* Regional integration will allow countries to bridge energy gaps using external
 2 linkages, including regional electricity integration and trade in hydrogen, biomass, and other fuels.
 3 Countries with greater integration can rely more heavily on imports and may therefore rely less on
 4 indigenous resources (Box 6.10).

5

6

7

8 **Figure 6.25 Characteristics of regional energy systems and emissions when energy and industrial CO₂**
 9 **emissions reach net zero. Regional differences are shown for residual emissions and carbon removal**
 10 **(panel a), energy resources (panel b), electrification (panel c), and energy intensity (panel d).**
 11 **Distributions of scenarios are shown along each axis for each region. Colour scheme is shown in panel a.**
 12 **Points represent different models and scenarios from the AR6 database.**

13 *Societal Preferences.* Citizens in every country have preferences for certain technological options or
 14 mitigation approaches over others that will influence energy system choices. The public generally
 15 prefers a future energy system based largely on renewables. Preferences for non-renewable energy
 16 differ across regions and groups. For example, studies have found that people in the U.K., Germany,
 17 the Netherlands, and Switzerland prefer renewable energy and personal energy efficiency and savings

1 to nuclear, fossil fuels and CCS (Demski et al. 2017; Jones et al. 2012; Scheer et al. 2013; Volken et al.
2 2018; Bessette and Arvai 2018; Steg 2018). Studies have found that people with higher education levels,
3 higher incomes, females, and liberals prefer renewables to fossil fuels and nuclear (Van Rijnsoever et
4 al. 2015; Bertsch et al. 2016; Blumer et al. 2018; Jobin et al. 2019). The willingness to pay for renewable
5 electricity differs by source (Ma et al. 2015; Sundt and Rehdanz 2015).

6 *Technological Leadership, Economic Opportunities, and Growth.* Countries may emphasize
7 technologies in which they intend to have technological leadership and a competitive advantage. These
8 could emerge over time or be based on current areas of opportunity or leadership. Industrial policy will
9 influence future energy system as technological choices can benefit or hamper incumbents or new
10 market actors.

11 *Energy Security.* Countries emphasizing import security will tend to rely more heavily on indigenous
12 resources (Section 6.3). Some indigenous resources may raise security of supply issues that will
13 influence energy system configurations. Bioenergy and hydropower, for example, can be subject to
14 import climate risks (6.5), and significant integration of VRE technologies will influence electricity
15 system infrastructure and management (6.6.2, Box 6.8).

16 *Other Factors.* Countries will consider a wide range of other factors in building toward low-carbon
17 energy systems. Population density, for example, will influence building and transportation energy
18 demands; economic transitions will influence industrial energy demands. Societal priorities beyond
19 climate, notably SDGs may influence technology choices and types of energy systems (Sections 6.3
20 and 6.7.7).

21 **[START BOX 6.10 HERE]**

22 **Box 6.10 Regional Integration of Energy Systems**

23 Energy systems are linked across countries in many ways: countries transport crude oil across the ocean
24 in supertankers, pipelines carry oil and natural gas across country boundaries, electric power lines cross
25 country boundaries, and countries trade industrial commodities that carry embodied energy or that are
26 essential inputs to mitigation technologies. Future systems will generate electricity using different
27 mixes of technologies, produce and transport different carriers (e.g., hydrogen or biofuels), and use far
28 less fossil fuel, among other major changes. Important examples include electricity, hydrogen, and
29 biomass.

30 **Electricity System Integration.** Net-zero energy systems will rely more heavily on electricity
31 generated from low-emissions technologies. Given the significant variations in the location of low-
32 carbon electricity resources and the temporal variability of some renewable electricity sources, notably
33 solar and wind power, regional electricity grids could reduce overall costs of net zero energy systems
34 (Section 6.4.5). Furthermore, electricity transmission interconnections could significantly reduce local
35 energy balancing costs and investment in peaking plants needed to meet security of supply
36 requirements, and it could increase system resilience, especially in the case of extreme events such as
37 heat waves or cold spells (Fasihi and Bogdanov 2016). Important challenges to regional electricity
38 integration include geopolitical concerns from cross-border trade and societal and technological
39 challenges associated with building new transmission lines.

40 **Hydrogen Trade.** Hydrogen may play an important role in future net zero energy systems, particularly
41 in applications where electricity is not economically advantageous (see Box 6.9). Hydrogen can be used
42 to decarbonize regions in which it is produced, and it can also be transported long distances to facilitate
43 decarbonization of sectors distant from sources of low-cost supply. Methods of long-distance, high-
44 volume hydrogen transport could include liquid storage, chemical carriers, and gaseous delivery via
45 pipelines (Section 6.4.5). In net zero systems with substantial wind and solar power generation,

1 hydrogen can be generated through electrolysis and then shipped to other locations. Important
2 challenges to hydrogen trade include cost-effective low carbon production, cost of delivery
3 infrastructure, storage, and end-use technology costs and safety.

4 **Trade in Biomass.** Biomass may also play an important role in net zero energy systems (Section 6.6.4,
5 Chapter 3). Large-scale bioenergy production and consumption is likely to trigger global biomass trade.
6 Global bioenergy trade volumes presently exceed 1 EJ yr⁻¹, of which 60% is directly traded for energy
7 purposes (Proskurina et al. 2019b). Established trade mechanisms include wood pellet transport,
8 ethanol, and biodiesel (Proskurina et al. 2019a). In a net zero global energy system, bioenergy trade
9 could be greater than current trade of coal or natural gas, but less than that of petroleum (Sharmina et
10 al. 2017) (Mandley et al, 2020). Some studies indicate that Latin America and Africa could become key
11 exporting regions, with the EU, the USA, and East Asia emerging as key importers (Rentizelas et al.
12 2019; Alsaleh and Abdul-Rahim 2018). Studies have found that net bioenergy exports could be as high
13 as 10% of GDP for some Latin American countries, while other regions like the EU may be faced with
14 burgeoning import reliance (Mahlknecht et al. 2020; Daioglou et al. 2020b). In addition to challenges
15 associated with bioenergy production (Section 6.4, Chapter 7), important challenges to biomass trade
16 include differences in sustainability criteria and land/biomass definitions in different jurisdictions, and
17 difficulties in establishing consistent monitoring and auditing systems (Lamers et al, 2016).

18 [END BOX 6.10 HERE]

21 **6.7 Low-Carbon Energy System Transitions in the Near- and Medium-** 22 **Term**

23 **6.7.1 Low-Carbon Energy System Transition Pathways**

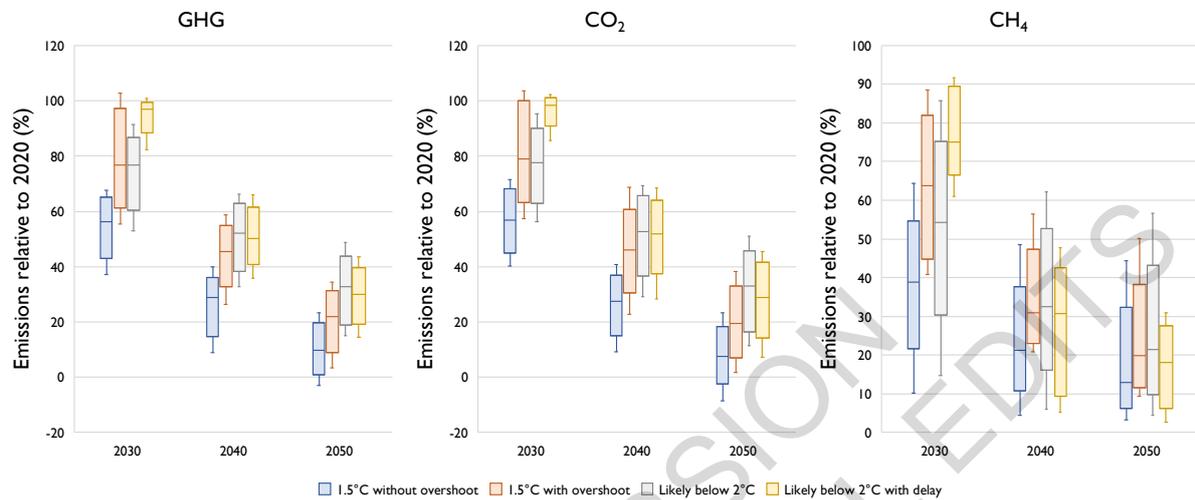

24 **6.7.1.1 Energy System Emissions**

25 Without additional efforts to reduce emissions, it is very unlikely that energy system CO₂ emissions
26 will decrease sufficiently to limit warming to well below 2°C (*high confidence*). Scenarios assuming
27 improvements in technology but no additional climate policies beyond those in place today provide a
28 benchmark for comparison against energy-related CO₂ emissions in mitigation scenarios (Figure 6.26).
29 Emissions in these reference scenarios increase through 2050 but span a broad range (Chapter 3 Figure
30 3.16; Riahi et al. 2017; Wei et al. 2018). The highest emissions levels are about four times current
31 emissions; the lowest are modestly below today's emissions. Emissions in these scenarios increase in
32 most regions, but they diverge significantly across regions (Bauer et al. 2017). Asia and the Middle East
33 and Africa account for the majority of increased emissions across these scenarios (Figure 6.27). While
34 it is unlikely that there will be no new climate policies in the future, these scenarios nonetheless support
35 the conclusion that the energy sector will not be decarbonized without explicit policy actions to reduce
36 emissions.

37 Warming cannot be limited to well below 2°C without rapid and deep reductions in energy system GHG
38 emissions (*high confidence*). Energy sector CO₂ emissions fall by 87-97% (interquartile range) by 2050
39 in scenarios limiting warming to 1.5°C with no or limited overshoot and 60-79% in scenarios limiting
40 likely warming to 2°C (Figure 6.26). Energy sector GHG emissions fall by 85-95% (interquartile range)
41 in scenarios limiting warming to 1.5°C with no or limited overshoot and 62-78% in scenarios limiting
42 likely warming to 2°C (Figure 6.26). In 2030, in scenarios limiting warming to 1.5°C with no or limited
43 overshoot, net CO₂ and GHG emissions fall by 35-51% and 38-52% respectively. Key characteristics
44 of emissions pathways – the year of peak emissions, the year when net emissions reach zero, and the
45 pace of emissions reductions – vary widely across countries and regions. These differences arise from

1 differences in economic development, demographics, resource endowments, land use, and potential
 2 carbon sinks (Schreyer et al. 2020)(Schaeffer, et al.2020; Schreyer, et al., 2020; van Soest, Heleen, et
 3 al., 2021;Figure 6.27, Figure 6.28, Box 6.11). If countries do not move quickly to reduce emissions – if
 4 reductions are delayed – a more rapid energy transition will subsequently be required to limit warming
 5 to 2°C or below (Rogelj et al. 2015a, 2018a; IPCC 2018).

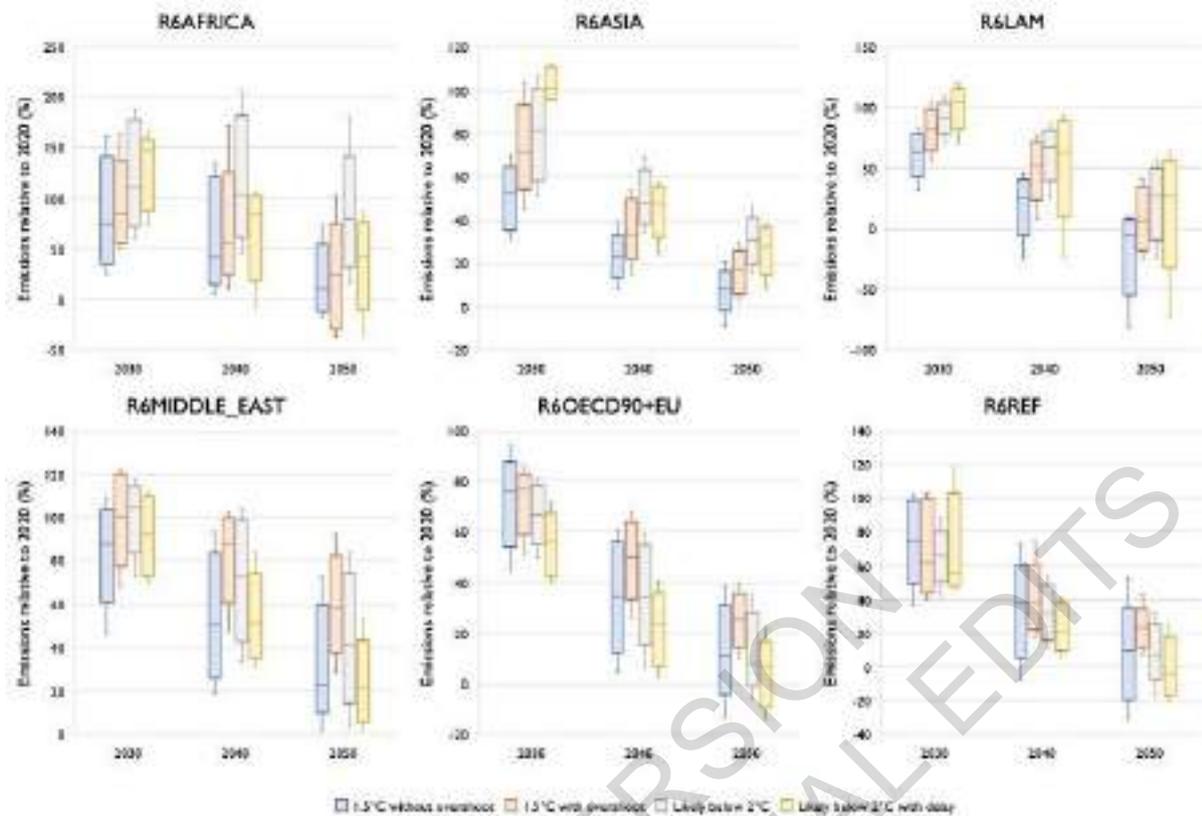

6

Figure 6.27 Net regional (R5) CO₂ emissions from energy across scenarios, for the 1.5°C scenarios (without and with overshoot), and likely below 2°C scenarios (without and with delayed policy action) during 2020-2050 (Source: AR6 Scenario Database). Boxes indicate 25th and 75th percentiles while whiskers indicate 5th and 95th percentiles. Most mitigation scenarios are based on a cost-minimizing framework that does not consider historical responsibility or other equity approaches.

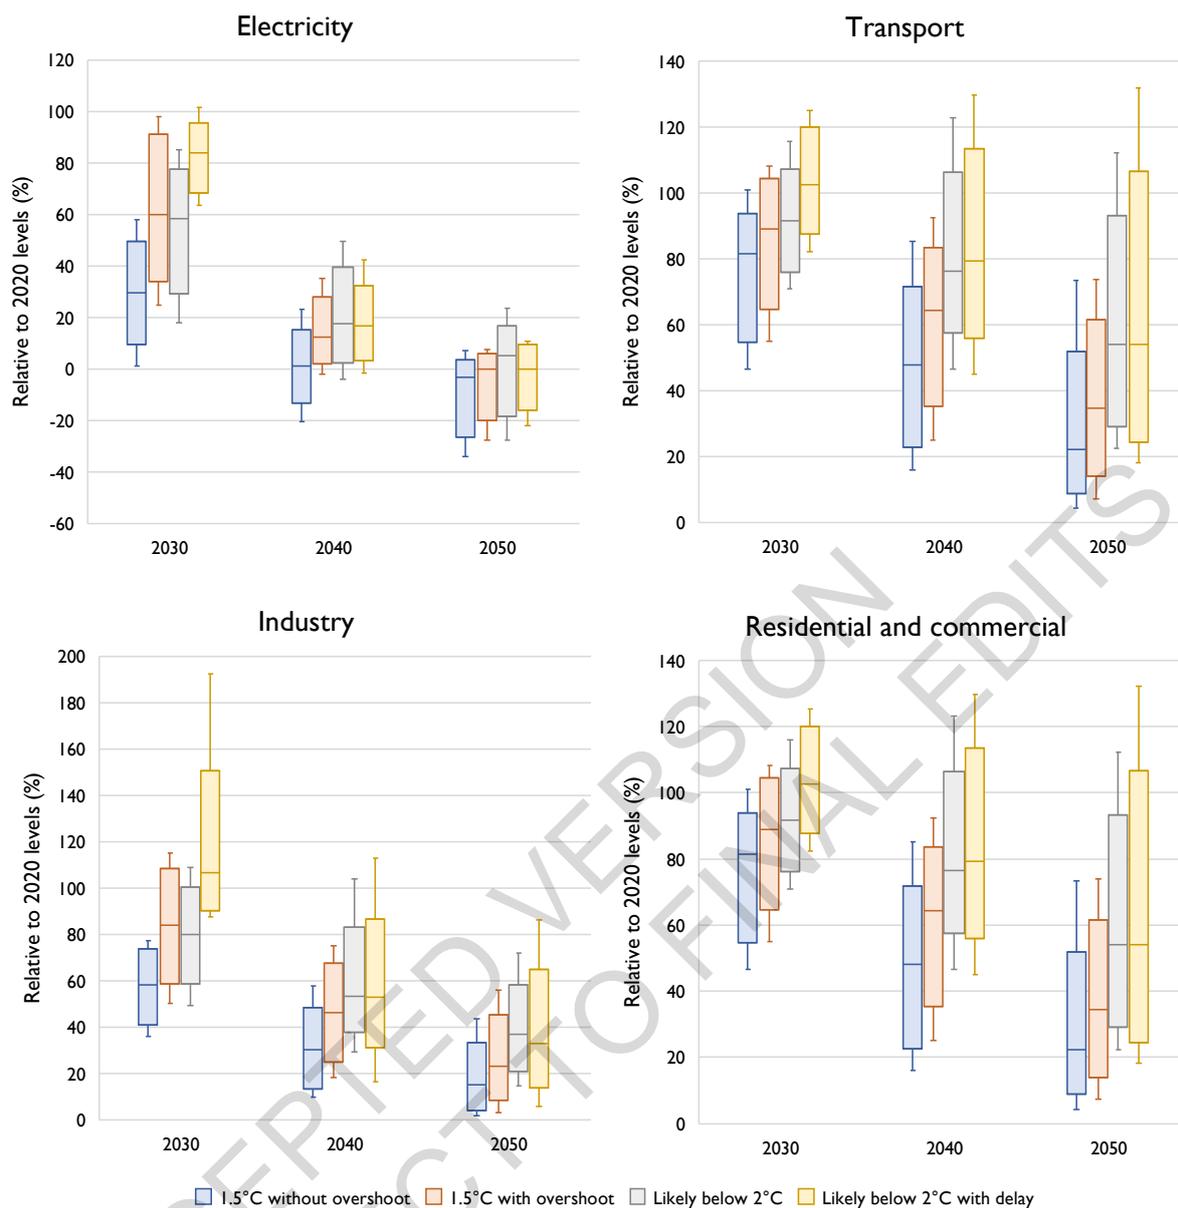

8

1 **Figure 6.28 The timing of net zero emissions for full economy GHGs, energy sector CO₂, and electricity**
2 **sector CO₂. Boxes indicate 25th and 75th percentiles, centre black line is the median, while whiskers**
3 **indicate 1.5x the inter-quartile range. The vertical dashed lines represent the median point at which**
4 **emissions in the scenarios have dropped by 95% (pink) and 97.5% (purple), respectively. Dots represent**
5 **individual scenarios. The fraction indicates the number of scenarios reaching net zero by 2100 out of the**
6 **total sample. (Source: AR6 Scenario Database)**

7 The timing of net zero energy system emissions varies substantially across scenarios. In scenarios
8 limiting warming to 1.5°C with no or limited overshoot (likely below 2°C), the energy system reaches
9 net zero CO₂ emissions (interquartile range) from 2060 onwards (2080-). (Figure 6.28). However, net
10 emissions reach near-zero more quickly. For example, in scenarios limiting warming to 1.5C with no
11 or limited overshoot (likely below 2C) net energy system CO₂ emissions drop by 95% between 2056
12 and 2075 (2073 and 2093). Net full economy GHG emissions reach zero more slowly than net CO₂
13 emissions. In some scenarios, net energy system CO₂ and total GHG emissions do not reach zero this
14 century, offset by CDR in other sectors.

15 The timing of emissions reductions will vary across the different parts of the energy sector (Figure
16 6.28). To decarbonize most cost-effectively, global net CO₂ emissions from electricity generation will
17 likely reach zero before the rest of the energy sector (*medium confidence*). In scenarios limiting
18 warming to 1.5C with no or limited overshoot (likely below 2C), net electricity sector CO₂ emissions
19 (interquartile range) reach zero globally between 2044 and 2055 (2052 and 2078) (Figure 6.28). It is
20 likely to be less-costly to reduce net CO₂ emissions close to or below zero in the electricity sector than
21 in other sectors, because there are relatively more low-emissions options in electricity. Sectors such as
22 long-distance transport, air transport, and process heat are anticipated to face greater challenges to
23 decarbonization than the electricity sector (Rogelj et al. 2018b, 2015b; Clark and Herzog 2014; IPCC
24 2018; Luderer et al. 2018).

25 In addition, there are potential options to remove CO₂ from the atmosphere in the electricity sector,
26 notably BECCS, which would allow electricity sector emissions to drop below zero. Without CDR
27 options, electricity sector emissions may not fall all the way to zero. If CDR is accomplished in other
28 sectors and not in electricity, some fossil fuel plants may still lead to positive net electricity sector CO₂
29 emissions even in net zero economies (Williams et al. 2021a; Bistline and Blanford 2021b)

We lack sufficient understanding to pin down precise dates at which energy system CO₂ emissions in individual countries, regions, or sectors will reach net zero. Net-zero timing is based on many factors that are not known today or are bound up in development of key technologies, such as energy storage, bioenergy, or hydrogen. Some countries have low-carbon resource bases that could support deep emissions reductions, while others do not. Timing is also affected by the availability of CDR options, whether these options are in the energy sector or elsewhere, and the discount rate used to assess strategies (Bednar et al. 2019; Emmerling et al. 2019). Moreover, while many scenarios are designed to minimize global mitigation costs, many other frameworks exist for allocating mitigation effort across countries (Chapter 4; van den Berg, N. J., et al., 2019).

1 **6.7.1.2 Low-carbon energy transition strategies**

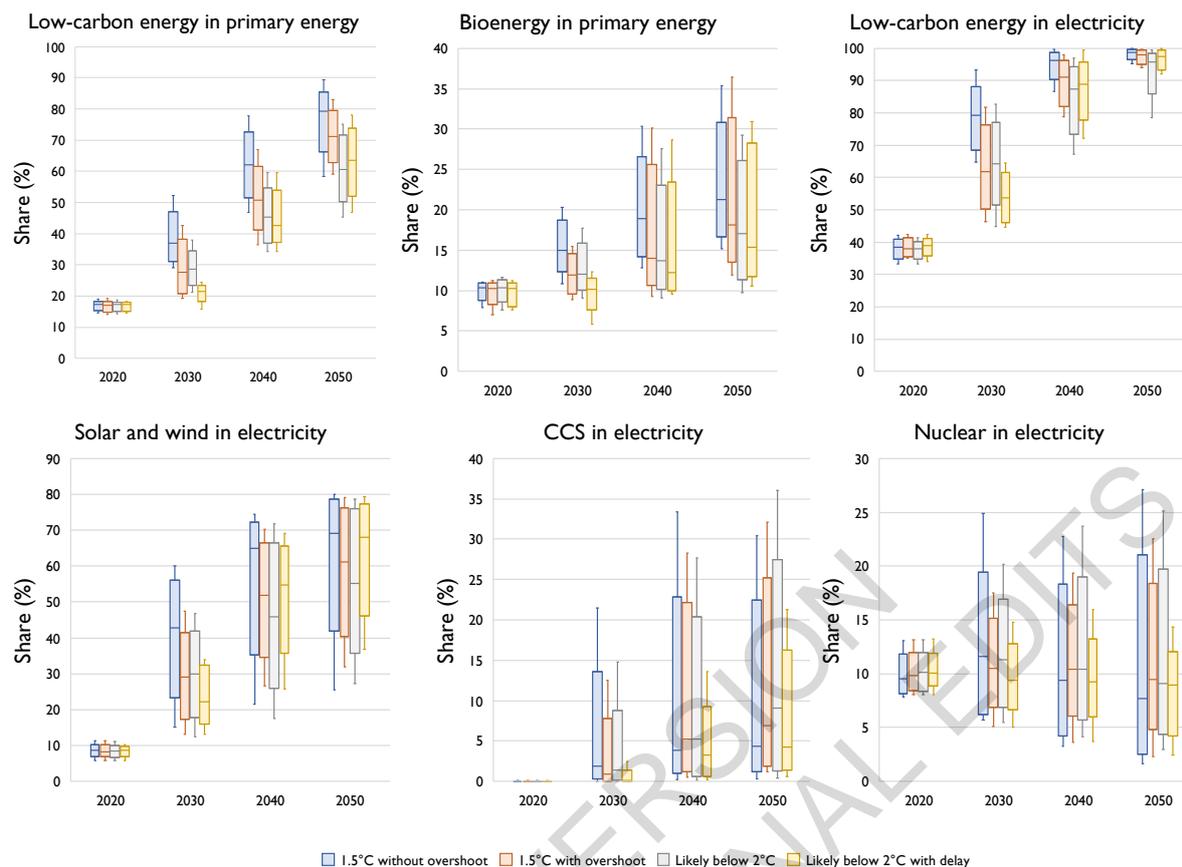

2 There are multiple technological routes to reduce energy system emissions (see Section 6.6). Here we
3 discuss three of these: (1) decarbonizing primary energy and electricity generation, (2) switching to
4 electricity, bioenergy, hydrogen, and other fuels produced from low-carbon sources, and (3) limiting
5 energy use through improvement of efficiency and conservation. CDR is discussed in Section 6.7.1.X;
6 Fossil fuel transitions are discussed in Section 6.7.4.

7 **Decarbonizing Primary Energy and Electricity Generation.** Limiting warming to well below 2°C
8 requires a rapid and dramatic increase in energy produced from low- or zero-carbon sources (*high*
9 *confidence*). Low- and zero-carbon technologies produce 74-82% (interquartile range) of primary
10 energy in 2050 in scenarios limiting warming to 1.5°C with no or limited overshoot and 55-68% in
11 likely below 2°C scenarios (Figure 6.29). The share of low-carbon technologies in global primary
12 energy supply today is below 20% (Section 6.3, Chapter 3, Figure 6.29). The percentage of low- and
13 zero-carbon energy will depend in part on the evolution of energy demand – the more that energy
14 demand grows, the more energy from low- and zero-carbon sources will be needed and the higher the
15 percentage of total primary energy these sources will represent.

16 Low- and zero-carbon sources produce 97-99% of global electricity in 2050 in scenarios limiting
17 warming to 1.5°C with no or limited overshoot and 93-97% in likely below 2°C scenarios (Figure 6.29)
18 (*medium confidence*). Decarbonizing electricity generation, in tandem with increasing use of electricity
19 (see below), is an essential near-term strategy for limiting warming. The increase in low- and zero-
20 carbon electricity will occur while electricity demand grows substantially. Studies have projected that
21 global electricity demand will roughly double by 2050 and quadruple to quintuple by 2100 irrespective
22 of efforts to reduce emissions (Bauer et al. 2017; Luderer et al. 2017; IEA 2019a).

23 Renewable energy, especially generation from solar and wind, is likely to have an important role in
24 many low-carbon electricity systems. The contributions of wind and solar electricity will depend on
25 their levelized costs relative to other options, integration costs, system value, and the ability to integrate
26 variable resources into the grid (Section 6.6). Electric sector technology mixes will vary by region but
27 will typically include additional resources such as hydropower, nuclear power, fossil generation with
28 CCS, energy storage resources, and geothermal energy, among others. Contributions of different
29 options vary widely across scenarios based on different assumptions about these factors (Figure 6.30).

30 Nonetheless, it is likely that wind and solar will dominate low-carbon generation and capacity growth
31 over the next couple decades due to supporting policies in many countries and due to their significant
32 roles in early electric sector decarbonization, alongside reductions in coal generation (Bistline and
33 Blanford 2021b; Pan et al. 2021). Clean firm technologies play important roles in providing flexibility
34 and on-demand generation for longer durations, though deployment of these technologies is typically
35 associated with deeper decarbonization levels (e.g., beyond 70-80% reductions), which are likely to be
36 more important after 2030 in many regions, and with more limited CDR deployment (Baik et al. 2021;
37 Williams et al. 2021a; Bistline and Blanford 2021a).

9 **Box 6.11 Illustrative Low-Carbon Energy System Transitions**

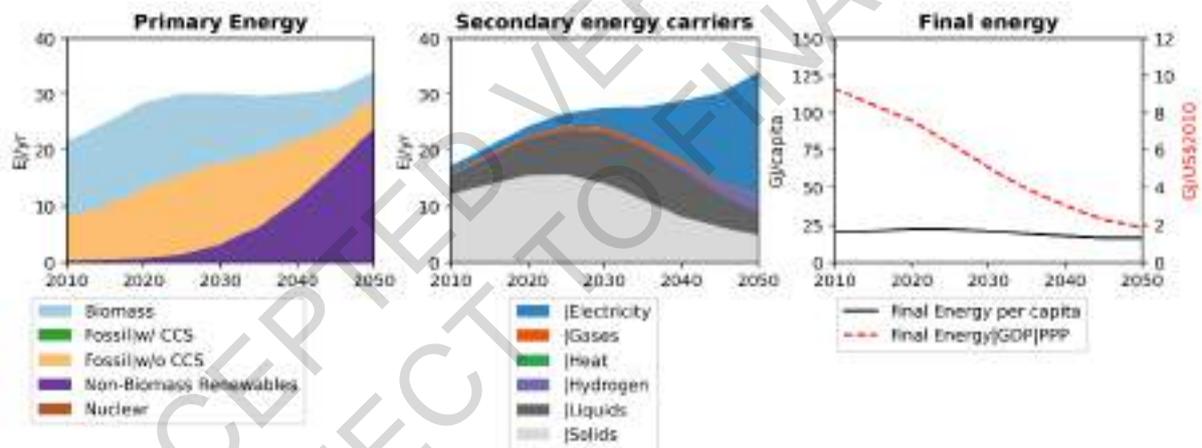

10 There are multiple possible strategies to transform the energy system to reach net zero CO₂ emissions
 11 and to limit likely warming to 2°C or below. All pathways rely on the strategies for net zero CO₂ energy
 12 systems highlighted in Section 6.6.2, but they vary in the emphasis that they put on different aspects of
 13 these strategies and the pace at which they approach net zero emissions. The pathway that any country
 14 or region might follow will depend on a wide variety of factors (Section 6.6.4), including, for example,
 15 resource endowments, trade and integration with other countries and regions, carbon sequestration
 16 potential, public acceptability of various technologies, climate, the nature of domestic industries, the
 17 degree of urbanization, and the relationship with other societal priorities such as energy access, energy
 18 security, air pollution, and economic competitiveness. The illustrative mitigation pathways presented
 19 in this box demonstrate four distinct strategies for energy system transformations and how each plays
 20 out for a different region, aligned with global strategies that would contribute to limiting warming to
 21 1.5°C. Each pathway represents a very different vision of a net zero energy system. Yet, all these
 22 pathways share the common characteristic of a dramatic system-wide transformation over the coming

1 decades.

3 **[END BOX 6.11 HERE]**

4

5 **Switching to Low-Carbon Energy Carriers.** Switching to energy carriers produced from low-carbon
6 sources will be an important strategy for energy sector decarbonization. Accelerated electrification of
7 end uses such as light duty transport, space heating, and cooking is a critical near-term mitigation
8 strategy (Waisman et al. 2019; Sugiyama 2012; Zou et al. 2015; Rockström et al. 2017; IEA 2019f;
9 Tang et al. 2021a). Electricity supplies 48-58% (interquartile range) of the global final energy demand
10 by 2050 in scenarios limiting warming to 1.5°C with no or limited overshoot and 36-47% in likely
11 below 2°C scenarios (Figure 6.29). Globally, the current level of electrification is about 20%.

12 Indirect electrification encompasses the use of electricity to produce hydrogen and synthetic fuels
13 (efuels or power fuels). The extent of indirect electrification of final energy will depend on resource
14 endowments and other regionally specific circumstances. Although indirect electrification is less
15 efficient compared to direct electrification, it allows low-carbon fuels to be imported from regions with
16 abundant low carbon electricity generation resources (Fasihi and Breyer 2020; Fasihi and Bogdanov
17 2016; Lehtveer et al. 2019, Box 6.10 on regional integration).

18 While electrifying end uses is a key decarbonization strategy, some end uses such as long-distance
19 transport (freight, aviation, and shipping) and energy-intensive industries will be harder to electrify. For
20 these sectors, alternative fuels or energy carriers such as biofuels, hydrogen, ammonia or synthetic
21 methane, may be needed (see Section 6.6 and Box 6.9). Most scenarios find that hydrogen consumption
22 will grow gradually, becoming more valuable when the energy system has become predominantly low-
23 carbon (Figure 6.31).

24

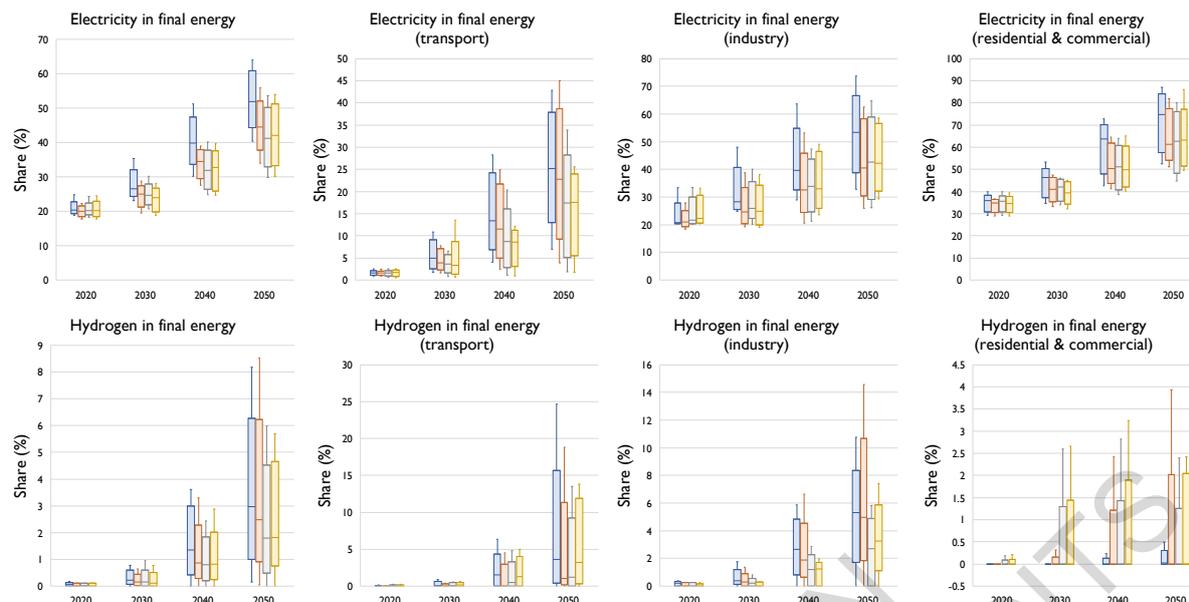

Figure 6.31 Shares of electricity and hydrogen in final energy for scenarios limiting warming to 1.5°C scenarios (without and with overshoot) and scenarios limiting likely warming to below 2°C (without and with delayed policy action) during 2020-2050 (Source: AR6 Scenario Database). Boxes indicate 25th and 75th percentiles while whiskers indicate 5th and 95th percentiles.

Reducing Energy Demand. Energy service demand is expected to continue to increase with growth of the economy, but there is great uncertainty about how much it will increase (Riahi et al. 2017; Bauer et al. 2017; Yu et al. 2018). Given the need to produce low-carbon energy, the scale of energy demand is a critical determinant of the mitigation challenge (Riahi et al. 2012). Higher energy demand calls for more low-carbon energy and increases the challenge; lower energy demand reduces the need for low-carbon sources and therefore can ease a low-carbon transition. Recent studies have shown that tempering the growth of energy demand, while ensuring services and needs are still satisfied, can materially affect the need for technological CDR (see below) (Grubler et al. 2018; van Vuuren et al. 2018). Two of the Illustrative Mitigation Pathways (IMP-SP, IMP-LD) feature substantially lower final energy demand across buildings, transport, and industry than most other pathways in the literature. In some cases, energy demand levels are lower in 2050 (and later) than in 2019. These lower demands result in less reliance on bioenergy and a more limited role for CDR. [Ch. 3, Figure 3.18]

6.7.1.3 Technology options to offset residual emissions

CDR technologies can offset emissions from sectors that are difficult to decarbonize (Section 6.6), altering the timeline and character of energy sector transitions. A number of studies suggest that CDR is no longer a choice but rather a necessity to limit warming to 1.5°C (Luderer et al. 2018; Rogelj et al. 2015a; van Vuuren et al. 2018; Detz et al. 2018; Strefler et al. 2018). The reliance on CDR varies across scenarios and is tightly linked future energy demand and the rate of emission reductions in the next two decades: deeper near-term emissions reductions will reduce the need to rely on CDR to constrain cumulative CO₂ emissions. Some studies have argued that only with a transition to lower energy demands will it be possible to largely eliminate the need for engineered CDR options (Grubler et al. 2018; van Vuuren et al. 2018). Overall, the amount of CDR will depend on CO₂ capture costs, lifestyle changes, reduction in non-CO₂ GHGs, and utilization of zero-emission end-use fuels (van Vuuren et al. 2018)(Muratori et al, 2017; van Vuuren et al, 2018).

There is substantial uncertainty about the amount of CDR that might ultimately be deployed. In most scenarios that limit warming to 1.5°C, CDR deployment is fairly limited through 2030 at less than 1 Gt-CO₂ yr⁻¹. The key projected increase in CDR deployment (BECCS and DAC only) occurs between

1 2030 and 2050 with annual CDR in 2050 projected at 2.5-7.5 Gt-CO₂ yr⁻¹ in 2050 (interquartile range)
2 in scenarios limiting warming to 1.5°C with limited or no overshoot and 0.7-1.4 Gt-CO₂ yr⁻¹ in 2050 in
3 scenarios limiting warming to 2°C with limited or no overshoot. This characteristic of scenarios largely
4 reflects substantial capacity addition of BECCS power plants. BECCS is also deployed in multiple ways
5 across sectors. For instance, the contribution (interquartile range) of BECCS to electricity is 1-5% in
6 2050 in scenarios limiting warming to 1.5°C with limited or no overshoot and 0-5% in scenarios limiting
7 likely warming to below 2°C. The contribution (interquartile range) of BECCS to liquid fuels is 9-21%
8 in 2050 in scenarios limiting warming to 1.5°C with limited or no overshoot and 2-11% in scenarios
9 limiting likely warming to below 2°C. Large-scale deployment of CDR allows flexibility in timing of
10 emissions reduction in hard-to-decarbonize sectors.

11 CDR will influence the potential fossil-related stranded assets (Box 6.13). Availability of low-cost CDR
12 can help reduce premature retirement for some fossil fuel infrastructure. CDR can allow countries to
13 reach net zero emissions without phasing out all fossil fuels. Specific infrastructure could also be
14 extended if it is used to burn biomass or other non-emitting sources. For example, existing coal-fired
15 power plants, particularly those with CCS, could be co-fired with biomass (Pradhan et al, 2021; Woolf
16 et al, 2016; Lu et al, 2019). In many scenarios, energy sector CDR is deployed to such an extent that
17 energy sector CO₂ emissions become negative in the second half of the century (Chapter 3).

18 [START BOX 6.12 HERE]

19 **Box 6.12 Taking Stock of the Energy System Transition**

20 The Global Stocktake is a regularly occurring process under the UNFCCC in which efforts will be made
21 to understand progress on, among other things, global mitigation. Collective progress of countries
22 towards the Paris Agreement goal will be assessed and its outcome will inform Parties in updating and
23 enhancing their NDCs. This box explores potential indicators to understand energy system mitigation
24 progress.

25 CO₂ emissions from fuel combustion are the bottom line on energy system progress. Beyond CO₂
26 emissions, primary energy demand by energy sources, final energy consumption by sectors, and total
27 electricity demand provide a first order assessment of energy system transitions. The year at which CO₂
28 emissions peak is also important. The Kaya Identity can be used to decompose energy system CO₂
29 emissions into carbon intensity of the energy system (CO₂ emissions from fossil-fuel combustion and
30 industry divided by energy use), energy intensity (energy use divided by economic output), and
31 economic output. The impacts of energy and climate policy are reflected in the changes of carbon
32 intensity and energy intensity. Carbon intensity captures decarbonization of energy supply systems, for
33 example through fuel switching from fossil fuels to non-fossil fuels, upscaling of low carbon energy
34 sources, and deploying carbon dioxide removal technologies. The carbon intensity of electricity is
35 specifically important, given the role of the electricity sector in near-term mitigation. Economy wide
36 energy intensity represents efforts of demand-side energy, such as energy conservation, increase of
37 energy performance of technologies, structural change of economy, and development of efficient urban
38 infrastructure.

39 Beyond these aggregate indicators, a second order assessment would capture more details, such as the
40 electrification rate, share of renewables, nuclear, CCS or other low carbon technologies in electricity
41 generation, land area used for energy production, and numbers of EV or PHEV. Consumption of coal,
42 oil and gas captures the underlying factors of CO₂ emissions. The emphasis of these indicators could
43 differ across countries in the context of national specific circumstances. Technology- or project-based
44 statistics are also useful to check the progress of the low-carbon transition, for example, the number of
45 CCS facilities.

1 A critical challenge in the assessment of energy sector progress is how to measure societal, institutional,
2 and political progress. These factors are difficult to quantify, yet they are fundamental determinants of
3 the ability to reduce emissions. Public opinion, special interest politics, implications of mitigation for
4 employment, energy subsidies, and energy policies are all critical indicators of progress. In addition,
5 while much of the literature focuses on national level action, mitigation is increasingly being led by
6 cities, states, provinces, businesses, and other subnational or non-national actors. Understanding the
7 progress of these actors will be critical to assess energy system mitigation progress. New research is
8 needed to better assess these “societal” indicators and the role of non-national actors.

9 **[END BOX 6.12 HERE]**

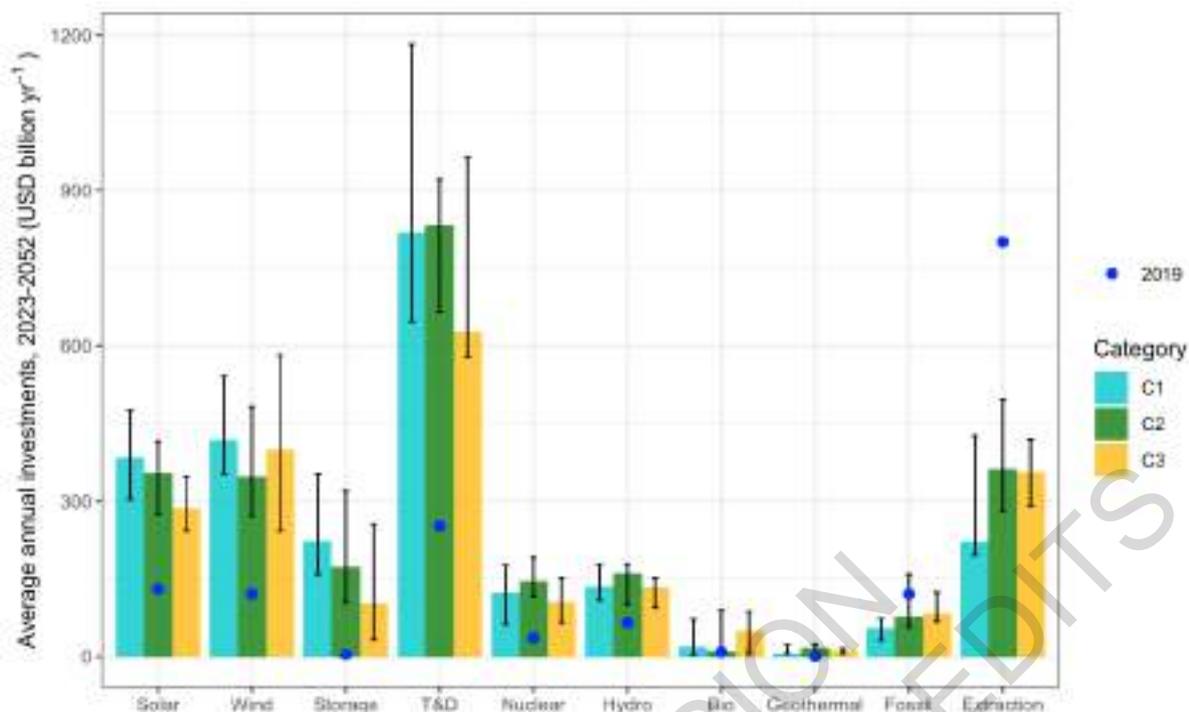

10 **6.7.2. Investments in Technology and Infrastructure**

11 Total global energy investment was roughly USD 1940 billion yr⁻¹ in 2019 (IEA 2021f). This total can
12 be broken down into the following main categories: fossil-related energy supply, including oil, gas, and
13 coal extraction and fossil electricity generation (USD 990 billion yr⁻¹); renewable electricity, primarily
14 solar and wind (USD 340 billion yr⁻¹); nuclear energy (USD 40 billion yr⁻¹); electricity networks (USD
15 270 billion yr⁻¹); and end-use energy efficiency (USD 270 billion yr⁻¹).

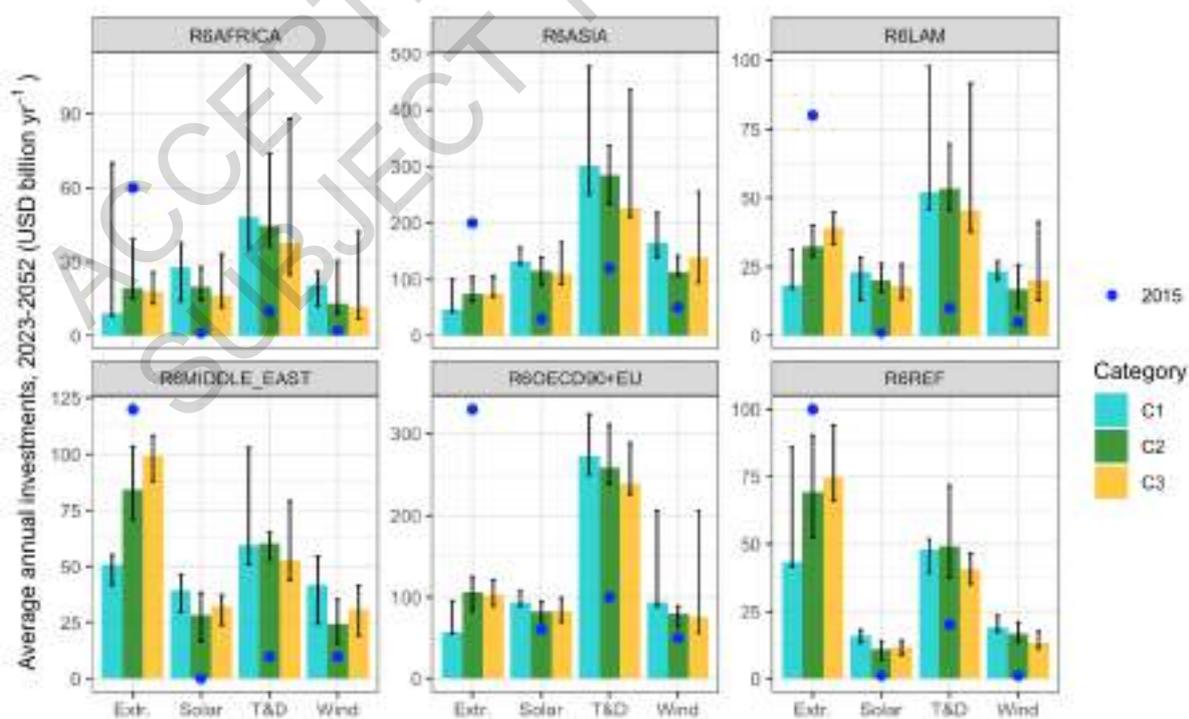

16 Energy investment needs are projected to rise going forward, according to investment-focused scenario
17 studies found in the literature (Bertram et al. 2021; McCollum et al. 2018a; Zhou et al. 2019). While
18 these increases are projected to occur in emissions-intensive pathways as well as low-carbon pathways,
19 they are projected to be largest in low-carbon pathways. Average annual global energy investments over
20 the 2016-2050 period range (across six models) from USD 2100 to 4100 billion yr⁻¹ in pathways likely
21 limiting warming to 2°C and from USD 2400 to 4700 billion yr⁻¹ in pathways limiting warming to 1.5°C
22 with no or limited overshoot (McCollum et al., 2018). Whatever the scenario, a significant and growing
23 share of investments between now and 2050 will be channelled toward infrastructure build-out in
24 emerging economies, particularly in Asia (Zhou et al. 2019).

25 More widespread electrification of buildings, transport, and industry means particularly substantial
26 investment in the electricity system. According to C1-C3 pathways in the AR6 scenario database, such
27 investments could be at the following average annual levels (inter-quartile range, USD₂₀₁₅) over the
28 2023-2052 timeframe: USD 1670 to 3070 billion yr⁻¹ (C1), 1600 to 2780 billion yr⁻¹ (C2), and 1330-
29 2680 billion yr⁻¹ (C3). (See also 3.6.1.3)

30 Beyond these sector-wide numbers, a key feature of stringent mitigation pathways is a pronounced
31 reallocation of investment flows across sub-sectors, namely from unabated fossil fuels (extraction,
32 conversion, and electricity generation) and toward renewables, nuclear power, CCS, electricity
33 networks and storage, and end-use energy efficiency (McCollum et al. 2018a; Bertram et al. 2021; IEA
34 2021f) (Figure 6.32). Investments in solar, wind, and electricity transmission, distribution, and storage
35 increase the most in mitigation scenarios. Up to 2050, the bulk of these investments are made in OECD
36 and Asian countries (Figure 6.33). While fossil fuel extraction investments exhibit a marked
37 downscaling across all regions, compared to reference scenarios, the declines are especially strong in
38 the Middle East, REF, and OECD.

1
 2 **Figure 6.32** Global average annual investments from 2023 to 2052 (undiscounted, in USD billion yr⁻¹) for
 3 electricity supply sub-sectors and for extraction of fossil fuels in C1-C3 pathways (Source: AR6 Scenario
 4 Database and Chapter 3). Historical investments are also shown for comparison (Source: IEA, 2021;
 5 approximations are made for hydro and geothermal based on available data; solar and wind values are
 6 for 2020). ‘T&D’: transmission and distribution of electricity. Bars show median values across models-
 7 scenarios, and whiskers the inter-quartile ranges. See Chapters 3 and 15 for additional information on
 8 investments and finance.

10

1 **Figure 6.33 Regional average annual investments from 2023 to 2052 (undiscounted, in USD billion yr⁻¹)**
2 **for four of the largest sub-sectors of the energy system in C1-C3 pathways (Source: AR6 Scenario**
3 **Database and Chapter 3). Historical investments are also shown for comparison (Source: IEA, 2016).**
4 **‘T&D’: transmission and distribution of electricity. ‘Extr.’: extraction of fossil fuels. Bars show median**
5 **values across models-scenarios, and whiskers the inter-quartile ranges. See Chapters 3 and 15 for**
6 **additional information on investments and finance.**

7 Investments into end-use energy efficiency are projected to also be substantial in mitigation pathways,
8 potentially upwards of several hundred USD billion yr⁻¹ on average to 2050, compared to USD 270
9 billion yr⁻¹ in 2019 (McCollum et al. 2018a; IEA 2021f). However, the literature is inconsistent in how
10 demand-side investments are calculated, as boundary conditions are less clear than for energy supply
11 investments. Taking a broader definition can result in estimates that are an order-of-magnitude higher,
12 meaning as large or larger than supply-side investments (IEA 2021f; Grubler et al. 2012).

13 Increasing low-carbon investment primarily requires shifting existing capital investment through
14 regulation and incentives as well as removing existing investment barriers (McCollum et al.
15 2018a)(Ameli, N. et al., 2021; Hafner et al. 2020; McCollum et al. 2018). While there is a considerable
16 amount of capital in the world, it is not always available to those wishing to invest in certain projects.
17 Total annual global investment in fixed capital was USD 22.4 trillion in 2021, over an order-of-
18 magnitude larger than energy sector investment (World Bank, 2021).

19 Future investment patterns will vary by region, as they do now, due to differences in risk profiles,
20 resource endowments and economic and governance structures (Zhou et al. 2019)(6.6; Ameli, N. et al.,
21 2021; Fizaine et al. 2016; Zhou et al., 2019). In rapidly growing countries, investments to support a
22 low-carbon energy system transition will be integrated with those needed to meet rapidly increasing
23 energy demands, irrespective of whether efforts are made to reduce emissions. In less-rapidly-growing
24 countries (Sun et al. 2019), investments will focus on transitioning current energy systems to low-
25 carbon configurations. Most current energy investments are concentrated in high- and upper-middle
26 income countries (IEA 2021f), but this will change as investment needs continue to grow in today’s
27 lower-middle and low-income countries (Bertram et al. 2021; McCollum et al. 2018a; Zhou et al. 2019;
28 IEA 2021f).

29 **6.7.3 Energy System Lock-In and Path Dependence**

30 Path dependence refers to resistance to change due to favourable socio-economic conditions with
31 existing systems; decisions made in the past unduly shape future trajectories. Carbon lock-in is a
32 specific type of path dependence (Seto et al. 2016). Given that energy system mitigation will require a
33 major course change from recent history, lock-in is an important issue for emission reductions in the
34 energy sector. While lock-in is typically expressed in terms of physical infrastructure that would need
35 to be retired early to reach mitigation goals, it involves a much broader set of issues that go beyond
36 physical systems and into societal and institutional systems (Table 6.11).

37

2 **6.7.3.1 Societal and Institutional Inertia**

3 A combination of factors - user, business, cultural, regulatory, and transnational - will hinder low-
4 carbon energy transitions. Strong path dependencies, even in early formative stages, can have lasting
5 impacts on energy systems, producing inertia that cuts across technological, economic, institutional and
6 political dimensions (*high confidence*) (Vadén et al. 2019; Rickards et al. 2014) Chapter 5).

7 Energy systems exemplify the ways in which massive volumes of labor, capital, and effort become sunk
8 into particular institutional configurations (Bridge et al. 2013, 2018). Several embedded factors affect
9 large-scale transformation of these systems and make technological diffusion a complex process:

- 10 • **User environments** affect purchase activities and can involve the integration of new technologies
11 into user practices and the development of new preferences, routines, habits and even values
12 (Kanger et al. 2019).
- 13 • **Business environments** can shape the development of industries, business models, supply and
14 distribution chains, instrument constituencies and repair facilities (Béland and Howlett 2016).
- 15 • **Culture** can encompass the articulation of positive discourses, narratives, and visions that enhance
16 cultural legitimacy and societal acceptance of new technologies. Regulatory embedding can capture
17 the variety of policies that shape production, markets and use of new technologies.
- 18 • **Transnational community** can reflect a shared understanding in a community of global experts
19 related to new technologies that transcends the borders of a single place, often a country.

20 While low-carbon innovation involves systemic change (Geels et al. 2018), these are typically less
21 popular than energy supply innovations among policymakers and the wider public. Managing low
22 carbon transitions is therefore not only a techno-managerial challenge (based on targets, policies, and
23 expert knowledge), but also a broader political project that involves the building of support coalitions
24 that include businesses and civil society (moderate evidence, high agreement).

25 Low-carbon transitions involve cultural changes extending beyond purely technical developments to
26 include changes in consumer practices, business models, and organizational arrangements. The
27 development and adoption of low-carbon innovations will therefore require sustained and effective
28 policies to create appropriate incentives and support. The implementation of such policies entails

1 political struggles because actors have different understandings and interests, giving rise to
2 disagreements and conflicts.

3 Such innovation also involves pervasive uncertainty around technical potential, cost, consumer demand,
4 and social acceptance. Such uncertainty carries governance challenges. Policy approaches facing deep
5 uncertainty must protect against and/or prepare for unforeseeable developments, whether it is through
6 resistance (planning for the worst possible case or future situation), resilience (making sure you can
7 recover quickly), or adaptation (changes to policy under changing conditions). Such uncertainty can be
8 hedged in part by learning by firms, consumers, and policymakers. Social interactions and network
9 building (e.g., supply and distribution chains, intermediary actors) and the articulation of positive
10 visions, such as in long-term, low-emission development strategies, all play a crucial role. This
11 uncertainty extends to the impacts of low carbon innovations on energy demand and other variables,
12 where unanticipated and unintended outcomes are the norm. For instance, rapid investments in public
13 transport networks could restrict car ownership from becoming common in developing countries (Du
14 and Lin 2017).

15 **6.7.3.2 Physical Energy System Lock-In**

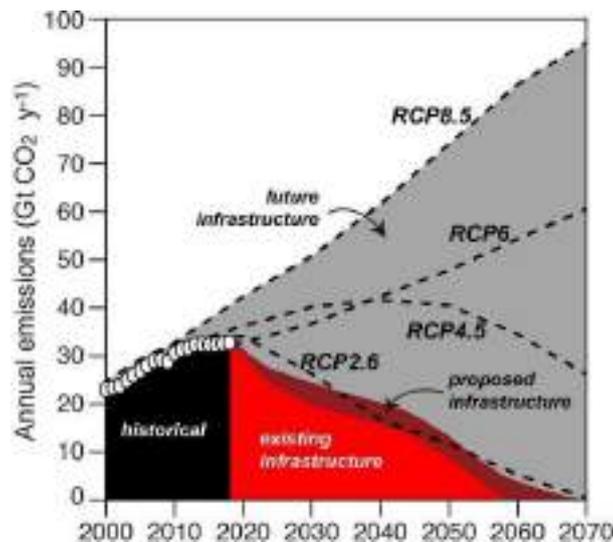

16 Current investments in fossil infrastructure have committed 500-700 Gt-CO₂ of emissions, creating
17 significant risks for limiting warming to 1.5°C (Callaghan 2020) (*high confidence*). These current
18 investments combined with emissions from proposed fossil infrastructure exceed the emissions required
19 to limit warming to 1.5°C (*medium confidence*). Existing coal and gas fired electricity generation
20 accounts for 200-300 Gt-CO₂ of committed emissions. Emissions from coal generation are larger than
21 for gas plants (Tong et al. 2019; Smith et al. 2019). The lifetime of coal-fired power plants is 25-50
22 years, creating long lasting risks to climate goals (Erickson and Tempest 2015). Gas-fired power plants
23 are generally younger than coal-fired power plants. Industry sector lock-in amounts for more than 100
24 Gt-CO₂, while buildings and transport sector together contribute another 50-100 Gt-CO₂ (Erickson and
25 Tempest 2015).

26 Lock-in is also relevant to fossil resources. Both coal and gas exploration continue, and new permits
27 are being issued, which may cause economic (Erickson et al. 2018) as well as non-economic issues
28 (Boettcher et al. 2019).

29 The nature of lock in varies across the energy system. For example, lock-in in urban and transport
30 sectors is different from the electricity sector. Broadly, urban environments involve infrastructural,
31 institutional, and behavioural lock-in (Ürge-Vorsatz et al. 2018). Addressing lock-in in these sectors
32 requires action by multiple stakeholders and is unlikely with just technological evolution (Table 6.11).

33 Committed carbon emissions are unevenly distributed. The disproportionate high share of committed
34 emissions in emerging economies is the result of rapid growth in recent years, which has led to a
35 comparably young fossil infrastructure with substantial remaining life (Shearer et al. 2017). Mature
36 industrialized countries tend to have older infrastructures, part of which will be up for retirement in the
37 near future (Tong et al. 2019). Coal-fired power plants currently planned or under construction are
38 associated with 150-300 Gt-CO₂, of which ~75% and ~10% are located in Asia and the OECD
39 respectively (Pfeiffer et al. 2018; Edenhofer et al. 2018). If implemented, these new fleets will further
40 shorten all coal plants' lifetimes by another 10 years for meeting climate goals (Cui et al. 2019)

41

1
2 **Figure 6.34 Annual emissions from existing, proposed, and future energy system infrastructure (Tong**
3 **et al. 2019).**

4 Despite the imperative to reduce use of fossil fuels and the multiple health and other benefits from
5 closing coal-based infrastructure (Liu et al. 2019a; Portugal-Pereira et al. 2018; Rauner et al. 2020;
6 Karlsson et al. 2020; Cui et al. 2021), coal power plants have continued to be commissioned globally
7 (Jewell et al. 2019; Jakob et al. 2020), most notably in Asian countries. Gas power plants also continue
8 to be built. In many regions, new fossil electricity generation exceeds needed capacity (Shearer et al.
9 2017).

10 Existing policies and the NDCs are insufficient to prevent an increase in fossil infrastructure and
11 associated carbon lock in (*high confidence*) (Bertram et al. 2015; Johnson et al. 2015). Current
12 investment decisions are critical because there is limited room within the carbon budget required to
13 limit warming to well below 2°C (Rosenbloom 2019; Kalkuhl et al. 2019). Delays in mitigation will
14 increase carbon lock-in and could result in large-scale stranded assets if stringency is subsequently
15 increased to limit warming (Box 6.11). Near-term implementation of stringent GHG mitigation policies
16 are likely to be most effective in reducing carbon lock-in (Haelg et al. 2018). Near-term mitigation
17 policies will also need to consider different energy transition strategies as a result of different resources
18 and carbon budgets between countries (Bos and Gupta 2018; Lucas 2016).

19 Near-term policy choices are particularly consequential for fast-growing economies. For example,
20 Malik et al. (2020) found that 133 to 227 GW of coal capacity would be stranded after 2030 if India
21 were to delay ambitious mitigation through 2030 and then pursue an ambitious, post-2030 climate
22 strategy. (Cui et al. 2021) identified 18% of old, small, inefficient coal plants for rapid near-term
23 retirement in China to help achieve air quality, health, water, and other societal goals and a feasible coal
24 phaseout under climate goals. Comparable magnitudes of stranded assets may also be created in Latin
25 America when adding all announced, authorized, and procured power plants up to 2060 (González-
26 Mahecha et al. 2019). Options to reduce carbon lock in include reducing fossil fuels subsidies (Box
27 6.3), building CCS-ready facilities, or ensuring that facilities are appropriately designed for fuel
28 switching (Budinis et al. 2018). Substantial lock-in may necessitate considerable deployment of CDR
29 to compensate for high cumulative emissions.

30 Past and present energy sector investments have created technological, institutional, and behavioural
31 path dependencies aligned towards coal, oil, and natural gas (*high confidence*). In several emerging
32 economies, large projects are planned that address poverty reduction and economic development. Coal
33 infrastructure may be the default choice for these investments without policies to invest in low-carbon
34 infrastructure instead (Steckel et al. 2020; Joshua and Alola 2020). Path dependencies frequently have

1 sustainability implications beyond carbon emissions. (Box 6.2 and Section 6.7.7). There are several
2 SDG co-benefits associated with decarbonization of energy systems (Section 6.7.7; Sörgel et al. 2021).
3 For example, coal mining communities frequently experience significant health and economic burdens
4 from resource extraction.

5 **[START BOX 6.13 HERE]**

6 **Box 6.13 Stranded Assets**

7 Limiting likely warming to 2°C or below will result in stranded assets (*high confidence*). Stranded assets
8 can be broadly defined as assets which “suffer from unanticipated or premature write-offs, downward
9 revaluations or [conversion] to liabilities.” Stranded assets may create risks for financial market stability
10 and macro-economic stability (Mercure et al. 2018, Battiston et al. 2017; Sen and von Schickfus 2020),
11 and they will result in a rapid loss of wealth for the owners of affected assets (Vogt-Schilb and
12 Hallegatte 2017; Ploeg and Rezai 2020).

13 There are two types of stranded assets: fossil-fuel resources that cannot be burned, and premature
14 retirement of fossil infrastructure (e.g., power plants). About 30% of oil, 50% of gas, and 80% of coal
15 reserves will remain unburnable if likely warming is limited to 2°C (Meinshausen et al. 2009; Leaton
16 2011; Leaton Ranger 2013; Pye et al. 2020; IRENA 2017b; Bauer et al. 2016; McGlade and Ekins 2015)
17 (*high confidence*). Significantly more reserves are expected to remain unburned if warming is limited
18 to 1.5°C. Countries with large oil, gas, and coal reserves are most at risk (Caldecott et al. 2017; Ansari
19 and Holz 2020)

20 About 200 GW of fossil fuel electricity generation per year will likely need to be retired prematurely
21 after 2030 to limit likely warming to 2°C, even if countries achieve their NDCs (Iyer et al. 2015;
22 Johnson et al. 2015; Fofrich et al. 2020) (*medium confidence*). Limiting warming to 1.5°C will require
23 significantly more rapid premature retirement of electricity generation capacity (Binsted et al. 2020).
24 Coal- and gas-fired power plants will likely need to retire about 25 years earlier than in the past to limit
25 likely warming to 2°C, and 30 years earlier to limit warming to 1.5°C (Cui et al. 2019; Fofrich et al.
26 2020). Coal-fired power plants are at significantly greater risk of stranding compared with gas-fired and
27 oil-fired plants (Iyer et al. 2015; Johnson et al. 2015; Fofrich et al. 2020). The risks of stranded power
28 plants are greatest in countries with newer fossil infrastructure.

29 If likely warming is limited to 2°C, the discounted economic impacts of stranded assets, including
30 unburned fossil reserves, could be as high as USD 1-4 trillion from 2015 through 2050 (USD 10-20
31 trillion in undiscounted terms) (Mercure et al. 2018), IRENA, 2017) (*medium confidence*). About 40%
32 of these impacts correspond to unburned fossil reserves (IRENA 2017b). If warming is limited to 1.5°C,
33 the economic impacts of stranded assets are expected to be significantly higher (Binsted et al. 2020)

34 Stronger near-term mitigation will reduce premature retirements of fossil infrastructure, because more
35 rapid mitigation will decrease new builds of fossil infrastructure that might later be stranded (Johnson
36 et al. 2015; Bertram et al. 2018) (*high confidence*). For example, if likely warming is limited to 2°C,
37 strengthening the NDC pledges beyond their 2015 levels could decrease stranded electricity sector
38 assets by more than 50% (Iyer et al. 2015). By contrast, if countries fail to meet their NDCs and continue
39 to build fossil infrastructure, mitigation will need to be accelerated beyond 2030, resulting up to double
40 the amount of stranded electricity generation capacity (Iyer et al. 2015). This corresponds to a total
41 undiscounted cost of about USD 2 trillion from electricity infrastructure alone, from the period 2015
42 to 2050 (IRENA 2017). CCS (6.4) could potentially help reduce hundreds of gigawatts stranded power
43 plant capacity along with other fossil-based capital (Clark and Herzog 2014; Fan et al. 2018; Iyer et al.
44 2017).

45 **[END BOX 6.13 HERE]**

1 **6.7.4 Fossil fuels in a low-carbon transition**

2 Global fossil fuel use will need to decline substantially by 2050 to limit likely warming to 2°C or below,
3 and it must decline substantially by 2030 to limit warming to 1.5°C with no or limited overshoot (*high*
4 *confidence*). Failing to reduce global fossil fuel use below today's levels by 2030 will make it more
5 challenging to limit likely warming to below 2°C. (*high confidence*). Fossil fuel use declines by 260-
6 330 EJ (52-73% from 2020 levels, interquartile range) through 2050 to limit warming to 1.5°C with no
7 or limited overshoot and 124-231 EJ (23-51% reduction compared to 2020 levels) to limit likely
8 warming to 2°C; this will require a significant reduction in coal, oil and gas investments. Fossil fuels
9 account for about 80% of primary energy today. In scenarios limiting warming to 1.5°C with limited or
10 no overshoot, fossil energy provides 59-69% (interquartile range) primary energy in 2030 and 25-40%
11 primary energy in 2050 (AR6 database). In scenarios limiting likely warming to 2°C or below, fossil
12 energy provides 71-75% (interquartile range) primary energy in 2030 and 41-57% primary energy in
13 2050 (AR6 database). The timeline for reducing production and usage varies across coal, oil, and gas
14 due to their differing carbon intensities and their differing uses.

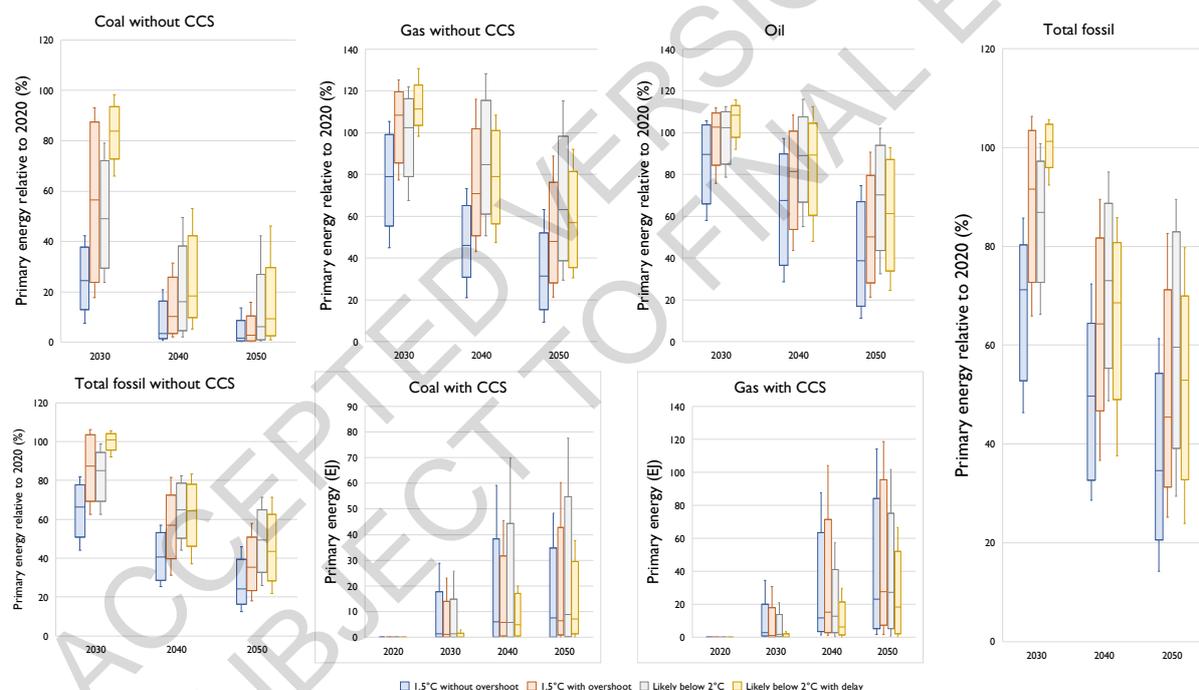

15 Global coal consumption without CCS needs to be largely eliminated by 2040-2050 to limit warming
16 to 1.5°C, and 2050-2060 to limit likely warming to 2°C (*high confidence*). New investments in coal-
17 fired electricity without CCS are inconsistent with limiting likely warming to 2°C or below (*high*
18 *confidence*) (Spencer et al. 2018; Pfeiffer et al. 2018; Edenhofer et al. 2018; Cui et al. 2019). Coal
19 consumption declines 130 EJ yr⁻¹ to 140 EJ yr⁻¹ in 2050 (79% to 99% compared to 2020 levels,
20 interquartile range) in scenarios limiting warming to 1.5°C and 118 EJ yr⁻¹ to 139 EJ yr⁻¹ (66% to 98%
21 compared to 2020 levels) in scenarios limiting likely warming to 2°C. Coal consumption without CCS
22 falls by 67% to 82% (interquartile range) in 2030 in scenarios limiting warming to 1.5°C with no or
23 limited overshoot. Studies indicate that coal use may decline substantially in the US and Europe over
24 the coming decade based on the increasing competitiveness of low-carbon sources and near-term policy
25 actions (Oei et al. 2020; Grubert and Brandt 2019). In several developing economies, the relative youth
26 of the coal-fired electricity fleet will make a complete phaseout before 2050 difficult (Garg and Shukla
27 2009; Jewell et al. 2016). There are considerable differences in projected coal phaseout timelines in
28 major Asian economies. Some studies suggest that coal may continue to be a part of the Chinese energy
29 mix composing around a third of the total primary energy consumption by 2050 even if emissions are
30 reduced by 50% by 2030 (He et al. 2020). Others indicate that a strategic transition would decrease the
31 risk of stranded assets and enable a near-complete phaseout by 2050 (Wang et al. 2020a; Cui et al.
32 2021). This would entail prioritizing earlier retirements of plants based on technical (efficiency),
33 economic (profitability, local employment) and environmental considerations (e.g., water scarcity for
34 cooling).

35 Natural gas may remain part of energy systems through mid-century, both for electricity generation and
36 use in industry and buildings, and particularly in developed economies, even if likely warming is limited
37 to 2°C or less (*medium confidence*). The decline in natural gas use in from 2020 to 2050 is 38 EJ yr⁻¹ to
38 78 EJ yr⁻¹ (21% to 61% decline from 2020 levels, interquartile range) in scenarios limiting warming to
39 1.5°C with no or limited overshoot and -22 EJ yr⁻¹ to 46 EJ yr⁻¹ (-13% to 36% decline from 2020 levels)
40 in scenarios limiting likely warming to 2°C. Scenarios indicate that gas use in electricity will likely
41 peak around 2035 and 2050 if warming is limited to 1.5°C with limited or no overshoot or likely below
42 2°C, respectively. There is variability in the role gas would play in future scenarios based on national
43 climate commitments and availability of cheap renewable (Vrontisi et al. 2020, (Vishwanathan and
44 Garg 2020; Malik et al. 2020). Note that these differences are not only present in the electricity sector
45 but also in other end-uses.

46 While oil use is anticipated to decline substantially, due to changes in the transport sector, its use will
47 likely continue through the mid-century, even if likely warming is limited to 2°C or less (*medium*
48 *confidence*). Oil use declines by 43 EJ yr⁻¹ to 91 EJ yr⁻¹ (19% to 54% from 2020 levels, interquartile

1 range) in scenarios that limit warming to 1.5°C with no or limited overshoot and 46 EJ yr⁻¹ to 109 EJ
 2 yr⁻¹ (21% 60% from 2020 levels) by 2050 in scenarios that limit likely warming to 2°C. While oil use
 3 is anticipated to decline immediately in scenarios limiting warming to 1.5°C, it is likely to continue to
 4 be used through 2050. Oil use continues to be a significant source of transport fuels in most scenarios
 5 limiting likely warming to 2°C (Welsby et al, 2021). Oil use may reduce to about half of the current
 6 levels as a transport fuels (Feijoo et al. 2020) if likely warming is limited to 2°C, because of the
 7 availability of other options (biofuels, green hydrogen) and rapid deployment of EVs. In the absence of
 8 rapid transport electrification, the decline is slower with some studies projecting peak oil use around
 9 2035 (Delgado et al. 2020; Pan et al. 2020).

10 There is a lack of consensus about how CCS might alter fossil fuel transitions for limiting likely
 11 warming to 2°C or below. CCS deployment will increase the shares of fossil fuels associated with
 12 limiting warming, and it can ease the economic transition to a low-carbon energy system (Muratori et
 13 al. 2016; Marcucci et al. 2019). While some studies find a significant role for fossil fuels with CCS by
 14 2050 (Koelbl et al. 2014; Eom et al. 2015; Vishwanathan and Garg 2020), others find that retirement of
 15 unabated coal far outpaces the deployment of coal with CCS (McJeon et al, 2021; Budinis et al. 2018;
 16 Xie et al. 2020) Moreover, several models also project that with availability of CO₂ capture technology,
 17 BECCS might become significantly more appealing than fossil CCS even before 2050 (Luderer et al.
 18 2018b; Muratori et al, 2017).

19

20 **Figure 6.35 Global fossil fuel pathways for the 1.5°C scenarios (without and with overshoot), and likely**
 21 **2°C scenarios (without and with delayed policy action) during 2020-2050 (Source: AR6 Scenario**
 22 **Database). Results for total consumption are expressed as a percentage relative to 2020 consumption.**
 23 **Results for fossil energy with CCS are expressed in total energy consumption. Boxes indicate 25th and**
 24 **75th percentiles while whiskers indicate 5th and 95th percentiles. Oil use with CCS is not shown here as it**
 25 **remains below 5% of total use.**

26 6.7.5 Policy and Governance

27 Policy and governance frameworks are essential for shaping near- and medium-term low-emissions
 28 energy system transitions (*high confidence*). While policy interventions are necessary to achieve low-
 29 carbon energy system transitions, appropriate governance frameworks are crucial to ensure policy
 30 implementation (*high confidence*). The policy environment in energy transition pathways relate to

1 climate policy goals, the characteristics of the policy regimes and measures to reach the policy goals
2 including implementation limits and obstacles, and the timing of the climate instrument (Kriegler et al.
3 2014b)

4 The literature discusses a broad set of policy approaches. Environmental economics focuses mainly on
5 market-based approaches as the least-cost policy to achieve emission reductions (Kube et al. 2018).
6 Many countries, however, have implemented policy mixes with a diverse set of complementary policies
7 to achieve energy and climate policy targets. One example is the German Energiewende, which includes
8 substantial support for renewables, an action plan for energy efficiency, and phase-out processes for
9 nuclear- and coal-based power generation next to carbon pricing (Löschel et al. 2019). The halving of
10 CO₂ emissions in UK power generation reflects multiple policies, particularly within the UK's Climate
11 Change Act 2008 (Grubb and Newbery 2018). More generally, the implementation of the NDCs under
12 the Paris Agreement are all characterized by diverse climate policy mixes.

13 These policy mixes (or policy packages) are shaped by different factors, including policy goals and
14 objectives (including political, social and technological influences), multiple market, governance or
15 behavioural failures or previous policy choices of earlier policy eras (Rogge 2017). When pursuing
16 multiple policy goals or targeting some type of imperfection, well designed policy mixes can in
17 principle reduce mitigation costs (Corradini et al. 2018) or address distributional concerns, especially
18 vulnerable populations. For example, the interaction between carbon pricing and the support for clean
19 energy technologies in the EU clean low-carbon strategy for 2050 can reduce mitigation costs and allow
20 for the early adoption of more stringent climate targets (Vandyck et al. 2016). Policy efforts to promote
21 adoption of low-carbon technologies are more successful if they focus not only on economic incentives
22 but include behavioural interventions that target relevant cognitive and motivational factors (Khanna et
23 al. 2021; Mundaca et al. 2019; see also Section 6.7.6). Overlapping nudges might not necessarily lead
24 to lower effectiveness (Brandon et al. 2019).

25 Well-designed policy mixes can support the pursuit of multiple policy goals, target effectively different
26 types of imperfections and framework conditions and take into account the technological, economical,
27 and societal situation (*high confidence*). Accounting for the different development stages of new
28 technologies will enhance low-emissions transitions (Graaf and Sovacool 2020). For prototype
29 technologies and technologies in the demonstration phase, research subsidies and demonstration
30 projects are most important. For technologies experiencing early adoption, infrastructure development
31 and strengthening of markets are increasingly important, while retiring or repurposing of existing assets
32 is important for mature technologies (IEA 2020h) Effective policy mixes will address different market
33 frictions and deal with various uncertainties, for example, those pertaining to technological, climate,
34 and socio-economic developments (Aldy 2020), but also with respect to outcomes of individual policies
35 (e.g. Borenstein et al. 2019). Therefore, policy mixes may balance the trade-off between stability and
36 the flexibility to change individual policies (Gawel and Lehmann 2019) and the policy mix over time
37 (Rayner et al. 2017). Some policy instruments may become feasible over time, for example, as
38 technological advancements reduce the transaction costs of comprehensive market-based approaches
39 (Andoni et al. 2019; Di Silvestre et al. 2020), or as weakened barriers to stringency enable policy
40 sequencing (Pahle et al. 2018) . Energy system policy mixes often include sector-specific regulation.
41 Compared to economy-wide approaches, sectoral policies may be able to directly target specific sectors
42 or mitigation options. However, uncoordinated implementation or limited coordination across sectors
43 may lead to efficiency losses (e.g. Rosendahl et al. 2017). These losses also depend on other policies,
44 such as pre-existing taxes (Goulder et al. 2016; Marten et al. 2018) or research and development policies
45 (Acemoglu et al. 2016). Moreover, unilateral policies – those taken by individual countries in the
46 absence of coordination with other countries – could raise carbon leakage risks, while balancing
47 potential issues of (industrial) competitiveness (Martin et al. 2014; Rosendahl et al. 2017). Energy
48 leakage may become more important during low-carbon energy systems. Numerous studies have

1 identified pathways for carbon leakage in electricity markets with incomplete emission markets (Caron
2 et al. 2015; Thurber et al. 2015; Murray and Maniloff 2015; Fell and Maniloff 2017; Duan et al. 2017;
3 Qian et al. 2018). Well-designed policy mixes will need to target the whole life-cycle or value chains,
4 for example, through policies on limiting fossil fuel extraction (Asheim et al. 2019), or they will need
5 to include measures to limit carbon leakage (e.g. Cosbey et al. 2019).

6 Interactions between policy measures including their scope, stringency, and timing, influence the costs
7 of reducing emissions (Corradini et al. 2018). In particular, some policy instruments may lead to lock-
8 in effects (Section 6.7.3.), compete with other regulations (Graaf and Sovacool 2020), or trigger
9 negative policy interactions (Perino 2015; Jarke-Neuert and Perino 2020). Existing policy mixes often
10 reflect different political economy constraints and sometimes not well coordinated goals. The resulting
11 policy mixes are often economically inefficient. However, comprehensive evaluation of policy mixes
12 requires a broader set of criteria that reflect different considerations, such as broader goals (e.g., SDGs)
13 and the feasibility of policies (*high confidence*).

14 Policy mixes might rather emerge piece-by-piece over time out of individual policy interventions rather
15 than be designed as a whole from the outset (Howlett 2014; Rogge 2017) and may reflect differences
16 across jurisdictions and sectors (Howlett 2014). For example, taking into account country-specific
17 objectives, failures, and limitations, carbon prices may be only one part of a broader policy mix and
18 thereby may not be uniform across countries (Bataille 2020). This lack of consistency makes it more
19 difficult to assess economic outcomes since costs of complementary policies are often less visible and
20 are often targeted at high-cost mitigation options (Borenstein et al. 2019).

21 Effective assessment of policy mixes requires comprehensive, validated international data,
22 methodologies, and indicators. Existing policy mixes are difficult to evaluate because they target
23 multiple objectives, and the evaluation must consider various criteria (Chapter 13, 6.7.7), such as
24 environmental and economic effectiveness, distributional effects, transformative potential, institutional
25 requirements, and feasibility. Economic outcomes depend on policy goals and implementation. Existing
26 studies on policy mixes suggest the benefits of a comprehensive approach (Rosenow et al. 2017), while
27 also highlighting that an “excessive” number of instruments may reduce overall effectiveness
28 (Costantini et al. 2017). Combining environmental regulation and innovation policies may be of
29 particular importance to tackle both emissions and innovation market failures (Fabrizi et al. 2018). The
30 consistency and credibility of policy mixes is positively associated with green innovation (Rogge and
31 Schleich 2018).

32 Potential future policies are difficult to evaluate due to methodological challenges (*high confidence*).
33 Recent model-based analyses of future policy mixes based on “current policy scenarios” try to
34 implement existing policies besides explicit or implicit carbon prices (den Elzen et al. 2016; Roelfsema
35 et al. 2020; van Soest et al. 2017; Rogelj et al. 2016). Many assessments of future low-carbon energy
36 transitions are still based on cost-optimal evaluation frameworks and include only limited analysis of
37 interactions between policy measures. Hence they are often not describing real-world energy transitions
38 properly, but rather differences in implied carbon prices, constraints in technology deployment, and
39 timing of policies (Trutnevte 2016).

41 **6.7.6 Behaviour and Societal Integration**

42 Members of societies, including individuals, civil society, and businesses, will all need to engage with
43 and be affected by low-carbon energy system transitions (*high confidence*). This raises questions about
44 the extent to which different strategies and policy would effectively promote mitigation behaviours and
45 the factors that increase the social acceptability of mitigation options, policies, and system changes.

1 **6.7.6.1 Strategies to encourage climate mitigation actions**

2 Climate policy will be particularly effective if it targets key factor inhibiting, enabling, and motivating
3 mitigation behaviours. As barriers differ across mitigation options, regions, and groups, tailored
4 approaches are more effective (Grubb et al. 2017). When people face important barriers to change (e.g.,
5 high costs, legal barriers), policy would be needed make low carbon actions more attractive, or to make
6 high carbon actions less attractive. As people generally face multiple barriers for change, combinations
7 of policies would be more effective (Rosenow et al. 2017).

8 Financial incentives can motivate mitigation actions (Santos 2008; Thøgersen 2009; Eliasson 2014;
9 Maki et al. 2016; Bolderdijk et al. 2011), particularly when actions are costly (Mundaca 2007). In many
10 countries, more residential solar PV were installed after the introduction of favourable financial
11 schemes such as feed-in-tariffs, federal income tax credits, and net metering (Wolske and Stern 2018).
12 Similarly, a subsidy promoted the installation of solar water heaters in Asia (Chang et al. 2009). Yet,
13 financial incentives may underperform expectations when other factors are overlooked. For example,
14 people may not respond to financial incentives when they do not trust the organization sponsoring the
15 program or when it takes too much effort to receive the incentive (Mundaca 2007; Stern et al. 2016a).
16 Financial incentives are more effective if combined with strategies addressing non-financial barriers.

17 Communicating financial consequences of behaviour seems less effective than emphasizing social
18 rewards (Handgraaf et al. 2013) or benefits of actions for people (e.g., public health, comfort) and the
19 environment (Asensio and Delmas 2015, 2016; Schwartz et al. 2015; Ossokina 2020; Bolderdijk et al.
20 2013). Financial appeals may have limited effects because they reduce people's focus on environmental
21 consequences, weaken intrinsic motivation to engage in mitigation actions, provide a license to pollute
22 (Agrawal et al. 2015; Bolderdijk and Steg 2015; Schwartz et al. 2015), and because pursuing small
23 financial gains is perceived not worth the effort (Dogan et al. 2014; Bolderdijk et al. 2013).

24 Providing information on the causes and consequences of climate change or on effective mitigation
25 actions increases people's knowledge and awareness, but generally does not promote mitigation actions
26 by individuals (Abrahamse et al. 2005) or organizations (Anderson and Newell 2004). Fear-inducing
27 representations of climate change may inhibit action when they make people feel helpless (O'Neill and
28 Nicholson-Cole 2009). Energy-related advice and feedback can promote energy savings, load shifting
29 in electricity use and sustainable travel, particularly when framed in terms of losses rather than gains
30 (Gonzales et al. 1988; Wolak 2011; Bradley et al. 2016; Bager and Mundaca 2017). Also, credible and
31 targeted information at the point of decision can promote action (Stern et al. 2016a). Information is
32 more effective when delivered by a trusted source, such as peers (Palm 2017), advocacy groups (Schelly
33 2014), and community organizations (Noll et al. 2014), and when tailored to actors' personal situation
34 and core values (Abrahamse et al. 2007; Boomsma and Steg 2014; van den Broek et al. 2017; Daamen
35 et al. 2001; Wolsko et al. 2016; Bolderdijk et al. 2013). This explains why home energy audits promoted
36 energy savings (Delmas et al. 2013; Alberini and Towe 2015), and investments in resource efficiency
37 and renewable energy generation (Kastner and Stern 2015).

38 Energy use feedback can promote energy saving behaviour within households (Grønhøj and Thøgersen
39 2011; Fischer 2008; Karlin et al. 2015; Delmas et al. 2013; Zangheri et al. 2019) and at work (Young
40 et al. 2015), particularly when provided in real-time or immediately after the action so that people learn
41 the impact of different actions (Faruqui et al. 2009; Delmas et al. 2013; Abrahamse et al. 2005;
42 Tiefenbeck et al. 2016; Stern et al. 2016a; Yu et al. 2015). Energy labels (Banerjee and Solomon 2003;
43 Stadelmann 2017), visualization techniques (Pahl et al. 2016), and ambient persuasive technology
44 (Midden and Ham 2012) can encourage energy savings as they immediately make sense and hardly
45 require users' conscious attention. Feedback can make people aware of their previous mitigation
46 behaviours, which can strengthen their environmental self-identity, and motivate them to engage in
47 other mitigation actions as well as to act in line with their self-image (Van der Werff et al. 2014).

1 Social influence approaches that communicate what other people do or think can encourage mitigation
2 actions (Clayton et al. 2015), as can social models of desired actions (Osbaldiston and Schott 2012;
3 Abrahamse and Steg 2013; Wolske et al. 2020; Sussman and Gifford 2013). Feedback on one's own
4 energy use relative to others can be effective (Nolan et al. 2008; Allcott 2011; Schultz et al. 2015),
5 although not always, and effect sizes are small (Abrahamse and Steg 2013) compared to other types of
6 feedback (Karlin et al. 2015).

7 Interventions that capitalize on people's motivation to be consistent can promote mitigation actions
8 (Steg 2016). Examples are commitment strategies where people pledge to act (Abrahamse and Steg
9 2013; Lokhorst et al. 2013), implementation intentions where they additionally explicate how and when
10 they will perform the relevant action and how they would cope with possible barriers (Rees et al. 2018;
11 Bamberg 2000, 2002), and hypocrisy-related strategies that make people aware of inconsistencies
12 between their attitudes and behaviour (Osbaldiston and Schott 2012).

13 Bottom-up approaches can promote mitigation action (Abrahamse and Steg 2013). Indeed, community
14 energy initiatives can encourage members' low carbon behaviour (Middlemiss 2011; Seyfang and
15 Haxeltine 2012; Abrahamse and Steg 2013; Sloot et al. 2018). Organizations can promote mitigation
16 behaviour among their employees and customers by communicating their mission and strategies to
17 mitigate climate change (van der Werff et al. 2021; Ruepert et al. 2017).

18 Default options, where a preset choice is implemented if users do not select another option, can promote
19 mitigation actions such as energy savings, green electricity uptake, and meat-free meals options (Liebe
20 et al. 2021; Pichert and Katsikopoulos 2008; Ölander and Thøgersen 2014; Kunreuther and Weber
21 2014; Bessette et al. 2014; Ebeling and Lotz 2015; Liebe et al. 2018; Campbell-Arvai et al. 2014).

22 **6.7.6.2 Acceptability of policy, mitigation options and system changes**

23 Public acceptability reflects the extent to which the public evaluates climate policy, mitigation options,
24 and system changes (un)favourably, which can shape, enable, or prevent low-carbon energy system
25 transitions. Public acceptability of policy and mitigation options is higher when people expect these
26 have more positive and less negative consequences for self, others, and the environment (Demski et al.
27 2015; Drews and Van den Bergh 2016; Perlaviciute and Steg 2014). Public opposition may result when
28 a culturally valued landscape is affected by renewable energy development (Warren et al. 2005; Devine-
29 Wright and Howes 2010), particularly place-based identities are threatened (Devine-Wright 2009, 2013;
30 Boudet 2019). Acceptability can increase after a policy or change has been implemented and the
31 consequences appear to be more positive than expected (Carattini et al. 2018; Schuitema et al. 2010;
32 Eliasson 2014; Weber 2015); effective policy trials can thus build public support.

33 Next, climate policy and low carbon options are evaluated as more fair and acceptable when costs and
34 benefits are distributed equally, and when nature, the environment and future generations are protected
35 (Schuitema et al. 2011; Drews and Van den Bergh 2016). Compensating affected groups for losses due
36 to policy or systems changes enhanced public acceptability in some cases (Perlaviciute and Steg 2014),
37 but people may disagree on which compensation would be worthwhile (Aitken 2010b; Cass et al. 2010),
38 on the distribution of compensation (Devine-Wright and Sherry-Brennan 2019; Leer Jørgensen et al.
39 2020), or feel they are being bribed (Perlaviciute and Steg 2014; Cass et al. 2010). Pricing policies are
40 more acceptable when revenues are earmarked for environmental purposes (Steg et al. 2006; Sælen and
41 Kallbekken 2011) or redistributed towards those affected (Schuitema and Steg 2008).

42 Climate policy and mitigation options, such as renewable energy projects, are also perceived as more
43 fair and acceptable when the public (Dietz 2013; Bidwell 2014; Bernauer et al. 2016b) or public society
44 organizations (Terwel et al. 2010; Bernauer et al. 2016b) could participate in the decision making
45 (Devine-Wright 2005; Terwel et al. 2012; Perlaviciute and Squintani 2020; Arvai 2003; Walker and
46 Baxter 2017). People are more motivated to participate in decision making on local projects than on
47 national or general policy goals (Perlaviciute and Squintani 2020). Public acceptability is also higher

1 when people can influence major rather than only minor decisions, particularly when trust in responsible
2 parties is low (Liu et al. 2019a). Public participation can enhance the quality and legitimacy of decisions
3 by including local knowledge and views that may otherwise be missed (Bidwell 2016; Dietz 2013).

4 Public support is higher when people trust responsible parties (Perlaviciute and Steg 2014; Jiang et al.
5 2018; Drews and Van den Bergh 2016; Michaels and Parag 2016; Liu et al. 2019a). Public support for
6 unilateral climate policy is rather strong and robust (Bernauer et al. 2016a), even in the absence of
7 reciprocal commitments by other states (Bernauer and Gampfer 2015).

8 Public acceptability of climate policy and low carbon options differs across individuals. Climate policy
9 and low carbon options are more acceptable when people strongly value protecting other people and
10 the environment, and support egalitarian worldviews, left-wing or green political ideologies, while
11 acceptability is lower when people strongly endorse self-centered values, and support individualistic
12 worldviews (Dietz et al. 2007; Perlaviciute and Steg 2014; Drews and Van den Bergh 2016). Similarly,
13 public decision makers support climate policy more when they endorse environmental values (Nilsson
14 et al. 2016). Climate and energy policy is more acceptable when people are more concerned about
15 climate change (Hornsey et al. 2016), when they believe their actions would help mitigating climate
16 change, and feel responsible to mitigate climate change (Steg 2005; Jakovcevic and Steg 2013; Ünal et
17 al. 2019; Eriksson et al. 2006; Drews and Van den Bergh 2016; Kim and Shin 2017).

18 19 **6.7.7 The Costs and Benefits of Low-Carbon Energy System Transitions in the Context** 20 **of Sustainable Development**

21 The attractiveness of energy sector mitigation ultimately depends on the way that it provides benefits
22 and reduces the costs for the many different priorities that societies value (Wei et al. 2018, 2020; Yang
23 et al. 2018a). While costs and benefits of climate mitigation are often considered in the context of pure
24 economic outcomes – for example, GDP effects or changes in value of consumption – costs and benefits
25 should be viewed with a broader lens that accounts for the many ways that the energy system interacts
26 with societal priorities (Karlsson et al. 2020). Climate mitigation is not separate from countries' broader
27 growth and development strategies, but rather as a key element of those strategies.

28 Cost reductions in key technologies, particularly in electricity and light-duty transport, have increased
29 the economic attractiveness of near-term low-carbon energy system transitions (*high confidence*). The
30 near-term, economic outcomes of low-carbon energy system transitions in some sectors and regions
31 may be on par with or superior to those of an emissions-intensive future (*high confidence*). Even in
32 cases when system costs are higher for low-carbon transitions, these transitions may still be
33 economically favourable when accounting for health impacts and other co-benefits (Gielen et al. 2019).
34 Past assessments have quantified the aggregate economic costs for climate change mitigation using
35 different metrics, for example carbon prices, GDP losses, investments in energy infrastructure, and
36 energy system costs. Assessments of mitigation costs from integrated assessment and energy system
37 models vary widely. For example, scenarios include carbon prices in 2030 of less than USD 20/t-CO₂,
38 but also more than USD 400/t-CO₂ depending on the region, sector boundary, and methodology (e.g.
39 (Bauer et al. 2016; Oshiro et al. 2017; Vaillancourt et al. 2017; Chen et al. 2019; Brouwer et al. 2016).
40 Those arise both from different methodologies (Guivarch and Rogelj 2017) and assumptions about
41 uncertainties in key factors that drive costs (Meyer et al. 2021)

42 Recent developments, however, raise the prospect that economic outcomes could be substantially
43 superior to prior estimates, particularly if key technologies continue to improve rapidly. In some regions
44 and circumstances, particularly in the electricity sector, near-term mitigation may well lead to superior
45 economic outcomes than continuing to invest in and utilize emissions-intensive infrastructure (e.g.
46 (Brown et al. 2017; Kumar et al. 2020). Given the importance of electricity decarbonization in near-
47 term mitigation strategies (see Section 6.7.1), decreasing costs of solar PV, wind power, and batteries

1 to support their integration, have an outsized influence on near-term economic outcomes from
2 mitigation. At the same time, economic outcomes may vary across regions depending, among other
3 things, on the characteristics of the current energy systems, energy resources, and needs for integrating
4 VRE technologies.

5 The long-term economic characteristics of low-emissions energy system transitions are not well
6 understood and depend on policy design and implementation along with future costs and availability of
7 technologies in key sectors (e.g., process heat, long-distance transport), and the ease of electrification
8 in end-use sectors (*high confidence*). The long-term aggregate economic outcomes from a low-
9 emissions future are not likely to be substantially worse than in an emissions-intensive future and may
10 prove superior (see, e.g., Bogdanov et al. 2021, Child et al. 2019, Farmer et al. 2020) (*medium*
11 *confidence*). For the whole economy, the interquartile range of estimated mitigation costs is between
12 USD₂₀₁₅ 140 and USD₂₀₁₅ 340/t-CO₂ in scenarios limiting likely warming to 2°C and between
13 USD₂₀₁₅ 430 and USD₂₀₁₅ 990/tCO₂ in scenarios limiting likely warming to 1.5°C (Chapter 3). For
14 energy sectors in various regions and globally, different scenarios show a wide range of implied carbon
15 prices in 2050 to limit warming to 1.5°C, from below USD 50/t-CO₂ to more than USD 900/t-CO₂
16 (Brouwer et al. 2016; Rogelj et al. 2018a). Mitigation costs for scenarios limiting likely warming to 2°C
17 were 3-11% in consumption losses in AR5, but the median in newer studies is about 3% in GDP losses
18 (Su et al. 2018; Gambhir et al. 2019).

19 Estimates of long run mitigation costs are highly uncertain and depend on various factors. Both faster
20 technological developments and international cooperation are consistently found to improve economic
21 outcomes (Paroussos et al. 2019). Long-term mitigation is likely to be more challenging than near-term
22 mitigation because low-cost opportunities get utilized first and efforts after that would require
23 mitigation in more challenging sectors (Section 6.6). Advances in low-carbon energy resources and
24 carriers such as next-generation biofuels, hydrogen produced from electrolysis, synthetic fuels, and
25 carbon-neutral ammonia would substantially improve the economics of net zero energy systems (*high*
26 *confidence*). Current estimates of cumulative mitigation costs are comparably high for developing
27 countries, amounting to up to 2-3% of GDP, indicating difficulties for mitigation without adequate
28 support from developed countries (Fujimori et al. 2020; Dorband et al. 2019). In scenarios involving
29 large amounts of stranded assets, the overall costs of low-carbon transitions also include the additional
30 costs of early retirements (Box 6.11).

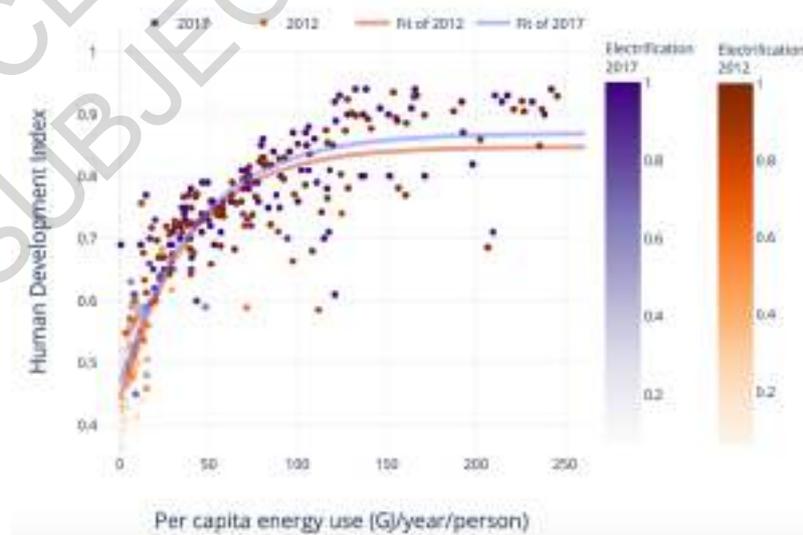

31 Focusing only on aggregate economic outcomes neglects distributional impacts, impacts on broader
32 SDGs, and other outcomes of broad societal importance. Strategies to increase energy efficiency and
33 energy conservation are, in most instances, mutually reinforcing with strategies to support sustainable
34 development. Improving efficiency and energy conservation will promote sustainable consumption and
35 production of energy and associated materials (SDG-12) (*high confidence*). Contrastingly, successful
36 implementation of demand-side options requires sustainable partnerships (SDG-17) between different
37 actors in energy systems, for example governments, utilities, distributors, and consumers. Many authors
38 have argued that energy efficiency has a large untapped potential in both supply and demand (Lovins
39 2018; Méjean et al. 2019). For example, improved fossil power plant efficiency has been estimated to
40 lower the costs of CCS from USD 80-100/t-CO₂ for a subcritical plant to <USD 40/t-CO₂ for a high
41 efficiency plant (Hu and Zhai 2017; Singh et al. 2017). This could enhance energy access and
42 affordability. Eliminating electricity transmission losses has been estimated to mitigate 500 Mt-CO₂ per
43 year globally (Surana and Jordaan 2019). For several other options, such as methane mitigation from
44 the natural gas sector, the costs of infrastructure refurbishing could be offset with the value of the
45 recovered natural gas (Kang et al. 2019).

46 Efficient end use technologies are likely to be particularly cost-effective in developing countries where
47 new infrastructure is rapidly getting built and there is an opportunity to create positive path
48 dependencies (Section 6.7.3). Aside from reducing energy consumption, efficient end use technologies

1 reduce the need for resource extraction, for example, fossil fuel extraction or mining for materials used
2 in wind turbines or solar PV cells (Luderer et al. 2019). Reduced resource extraction is an important
3 precursor to SDG-12 on sustainable consumption and production of minerals. End use efficiency
4 strategies also reduce the need for, and therefore SDG tradeoffs associated with, CDR towards the end
5 of the century and avoid temperature overshoot (van Vuuren et al. 2018). But fully leveraging the
6 demand-side efficiency would entail behavioural changes and thus rely on strong partnerships with
7 communities (SDG-17). For instance, approaches that inform households of the economic value of
8 conservation strategies at home could be particularly useful (Niamir et al. 2018). Improved energy
9 efficiency is interlinked with higher economic growth in Africa (Ohene-Asare et al. 2020; Lin and
10 Abudu 2020). An important distinction here between SDGs focusing on infrastructural and behavioural
11 interventions is the temporal context. Improving building heat systems or the electricity grid with
12 reduced T&D losses would provide climate mitigation with one-time investments and minor
13 maintenance over decades. On the other hand, behavioural changes would be an ongoing process
14 involving sustained, long-term societal interactions.

15 Increasing electrification will support and reduce the costs of key elements of human development, such
16 as education, health, and employment) (*high confidence*). Greater access to electricity might offer
17 greater access to irrigation opportunities for agricultural communities (Peters and Sievert 2016) which
18 could have the potential increasing farmer incomes in support of SDG-1. Coordinated electrification
19 policies also improve enrolment for all forms of education (Kumar and Rauniyar 2018; López-
20 González et al. 2020). Empirical evidence from India suggests that electrification reduced the time for
21 biomass collection thus improved the time children have available for schooling (SDG-4/5) (Khandker
22 et al. 2014). Reduced kerosene use in developing countries has improved indoor air quality (SDG-3)
23 (Barron and Torero 2017; Lewis and Severnini 2020). These positive linkages between climate change
24 mitigation and other goals have improved perceptions of solar PV among the public and policymakers.
25 “Goodwill” towards solar PV is the highest among all the major mitigation options considered in this
26 chapter (Section 6.4.2).

27 Past trends have also indicated that in some Asian countries, electrification has been obtained at lower
28 income levels as compared to developed countries (Rao and Pachauri 2017), with corresponding
29 impacts for development goals For example, a human development index (HDI) greater than 0.7 (Figure
30 6.36) which signifies high development is now possible at close to 30 GJ yr⁻¹ per person. This was
31 attainable only at the energy consumption of 50 GJ yr⁻¹ per person in preceding decades.

32

1 **Figure 6.36 The relationship between total per capita energy use, rate of electrification and human**
2 **development index. Improved efficiency has lowered the energy demand required for meeting a threshold**
3 **HDI during 2012-2017**

4 Electrification also improves energy efficiency, with corresponding implications for development goals
5 For example, the availability of electric cooking may reduce the cooking primary energy requirement
6 considerably compared to traditional stoves (Batchelor et al. 2019; Yang and Yang 2018; Khan and
7 Alam 2020) while also promoting improved indoor air quality (SDG-3). Similarly, PV-powered
8 irrigation and water pumping reduces pumping energy demands, which has the added advantage of
9 promoting SDG-6 on clean water (Elkadeem et al. 2019; Rathore et al. 2018).

10 Phasing out fossil fuels in favour of low-carbon sources, is likely to have considerable SDG benefits,
11 particularly if tradeoffs such as unemployment to fossil fuel workers are minimized (*high confidence*).
12 A phaseout of coal (Box 6.2, Section 6.3) will support SDGs 3, 7 and 14, but it is also anticipated to
13 create large job losses if not properly managed. At the same time, there are large potential employment
14 opportunities that may be created in alternative sectors such as renewables and bioenergy for both
15 skilled and unskilled workers. “Sustainable transition” pathways have indicated a complete fossil
16 phaseout which could entail numerous other co-benefits. For instance, fossil fuels are estimated to
17 generate only 2.65 jobs per USD 1M as compared to projected 7.49 from renewables (Garrett-Peltier
18 2017). Similar synergies may also emerge for nuclear power in the long-term though the high costs
19 create tradeoffs in developing country contexts (Castor et al. 2020; Agyekum et al. 2020). While
20 bioenergy production may create jobs, it may also be problematic for SDG-2 on zero hunger by affecting
21 the supplies and prices of food. Phasing out of fossil fuels will also improve air quality (SDG-3) and
22 premature deaths by reducing PM_{2.5} emissions, (He et al. 2020; Li et al. 2020c). Energy transitions
23 from fossil fuels to renewables, as well as within fossil fuels (coal to gas switching), are already
24 occurring in some regions, spurred by climate concerns, health concerns, market dynamics, or consumer
25 choice (for example in the transport sector).

26 CDR and CCS can create significant land and water tradeoffs (*high confidence*). For large-scale CDR
27 and CCS deployment to not conflict with development goals requires efforts to reduce implications on
28 water and food systems. The water impacts of carbon capture are large, but these impacts can be
29 strategically managed (Giannaris et al. 2020c; Magneschi et al. 2017; Realmonte et al. 2019; Liu et al.
30 2019a). In addition, high-salinity brines are produced from geologic carbon storage, which may be a
31 synergy or tradeoff depending on the energy intensity of the treatment process and the reusability of the
32 treated waters (Arena et al. 2017; Klapperich et al. 2014); if the produced brine from geologic
33 formations can be treated via desalination technologies, there is an opportunity to keep the water
34 intensity of electricity as constant (section 6.4.2.5). Both implications of CCS and CDR are related to
35 SDG-6 on clean water. CDR discussions in the context of energy systems frequently pertains to BECCS
36 which could affect food prices based on land management approaches (Daioglou et al. 2020a). Several
37 CDR processes also require considerable infrastructure refurbishment and electrification to reduce
38 upstream CO₂ emissions (Singh and Colosi 2021). Large-scale CDR could also open the potential for
39 low-carbon transport and urban energy (by offsetting emissions in these sectors) use that would create
40 synergies with SDG-11 (sustainable cities and communities). Effective siting of CDR infrastructure
41 therefore requires consideration of tradeoffs with other priorities. At the same time, several SDG
42 synergies have also been reported to accompany CCS projects such as with reduced air pollution (SDG-
43 3) (Mikunda et al. 2021).

44 Greater energy system integration (Section 6.4.3, Section 6.6.2) would enhance energy-SDG synergies
45 while eliminating tradeoffs associated with deploying mitigation options (*high confidence*). Energy
46 system integration strategies focus on codependence of individual technologies in ways that optimize
47 system performance. Accordingly, they can improve economic outcomes and reduce negative
48 implications for SDG. For example, VRE electricity options raise intermittency concerns and hydrogen

1 can be expensive due to the costs of electricity. Both are relevant to SDG-7 on affordable and reliable
 2 energy access. Routing excess solar generation during daytime for hydrogen production will improve
 3 grid stability as lower hydrogen costs (Tarroja et al. 2015). Due to the varying patterns of solar and
 4 wind energy, these two energy sources could be operated in tandem, thus reducing the material needs
 5 for their construction and for storage, thus promoting SDG-12 on sustainable production (Weitemeyer
 6 et al. 2015; Wang et al. 2019d). For CCS facilities, co-firing of fossil fuels and biomass could enable a
 7 more gradual, near-term low-carbon transition (Lu et al. 2019). This could enable early retirements
 8 (associated with SDG-1) while also providing air pollution reductions (associated with SDG-3).

9 Overall, the scope for positive interactions between low-carbon energy systems and SDGs is
 10 considerably larger than the tradeoffs (Figure 6.37) (McCollum et al. 2018b). Some critical tradeoffs
 11 include impact to biodiversity due to large-scale mineral mining needed for renewable infrastructure
 12 (Sontner et al. 2020).

16

17 Frequently Asked Questions

18 **FAQ 6.1. Will energy systems that emit little or no CO₂ be different than those of today?**

19 Low-carbon energy systems will be similar to those of today in that they will provide many of the same
 20 services as today – for example, heating and cooling homes, travelling to work or on vacation,
 21 transporting goods and services, and powering manufacturing. But future energy systems may be
 22 different in that people may also demand new services that aren't foreseen today, just as people now
 23 use energy for many information technology uses that were not anticipated 50 years ago. More
 24 importantly, low-carbon energy systems will be different in the way that energy is produced,
 25 transformed, and used to provide these services. In the future, almost all electricity will be produced
 26 from sources that emit little or no CO₂, such as solar power, wind power, nuclear power, bioenergy,
 27 hydropower, geothermal power, or fossil energy in which the CO₂ is captured and stored. Electricity,
 28 hydrogen, and bioenergy will be used in many situations where fossil fuels are used today, for example,
 29 in cars or heating homes. And energy is likely to be used more efficiently than today, for example,
 30 through more efficient cars, trucks, and appliances, buildings that use very little energy, and greater use
 31 or public transportation. All of these changes may require new policies, institutions, and even new ways
 32 for people to live their lives. And fundamental to all of these changes is that low-carbon energy systems
 33 will use far less fossil fuel than today.

34 **FAQ 6.2. Can renewable sources provide all the energy needed for energy systems that emit little** 35 **or no CO₂?**

1 Renewable energy technologies harness energy from natural sources that are continually replenished,
2 for example, from the sun (solar energy), the wind (wind energy), plants (bioenergy), rainfall
3 (hydropower), or even the ocean. The energy from these sources exceeds the world's current and future
4 energy needs many times. But that does not mean that renewable sources will provide all energy in
5 future low-carbon energy systems. Some countries have a lot of renewable energy, whereas others do
6 not, and other energy sources, such as nuclear power or fossil energy in which CO₂ emissions are
7 captured and stored (carbon dioxide capture and storage, or CCS) can also contribute to low-carbon
8 energy systems. The energy from sources such as solar energy, wind energy, and hydropower can vary
9 throughout the day or over seasons or years. All low-carbon energy sources have other implications for
10 people and countries, some of which are desirable, for example, reducing air pollution or making it easy
11 to provide electricity in remote locations, and some of which are undesirable, for example decreasing
12 biodiversity or mining of minerals to produce low-emissions technologies. For all of these reasons, it is
13 unlikely that all low-carbon energy systems around the world will rely entirely on renewable energy
14 sources.

15 **FAQ 6.3. What are the most important steps to decarbonize the energy system?**

16 To create a low-carbon energy system, emissions must be reduced across all parts of the system, and
17 not just one or two. This means, for example, reducing the emissions from producing electricity, driving
18 cars, hauling freight, heating and cooling buildings, powering data centers, and manufacturing goods.
19 There are more opportunities to reduce emissions over the next decade in some sectors compared to
20 others. For example, it's possible to substantially reduce electricity emissions over the next decade by
21 investing in low-carbon electricity sources, while at the same time halting the construction of new coal-
22 fired power plants, retiring existing coal-fired power plants or retrofitting them with CCS, and limiting
23 the construction of new gas-fired power plants. There are also opportunities to increase the number of
24 electric cars, trucks, and other vehicles on the road, or to use electricity rather than natural gas or coal
25 to heat homes. And across the whole energy system, emissions can be reduced by using more efficient
26 technologies. While these and other actions will be critical over the coming decade, it is also important
27 to remember that the low-carbon energy transition needs to extend for many decades into the future to
28 limit warming. This means that it is important now to improve and test out options that could be useful
29 later on, for example, producing hydrogen from low-carbon sources or producing bioenergy from crops
30 that require less land than those of today.
