ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1 Executive summary

2 **The Agriculture, Forestry and Other Land Uses¹ (AFOLU) sector encompasses managed**
3 **ecosystems and offers significant mitigation opportunities while delivering food, wood and other**
4 **renewable resources as well as biodiversity conservation, provided the sector adapts to climate**
5 **change.** Land-based mitigation measures represent some of the most important options currently
6 available. They can both deliver carbon dioxide removal (CDR) and substitute for fossil fuels, thereby
7 enabling emissions reductions in other sectors. The rapid deployment of AFOLU measures is essential
8 in all pathways staying within the limits of the remaining budget for a 1.5°C target (*high confidence*).
9 Where carefully and appropriately implemented, AFOLU mitigation measures are uniquely positioned
10 to deliver substantial co-benefits and help address many of the wider challenges associated with land
11 management. If AFOLU measures are deployed badly then, when taken together with the increasing
12 need to produce sufficient food, feed, fuel and wood, they may exacerbate trade-offs with the
13 conservation of habitats, adaptation, biodiversity and other services. At the same time the capacity of
14 the land to support these functions may be threatened by climate change itself (*high confidence*). {WGI,
15 Figure SPM7; WGII, 7.1, 7.6}

16 **The AFOLU (managed land) sector, on average, accounted for 13-21% of global total**
17 **anthropogenic greenhouse gas (GHG) emissions in the period 2010-2019 (*medium confidence*).** At
18 **the same time managed and natural terrestrial ecosystems were a carbon sink, absorbing around**
19 **one third of anthropogenic CO₂ emissions (*medium confidence*).** Estimated anthropogenic net CO₂
20 emissions from AFOLU (based on bookkeeping models) result in a net source of $+5.9 \pm 4.1$ GtCO₂ yr⁻¹
21 between 2010 and 2019 with an unclear trend. Based on FAOSTAT or national GHG inventories, the
22 net CO₂ emissions from AFOLU were 0.0 to $+0.8$ GtCO₂ yr⁻¹ over the same period. There is a
23 discrepancy in the reported CO₂ AFOLU emissions magnitude because alternative methodological
24 approaches that incorporate different assumptions are used. If the managed and natural responses of all
25 land to both anthropogenic environmental change and natural climate variability, estimated to be a gross
26 sink of -12.5 ± 3.2 GtCO₂ yr⁻¹ for the period 2010–2019, are included with land use emissions, then
27 land overall, constituted a net sink of -6.6 ± 5.2 GtCO₂ yr⁻¹ in terms of CO₂ emissions (*medium*
28 *confidence*). {WGI; 7.2, 7.2.2.5, Table 7.1}

29 **AFOLU CO₂ emission fluxes are driven by land use change. The rate of deforestation, which**
30 **accounts for 45% of total AFOLU emissions, has generally declined, while global tree cover and**
31 **global forest growing stock levels are likely increasing (*medium confidence*).** There are substantial
32 regional differences, with losses of carbon generally observed in tropical regions and gains in temperate
33 and boreal regions. Agricultural CH₄ and N₂O emissions are estimated to average 157 ± 47.1 MtCH₄
34 yr⁻¹ and 6.6 ± 4.0 MtN₂O yr⁻¹ or 4.2 ± 1.3 and 1.8 ± 1.1 GtCO₂-eq yr⁻¹ (using IPCC AR6 GWP₁₀₀ values
35 for CH₄ and N₂O) respectively between 2010 and 2019. AFOLU CH₄ emissions continue to increase
36 (*high confidence*), the main source of which is enteric fermentation from ruminant animals (*high*
37 *confidence*). Similarly, AFOLU N₂O emissions are increasing, dominated by agriculture, notably from
38 manure application, nitrogen deposition, and nitrogen fertiliser use (*high confidence*). In addition to
39 being a source and sink for GHG emissions, land plays an important role in climate through albedo
40 effects, evapotranspiration and volatile organic compounds (VOCs) and their mix, although the

FOOTNOTE ¹ For the AFOLU Sector, anthropogenic greenhouse gas emissions and removals by sinks are defined as all those occurring on ‘managed land’. Managed land is land where human interventions and practices have been applied to perform production, ecological or social functions.

1 combined role in total climate forcing is unclear and varies strongly with bioclimatic region and
2 management type. {2.4.2.5, 7.2, 7.2.1, 7.2.3, 7.3}

3 **The AFOLU sector offers significant near-term mitigation potential at relatively low cost but**
4 **cannot compensate for delayed emission reductions in other sectors. (*high evidence, medium***
5 ***agreement*)**. The AFOLU sector can provide 20–30% (interquartile range) of the global mitigation
6 needed for a 1.5 or 2°C pathway towards 2050 (*robust evidence, medium agreement*), though there are
7 highly variable mitigation strategies for how AFOLU potential can be deployed for achieving climate
8 targets. The estimated *likely* economic (< USD100 tCO₂-eq⁻¹) AFOLU sector mitigation potential is 8
9 to 14 GtCO₂-eq yr⁻¹ between 2020-2050, with the bottom end of this range representing the mean from
10 integrated assessment models (IAMs) and the upper end representing the mean estimate from global
11 sectoral studies. The economic potential is about half of the technical potential from AFOLU, and about
12 30-50% could be achieved under USD20 tCO₂-eq⁻¹. The implementation of robust measurement,
13 reporting and verification processes is paramount to improving the transparency of net-carbon-stock-
14 changes per land unit to prevent misleading assumptions or claims on mitigation. {7.1, 7.4, 7.5}

15 **Between 2020 and 2050, mitigation measures in forests and other natural ecosystems provide the**
16 **largest share of the economic (up to USD100 tCO₂-eq⁻¹) AFOLU mitigation potential, followed by**
17 **agriculture and demand-side measures (*high confidence*)**. In the global sectoral studies, the
18 protection, improved management, and restoration of forests, peatlands, coastal wetlands, savannas and
19 grasslands have the potential to reduce emissions and/or sequester 7.3 mean (3.9–13.1 range) GtCO₂-
20 eq yr⁻¹. Agriculture provides the second largest share of the mitigation potential, with 4.1 (1.7–6.7)
21 GtCO₂-eq yr⁻¹ (up to USD100 tCO₂-eq⁻¹) from cropland and grassland soil carbon management,
22 agroforestry, use of biochar, improved rice cultivation, and livestock and nutrient management.
23 Demand-side measures including shifting to sustainable healthy diets, reducing food waste, and
24 building with wood and biochemicals and bio-textiles have a mitigation potential of 2.2 (1.1–3.6)
25 GtCO₂-eq yr⁻¹. Most mitigation options are available and ready to deploy. Emissions reductions can be
26 unlocked relatively quickly, whereas CDR needs upfront investment. Sustainable intensification in
27 agriculture, shifting diets, and reducing food waste could enhance efficiencies and reduce agricultural
28 land needs, and are therefore critical for enabling supply-side measures such as reforestation,
29 restoration, as well as decreasing CH₄ and N₂O emissions from agricultural production. In addition,
30 emerging technologies (e.g., vaccines or inhibitors) have the potential to substantially increase CH₄
31 mitigation potential beyond current estimates. AFOLU mitigation is not only relevant in countries with
32 large land areas. Many smaller countries and regions, particularly with wetlands, have
33 disproportionately high levels of AFOLU mitigation potential density. {7.4, 7.5}

34 **The economic and political feasibility of implementing AFOLU mitigation measures is hampered**
35 **by persistent barriers. Assisting countries to overcome barriers will help to achieve significant**
36 **short-term mitigation (*medium confidence*)**. Finance forms a critical barrier to achieving these gains
37 as currently mitigation efforts rely principally on government sources and funding mechanisms which
38 do not provide sufficient resources to enable the economic potential to be realised. Differences in
39 cultural values, governance, accountability and institutional capacity are also important barriers.
40 Climate change could also emerge as a barrier to AFOLU mitigation, although the IPCC WGI
41 contribution to AR6 indicated that an increase in the capacity of natural sinks may occur, despite
42 changes in climate (*medium confidence*). The continued loss of biodiversity makes ecosystems less
43 resilient to climate change extremes and this may further jeopardise the achievement of the AFOLU
44 mitigation potentials indicated in this chapter (WGII and IPBES) (*high confidence*). {WGI Figure
45 SPM7; 7.4, 7.6}

1 **Bioenergy and other biobased options represent an important share of the total mitigation**
2 **potential. The range of recent estimates for the technical bioenergy potential when constrained**
3 **by food security and environmental considerations is 5–50 and 50–250 EJ yr⁻¹ by 2050 for residues**
4 **and dedicated biomass production system respectively. These estimates fall within previously**
5 **estimated ranges (*medium agreement*). Poorly planned deployment of biomass production and**
6 **afforestation options for in-forest carbon sequestration may conflict with environmental and social**
7 **dimensions of sustainability (*high confidence*). The global technical CDR potential of BECCS by 2050**
8 **(considering only the technical capture of CO₂ and storage underground) is estimated at 5.9 mean (0.5-**
9 **11.3) GtCO₂ yr⁻¹, of which 1.6 (0.8-3.5) GtCO₂ yr⁻¹ is available at below USD100 tCO₂⁻¹ (*medium***
10 ***confidence*). Bioenergy and other bio-based products provide additional mitigation through the**
11 **substitution of fossil fuels fossil based products (*high confidence*). These substitution effects are**
12 **reported in other sectors. Wood used in construction may reduce emissions associated with steel and**
13 **concrete use. The agriculture and forestry sectors can devise management approaches that enable**
14 **biomass production and use for energy in conjunction with the production of food and timber, thereby**
15 **reducing the conversion pressure on natural ecosystems (*medium confidence*). {7.4}**

16 **The deployment of all land-based mitigation measures can provide multiple co-benefits, but there**
17 **are also risks and trade-offs from misguided or inappropriate land management (*high***
18 ***confidence*). Such risks can best be managed if AFOLU mitigation is pursued in response to the**
19 **needs and perspectives of multiple stakeholders to achieve outcomes that maximize synergies**
20 **while limiting trade-offs (*medium confidence*). The results of implementing AFOLU measures are**
21 **often variable and highly context specific. Depending on local conditions (e.g., ecosystem, climate,**
22 **food system, land ownership) and management strategies (e.g., scale, method), mitigation measures**
23 **have the potential to positively or negatively impact biodiversity, ecosystem functioning, air quality,**
24 **water availability and quality, soil productivity, rights infringements, food security, and human**
25 **wellbeing. Mitigation measures addressing GHGs may also affect other climate forcers such as albedo**
26 **and evapotranspiration. Integrated responses that contribute to mitigation, adaptation, and other land**
27 **challenges will have greater likelihood of being successful (*high confidence*); measures which provide**
28 **additional benefits to biodiversity and human well-being are sometimes described as ‘Nature-based**
29 **Solutions’. {7.1, 7.4, 7.6}**

30 **AFOLU mitigation measures have been well understood for decades but deployment remains**
31 **slow and emissions trends indicate unsatisfactory progress despite beneficial contributions to**
32 **global emissions reduction from forest-related options (*high confidence*). Globally, the AFOLU**
33 **sector has so far contributed modestly to net mitigation, as past policies have delivered about 0.65**
34 **GtCO₂ yr⁻¹ of mitigation during 2010–2019 or 1.4% of global gross emissions (*high confidence*). The**
35 **majority (>80%) of emission reduction resulted from forestry measures (*high confidence*). Although**
36 **the mitigation potential of AFOLU measures is large from a biophysical and ecological perspective, its**
37 **feasibility is hampered by lack of institutional support, uncertainty over long-term additionality and**
38 **trade-offs, weak governance, fragmented land ownership, and uncertain permanence effects. Despite**
39 **these impediments to change, AFOLU mitigation options are demonstrably effective and with**
40 **appropriate support can enable rapid emission reductions in most countries. {7.4, 7.6}**

41 **Concerted, rapid and sustained effort by all stakeholders, from policy makers and investors to**
42 **land owners and managers is a pre-requisite to achieving high levels of mitigation in the AFOLU**
43 **sector (*high confidence*). To date USD0.7 billion yr⁻¹ is estimated to have been spent on AFOLU**
44 **mitigation. This is well short of the more than USD400 billion yr⁻¹ that is estimated to be necessary to**
45 **deliver the up to 30% of global mitigation effort envisaged in deep mitigation scenarios (*medium***
46 ***confidence*). This estimate of the global funding requirement is smaller than current subsidies provided**

1 to agriculture and forestry. Making this funding available would require a change in flows of money
2 and determination of who pays. A gradual redirection of existing agriculture and forestry subsidies
3 would greatly advance mitigation. Effective policy interventions and national (investment) plans as part
4 of Nationally Determined Contributions (NDCs), specific to local circumstances and needs, are
5 urgently needed to accelerate the deployment of AFOLU mitigation options. These interventions are
6 effective when they include funding schemes and long-term consistent support for implementation with
7 governments taking the initiative together with private funders and non-state actors. {7.6}

8 **Realizing the mitigation potential of the AFOLU sector depends strongly on policies that directly**
9 **address emissions and drive the deployment of land-based mitigation options, consistent with**
10 **carbon prices in deep mitigation scenarios (*high confidence*).** Examples of successful policies and
11 measures include establishing and respecting tenure rights and community forestry, improved
12 agricultural management and sustainable intensification, biodiversity conservation, payments for
13 ecosystem services, improved forest management and wood chain usage, bioenergy, voluntary supply
14 chain management efforts, consumer behaviour campaigns, private funding and joint regulatory efforts
15 to avoid e.g., leakage. The efficacy of different policies, however, will depend on numerous region-
16 specific factors. In addition to funding, these factors include governance, institutions, long-term
17 consistent execution of measures, and the specific policy setting (*high confidence*). {7.6}

18 **There is a discrepancy, equating to 5.5 GtCO₂ yr⁻¹ between alternative methods of accounting for**
19 **anthropogenic land CO₂ fluxes. Reconciling these methods greatly enhances the credibility of**
20 **AFOLU-based emissions offsetting. It would also assist in assessing collective progress in a global**
21 **stocktake (*high confidence*).** The principal accounting approaches are National GHG inventories
22 (NGHGI) and global modelling approaches. NGHGI, based on IPCC guidelines, consider a much larger
23 area of forest to be under human management than global models. NGHGI consider the fluxes due to
24 human-induced environmental change on this area to be anthropogenic and are thus reported. Global
25 models², in contrast, consider these fluxes to be natural and are excluded from the total reported
26 anthropogenic land CO₂ flux. To enable a like-with-like comparison, the remaining cumulative global
27 CO₂ emissions budget can be adjusted (*medium confidence*). In the absence of these adjustments,
28 collective progress would appear better than it is. {Cross-Chapter Box 6 in this Chapter, 7.2}

29 **Addressing the many knowledge gaps in the development and testing of AFOLU mitigation**
30 **options can rapidly advance the likelihood of achieving sustained mitigation (*high confidence*).**
31 Research priorities include improved quantification of anthropogenic and natural GHG fluxes and
32 emissions modelling, better understanding of the impacts of climate change on the mitigation potential,
33 permanence and additionality of estimated mitigation actions, and improved (real time & cheap)
34 measurement, reporting and verification. There is a need to include a greater suite of mitigation
35 measures in IAMs, informed by more realistic assessments that take into account local circumstances
36 and socio-economic factors and cross-sector synergies and trade-offs. Finally, there is a critical need
37 for more targeted research to develop appropriate country-level, locally specific, policy and land
38 management response options. These options could support more specific NDCs with AFOLU
39 measures that enable mitigation while also contributing to biodiversity conservation, ecosystem
40 functioning, livelihoods for millions of farmers and foresters, and many other Sustainable Development
41 Goals (SDGs) (*high confidence*). {7.7}

FOOTNOTE ² Book keeping models and dynamic global vegetation models

1 **7.1 Introduction**

2 **7.1.1 Key findings from previous reports**

3 Agriculture, Forestry and Other Land Uses (AFOLU) is unique due to its capacity to mitigate climate
4 change through greenhouse gas (GHG) emission reductions, as well as enhance removals (IPCC 2019).
5 However, despite the attention on AFOLU since early 1990s it was reported in the SRCCL as
6 accounting for almost a quarter of anthropogenic emission (IPCC (2019a), with three main GHGs
7 associated with AFOLU; carbon dioxide (CO₂), methane (CH₄) and nitrous oxide (N₂O). Overall
8 emission levels had remained similar since the publication of AR4 (Nabuurs et al. 2007). The diverse
9 nature of the sector, its linkage with wider societal, ecological and environmental aspects and the
10 required coordination of related policy, was suggested to make implementation of known and available
11 supply- and demand-side mitigation measures particularly challenging (IPCC 2019a). Despite such
12 implementation barriers, the considerable mitigation potential of AFOLU as a sector on its own and its
13 capacity to contribute to mitigation within other sectors was emphasised, with land-related measures,
14 including bioenergy, estimated as capable of contributing between 20 and 60% of the total cumulative
15 abatement to 2030 identified within transformation pathways (IPCC 2018). However, the vast
16 mitigation potential from AFOLU initially portrayed in literature and in Integrated Assessment Models
17 (IAMs), as explored in SR1.5, is being questioned in terms of feasibility (Roe et al. 2021) and a more
18 balanced perspective on the role of land in mitigation is developing, while at the same time, interest by
19 private investors in land-based mitigation is increasing fast.

20 The SRCCL (IPCC 2019a) outlined with *medium evidence* and *medium agreement* that supply-side
21 agriculture and forestry measures had an economic (at USD100 tCO₂-eq⁻¹) mitigation potential of 7.2-
22 10.6 GtCO₂-eq⁻¹ in 2030 (using GWP₁₀₀ and multiple IPCC values for CH₄ and N₂O) of which about a
23 third was estimated as achievable at < USD20 tCO₂-eq⁻¹. Agricultural measures were reported as
24 sensitive to carbon price, with cropland and grazing land soil organic carbon management having the
25 greatest potential at USD20 tCO₂-eq⁻¹ and restoration of organic soils at USD100 tCO₂-eq⁻¹. Forestry
26 measures were less sensitive to carbon price, but varied regionally, with reduced deforestation, forest
27 management and afforestation having the greatest potential depending on region. Although demand-
28 side measures related to food could in theory make a large contribution to mitigation, in reality the
29 contribution has been very small. Overall, the dependency of mitigation within AFOLU on a complex
30 range of factors, from population growth, economic and technological developments, to the
31 sustainability of mitigation measures and impacts of climate change, was suggested to make realisation
32 highly challenging (IPCC 2019a).

33 Land can only be part of the solution alongside rapid emission reduction in other sectors (IPCC 2019a).
34 It was recognised that land supports many ecosystem services on which human existence, wellbeing
35 and livelihoods ultimately depend. Yet over-exploitation of land resources was reported as driving
36 considerable and unprecedented rate of biodiversity loss, and wider environmental degradation (IPCC
37 2019a,IPBES 2019a). Urgent action to reverse this trend was deemed crucial in helping to accommodate
38 the increasing demands on land and enhance climate change adaptation capacity. There was *high*
39 *confidence* that global warming was already causing an increase in the frequency and intensity of
40 extreme weather and climate events, impacting ecosystems, food security, disturbances and production
41 processes, with existing (and new) carbon stocks in soils and biomass at serious risk. The impact of
42 land cover on regional climate (through biophysical effects) was also highlighted, although there was
43 *no confidence* regarding impacts on global climate.

44 Since AR5, the share of AFOLU to anthropogenic GHG emissions had remained largely unchanged at
45 13-21% of total GHG emissions (*medium confidence*), though uncertainty in estimates of both sources

1 and sinks of CO₂, exacerbated by difficulties in separating natural and anthropogenic fluxes, was
2 emphasised. Models indicated land (including the natural sink) to have *very likely* provided a net
3 removal of CO₂ between 2007 and 2016. As in AR5, land cover change, notably deforestation, was
4 identified as a major driver of anthropogenic CO₂ emissions whilst agriculture was a major driver of the
5 increasing anthropogenic CH₄ and N₂O emissions.

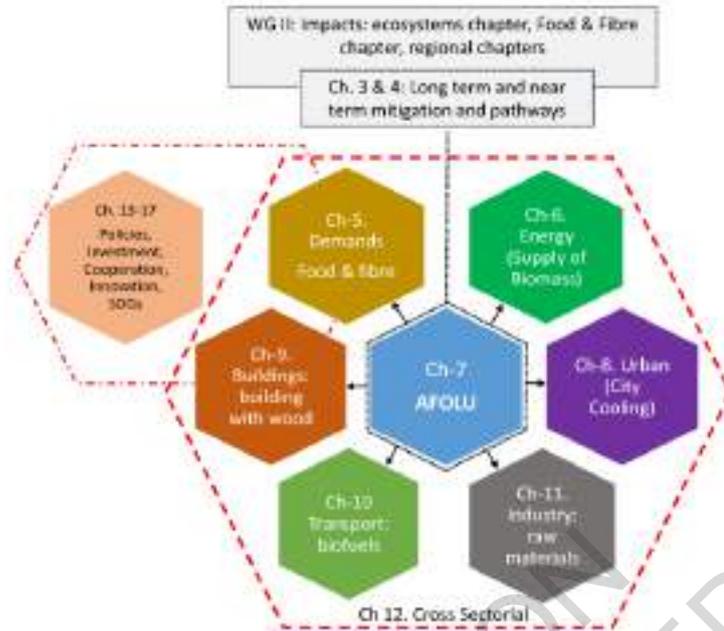

6 In terms of mitigation, without reductions in overall anthropogenic emissions, increased reliance on
7 large-scale land-based mitigation was predicted, which would add to the many already competing
8 demands on land. However, some mitigation measures were suggested to not compete with other land
9 uses, while also having multiple co-benefits, including adaptation capacity and potential synergies with
10 some Sustainable Development Goals (SDGs). As in AR5, there was large uncertainty surrounding
11 mitigation within AFOLU, in part because current carbon stocks and fluxes are unclear and subject to
12 temporal variability. Additionally, the non-additive nature of individual measures that are often inter-
13 linked and the highly context specific applicability of measures, causes further uncertainty. Many
14 AFOLU measures were considered well-established and some achievable at low to moderate cost, yet
15 contrasting economic drivers, insufficient policy, lack of incentivisation and institutional support to
16 stimulate implementation among the many stakeholders involved, in regionally diverse contexts, was
17 recognised as hampering realisation of potential.

18 None the less, the importance of mitigation within AFOLU was highlighted in all IPCC reports, with
19 modelled scenarios demonstrating the considerable potential role and land-based mitigation forming an
20 important component of pledged mitigation in Nationally Determined Contributions (NDCs) under the
21 Paris Agreement. The sector was identified as the only one in which large-scale Carbon Dioxide
22 Removal (CDR) may currently and at short term be possible (e.g. through afforestation/reforestation or
23 soil organic carbon management). This CDR component was deemed crucial to limit climate change
24 and its impacts, which would otherwise lead to enhanced release of carbon from land. However, the
25 SRCCL emphasised that mitigation cannot be pursued in isolation. The need for integrated response
26 options, that mitigate and adapt to climate change, but also deal with land degradation and
27 desertification, while enhancing food and fibre security, biodiversity and contributing to other SDGs
28 has been made clear (IPCC 2019a; Díaz et al. 2019; IPBES-IPCC 2021).

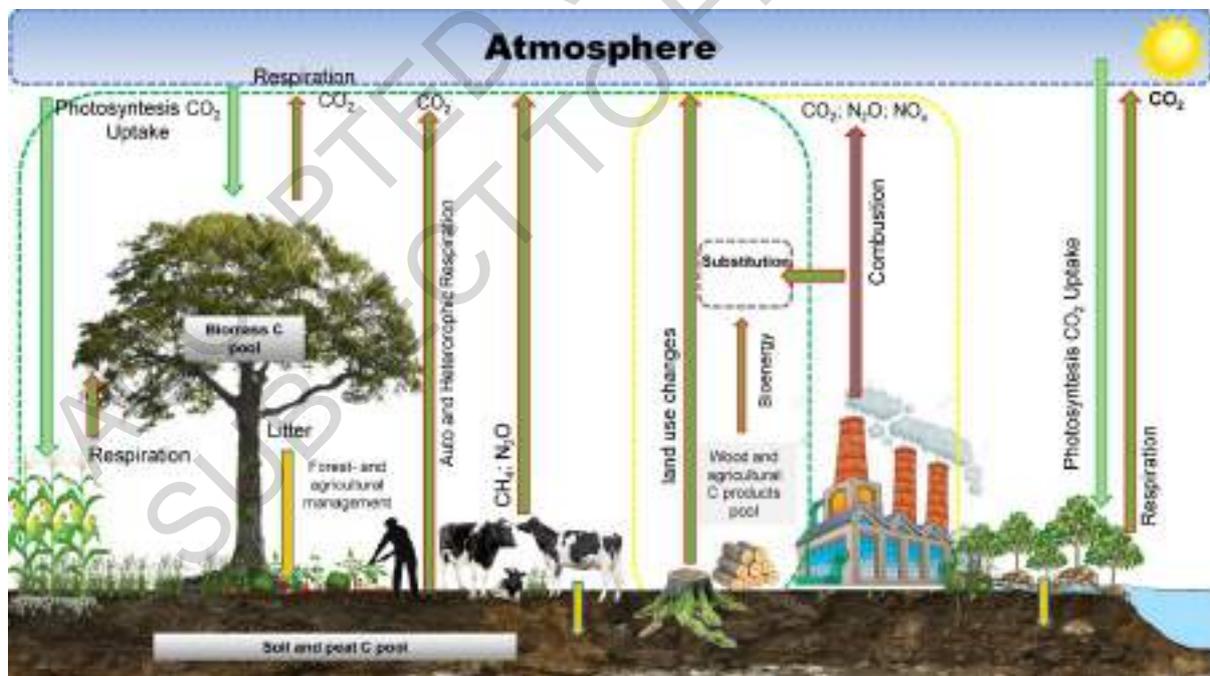

29 **7.1.2 Boundaries, scope and changing context of the current report**

30 This chapter assesses GHG fluxes between land and the atmosphere due to AFOLU, the associated
31 drivers behind these fluxes, mitigation response options and related policy, at time scales of 2030 and
32 2050. Land and its management has important links with other sectors and therefore associated chapters
33 within this report, notably concerning the provision of food, feed, fuel or fibre for human consumption
34 and societal wellbeing (Chapter 5), for bioenergy (Chapter 6), the built environment (Chapter 9),
35 transport (Chapter 10) and industry (Chapter 11). Mitigation within these sectors may in part, be
36 dependent on contributions from land and the AFOLU sector, with interactions between all sectors
37 discussed in Chapter 12. This chapter also has important links with IPCC WGII regarding climate
38 change impacts and adaptation. Linkages are illustrated in Figure 7.1.

39

1
2 **Figure 7.1 Linkage between Chapter 7 and other chapters within this report as well as to WGII.**
3 **Mitigation potential estimates in this chapter consider potential emission reductions and removals only**
4 **within the AFOLU sector itself, and not the substitution effects from biomass and biobased products in**
5 **sectors such as Energy, Transport, Industry, Buildings, nor biophysical effects of e.g. cooling of cities.**
6 **These are covered in their respective chapters.**

8
9 **Figure 7.2 Summarised representation of interactions between land management, its products in terms of**
10 **food and fibre, and land - atmospheric GHG fluxes. For legibility reasons only a few of the processes and**
11 **management measures are depicted.**

1 As highlighted in both AR5 and the SRCCL, there is a complex interplay between land management
2 and GHG fluxes as illustrated in Figure 7.2, with considerable variation in management regionally, as
3 a result of geophysical, climatic, ecological, economic, technological, institutional and socio-cultural
4 diversity. The capacity for land-based mitigation varies accordingly. The principal focus of this chapter
5 is therefore, on evaluating regional land-based mitigation potential, identifying applicable AFOLU
6 mitigation measures, estimating associated costs and exploring policy options that could enable
7 implementation.

8 Mitigation measures are broadly categorised as those relating to (1) forests and other ecosystems (2)
9 agriculture (3) biomass production for products and bioenergy and (4) demand-side levers. Assessment
10 is made in the context that land-mitigation is expected to contribute roughly 25% of the 2030 mitigation
11 pledged in Nationally Determined Contributions (NDCs) under the Paris Agreement (Grassi et al.
12 2017), yet very few countries have provided details on how this will be achieved. In light of AR5 and
13 the SRCCL findings, that indicate large land-based mitigation potential, considerable challenges to its
14 realisation, but also a clear nexus at which humankind finds itself, whereby current land management,
15 driven by population growth and consumption patterns, is undermining the very capacity of land, a
16 finite resource, to support wider critical functions and services on which humankind depends.
17 Mitigation within AFOLU is occasionally and wrongly perceived as an opportunity for in-action within
18 other sectors. AFOLU simply cannot compensate for mitigation shortfalls in other sectors. As the
19 outcomes of many critical challenges (UN Environment 2019), including biodiversity loss (Díaz et al.
20 2019) and soil degradation (FAO and ITPS 2015), are inextricably linked with how we manage land,
21 the evaluation and assessment of AFOLU is crucial. This chapter aims to address three core topics;

- 22 1. What is the latest estimated (economic) mitigation potential of AFOLU measures according to
23 both sectoral studies and integrated assessment models, and how much of this may be realistic
24 within each global region?
- 25 2. How do we realise the mitigation potential, while minimising trade-offs and risks and
26 maximising co-benefits that can enhance food and fibre security, conserve biodiversity and
27 address other land challenges?
- 28 3. How effective have policies been so far and what additional policies or incentives might enable
29 realisation of mitigation potential and at what costs?

30 This chapter first outlines the latest trends in AFOLU fluxes and the methodology supporting their
31 estimation (Section 7.2). Direct and indirect drivers behind emission trends are discussed in Section
32 7.3. Mitigation measures, their costs, co-benefits, trade-offs, estimated regional potential and
33 contribution within integrated global mitigation scenarios, is presented in Sections 7.4 and 7.5
34 respectively. Assessment of associated policy responses and links with SDGs are explored in Section
35 7.6. The chapter concludes with gaps in knowledge (Section 7.7) and frequently asked questions.

37 **7.2 Historical and current trends in GHG emission and removals; their** 38 **uncertainties and implications for assessing collective climate progress**

39 The biosphere on land and in wetlands is a source and sink of CO₂ and CH₄, and a source of N₂O due
40 to both natural and anthropogenic processes that happen simultaneously and are therefore difficult to
41 disentangle (IPCC 2010; Angelo and Du Plessis 2017; IPCC 2019a). AFOLU is the only GHG sector to
42 currently include anthropogenic sinks. A range of methodological approaches and data have been
43 applied to estimating AFOLU emissions and removals, each developed for their own purposes, with
44 estimates varying accordingly. Since the SRCCL (Jia et al. 2019), emissions estimates have been

1 updated (Sections 7.2.2 and 7.2.3), while the assessment of biophysical processes and short-lived
 2 climate forcers (Section 7.2.4) is largely unchanged. Further progress has been made on the implications
 3 of differences in AFOLU emissions estimates for assessing collective climate progress (Section 7.2.2.2,
 4 Cross-Chapter Box 6 in this Chapter).

5 7.2.1 Total net GHG flux from AFOLU

6 National Greenhouse Gas Inventory (NGHGI) reporting following the IPCC 1996 guidelines (IPCC
 7 1996), separates the total anthropogenic AFOLU flux into: (i) net anthropogenic flux from Land Use,
 8 Land-Use Change, and Forestry (LULUCF) due to both change in land cover and land management;
 9 and (ii) the net flux from Agriculture. While fluxes of CO₂ (Section 7.2.2) are predominantly from
 10 LULUCF and fluxes of CH₄ and N₂O (Section 7.2.3) are predominantly from agriculture, fluxes of all
 11 three gases are associated with both sub-sectors. However, not all methods separate them consistently
 12 according to these sub-sectors, thus here we use the term AFOLU, separate by gas and implicitly include
 13 CO₂ emissions that stem from the agriculture part of AFOLU, though these account for a relatively
 14 small portion.

15

16 **Table 7.1 Net anthropogenic emissions (annual averages for 2010–2019^a) from Agriculture, Forestry and**
 17 **Other Land Use (AFOLU). For context, the net flux due to the natural response of land to climate and**
 18 **environmental change is also shown for CO₂ in column E. Positive values represent emissions, negative**
 19 **values represent removals.**

Anthropogenic						Natural Response	Natural + Anthropogenic
Gas	Units	AFOLU Net anthropogenic emissions ^b	Non-AFOLU anthropogenic GHG emissions ^{d,f}	Total net anthropogenic emissions (AFOLU + non-AFOLU) by gas	AFOLU as a % of total net anthropogenic emissions by gas	Natural land sinks including natural response of land to anthropogenic environmental change and climate variability ^e	Net-land atmosphere CO ₂ flux (i.e. anthropogenic AFOLU + natural fluxes across entire land surface)
		A	B	C = A+B	D = (A/C) *100	E	F=A+E
CO ₂	GtCO ₂ -eq yr ⁻¹	5.9 ± 4.1 ^{b,f} (bookkeeping models only). 0 to 0.8 (NGHGI/FAOSTAT data)	36.2 ± 2.9	42.0 ± 29.0	14%	-12.5 ± 3.2	-6.6 ± 4.6
	MtCH ₄ yr ⁻¹	157.0 ± 47.1 ^c	207.5 ± 62.2	364.4 ± 109.3		- ⁱ	
CH ₄	GtCO ₂ -eq yr ⁻¹	4.2 ± 1.3 ^g	5.9 ± 1.8	10.2 ± 3.0	41%		
	MtN ₂ O yr ⁻¹	6.6 ± 4.0 ^c	2.8 ± 1.7	9.4 ± 5.6			
N ₂ O	GtCO ₂ -eq yr ⁻¹	1.8 ± 1.1 ^g	0.8 ± 0.5	2.6 ± 1.5	69%		
Total^h	GtCO ₂ -eq yr ⁻¹	11.9 ± 4.4 (CO ₂ component considers bookkeeping models only)	44 ± 3.4	55.9 ± 6.1	21%		

20

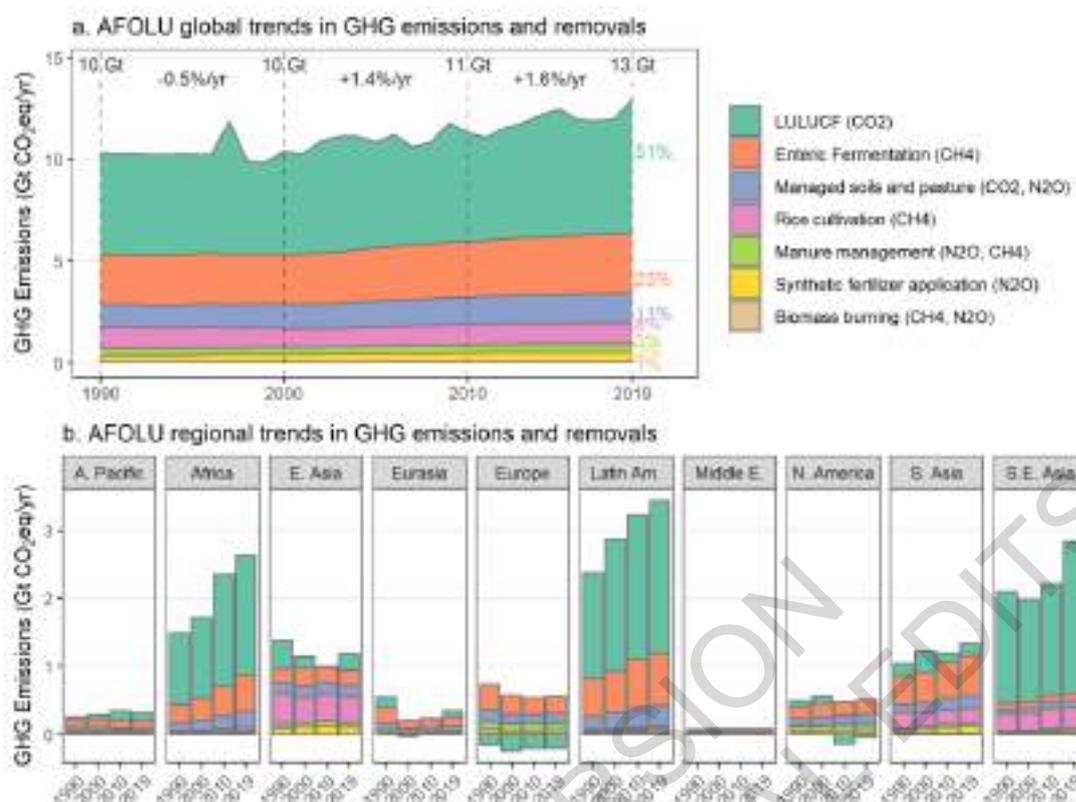

21 ^a Estimates are given until 2019 as this is the latest date when data are available for all gases, consistent with
 22 Chapter 2, this report. Positive fluxes are emission from land to the atmosphere. Negative fluxes are removals.

23

24 ^b Net anthropogenic flux of CO₂ are due to land-use change such as deforestation and afforestation and land
 25 management, including wood harvest and regrowth, peatland drainage and fires, cropland and grassland
 26 management. Average of three bookkeeping models (Hansis et al. 2015; Houghton and Nassikas 2017; Gasser et al. 2020), complemented by data on peatland drainage and fires from FAOSTAT (Prosperi et al. 2020) and

- 1 GFED4s (Van Der Werf et al. 2017). This number is used for consistency with WGI and Chapter 2, this report.
2 Comparisons with other estimates are discussed in 7.2.2. Based on NGHGs and FAOSTAT, the range is 0 to
3 0.8 Gt CO₂ yr⁻¹.
- 4 ^c CH₄ and N₂O emission estimates and assessed uncertainty of 30 and 60% respectively, are based on EDGAR
5 data (Crippa et al. 2021) in accordance with Chapter 2, this report (Sections 2.2.1.3 and 2.2.1.4). Both
6 FAOSTAT (FAO 2021a; Tubiello 2019; USEPA 2019) and the USA EPA (USEPA 2019) also provide data
7 on agricultural non-CO₂ emissions, however mean global CH₄ and N₂O values considering the three databases
8 are within the uncertainty bounds of EDGAR. EDGAR only considers agricultural and not overall AFOLU
9 non-CO₂ emissions. Agriculture is estimated to account for approximately 89 and 96% of total AFOLU CH₄
10 and N₂O emissions respectively. See Section 7.2.3 for further discussion.
- 11 ^d Total non-AFOLU emissions are the sum of total CO₂-eq emissions values for energy, industrial sources, waste
12 and other emissions with data from the Global Carbon Project for CO₂, including international aviation and
13 shipping, and from the PRIMAP database for CH₄ and N₂O averaged over 2007-2014, as that was the period
14 for which data were available.
- 15 ^e The modelled CO₂ estimates include natural processes in vegetation and soils and how they respond to both
16 natural climate variability and to human-induced environmental changes i.e. the response of vegetation and
17 soils to environmental changes such as increasing atmospheric CO₂ concentration, nitrogen deposition, and
18 climate change (indirect anthropogenic effects) on both managed and unmanaged lands. The estimate shown
19 represents the average from 17 Dynamic Global Vegetation Models with 1SD uncertainty (Friedlingstein et
20 al. 2020)
- 21 ^f The NGHGs take a different approach to calculating “anthropogenic” CO₂ fluxes than the models (Section
22 7.2.2). In particular the sinks due to environmental change (indirect anthropogenic fluxes) on managed lands
23 are generally treated as anthropogenic in NGHGs and non-anthropogenic in models such as bookkeeping and
24 IAMs. A reconciliation of the results between IAMs and NGHGs is presented in Cross-Chapter Box 6 in this
25 Chapter. If applied to this table, it would transfer approximately -5.5 GtCO₂ y⁻¹(a sink) from Column E (which
26 would become -7.2 GtCO₂ yr⁻¹) to Column A (which would then be 0.4 GtCO₂ yr⁻¹).
- 27 ^g All values expressed in units of CO₂-eq are based on IPCC AR6 100-year Global Warming Potential (GWP₁₀₀)
28 values with climate-carbon feedbacks (CH₄ = 27, N₂O = 273) (Chapter 2, Supplementary Material SM2.3 and
29 IPCC WGI AR6 Section 7.6).
- 30 ^h For assessment of cross-sector fluxes related to the food sector, see Chapter 12, this report.
- 31 ⁱ While it is acknowledged that soils are a natural CH₄ sink (Jackson et al. 2020) with soil microbial removals
32 estimated to be 30 ± 19 MtCH₄ yr⁻¹ for the period 2008-2017 (according to bottom-up estimates), natural CH₄
33 sources are considerably greater (371 (245-488) MtCH₄ yr⁻¹) resulting in natural processes being a net CH₄
34 source (IPCC WGI AR6 Section 5.2.2). The soil CH₄ sink is therefore omitted from Column E.
- 35 ^j Total GHG emissions concerning non-AFOLU sectors and all sectors combined (Columns B and C) include
36 fluorinated gases in addition to CO₂, CH₄ and N₂O. Therefore, total values do not equal the sum of estimates
37 for CO₂, CH₄ and N₂O.

38

1
2 **Figure 7.3** Subdivision of the total AFOLU emissions from Table 7.1 by activity and gas for the period
3 1990 to 2019. Positive values are emissions from land to atmosphere, negative values are
4 removals. Panel A shows emissions divided into major activity and gases. Note that ‘biomass burning’
5 is only the burning of agriculture residues in the fields. The indicated growth rates between 1990-2000,
6 2000-2010, 2010-2019 are annualised across each time period. Panel B illustrates regional emissions in
7 the years 1990, 2000, 2010, 2019 AFOLU CO₂ (green shading) represents all AFOLU CO₂ emissions. It
8 is the mean from three bookkeeping models (Hansis et al. 2015; Houghton and Nassikas 2017; Gasser
9 et al. 2020) as presented in the Global Carbon Budget (Friedlingstein et al. 2020) and is not directly
10 comparable to LULUCF in NGHGs (Section 7.2.2). Data on CH₄ and N₂O emissions are from the
11 EDGAR database (Crippa et al. 2021). See Sections 7.2.2 and 7.2.3 for comparison of different
12 datasets. All values expressed are asCO₂-eq with GWP₁₀₀ values: CH₄ = 27, N₂O = 273.

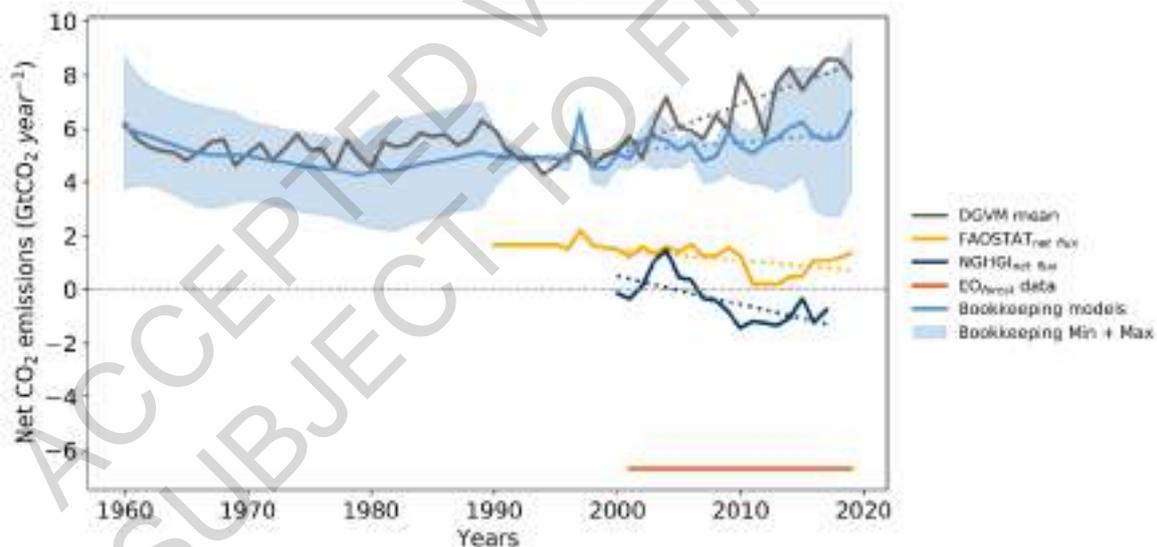

13 Total global net anthropogenic GHG emissions from AFOLU were 11.9 ± 4.4 GtCO₂-eq yr⁻¹ on average
14 over the period 2010-2019, around 21% of total global net anthropogenic GHG emissions (Table 7.1,
15 Figure 7.3, using the sum of bookkeeping models for the CO₂ component). When using
16 FAOSTAT/NGHGs CO₂ flux data, then the contribution of AFOLU to total emissions amounts to 13%
17 of global emissions.

18 This AFOLU flux is the net of anthropogenic emissions of CO₂, CH₄ and N₂O, and anthropogenic
19 removals of CO₂. The contribution of AFOLU to total emissions varies regionally with highest in Latin
20 America and Caribbean with 58% an lowest in Europe and North America with each 7% (Chapter 2,
21 Section 2.2.3). There is a discrepancy in the reported CO₂ AFOLU emissions magnitude because
22 alternative methodological approaches that incorporate different assumptions are used (see 7.2.2.2).
23 While there is *low agreement* in the trend of global AFOLU CO₂ emissions over the past few decades
24 (7.2.2), they have remained relatively constant (*medium confidence*) (Chapter 2). Average non-CO₂
25 emission (aggregated using GWP₁₀₀ IPCC AR6 values) from agriculture have risen from 5.2 ± 1.4
26 GtCO₂-eq yr⁻¹ for the period 1990 to 1999, to 6.0 ± 1.7 GtCO₂-eq yr⁻¹ for the period 2010 to 2019 (Crippa
27 et al. 2021), Section 7.2.3).

1 To present a fuller understanding of land-atmosphere interactions, Table 7.1 includes an estimate of the
 2 natural sink of land to atmospheric CO₂ (IPCC WGI Chapter 5 and (Jia et al. 2019)). Land fluxes respond
 3 naturally to human-induced environmental change (e.g. climate change, and the fertilising effects of
 4 increased atmospheric CO₂ concentration and nitrogen deposition), known as “indirect anthropogenic
 5 effects”, and also to “natural effects” such as climate variability (IPCC 2010) (Table 7.1, Section 7.2.2).
 6 This showed a removal of -12.5 ± 3.2 GtCO₂ yr⁻¹ (*medium confidence*) from the atmosphere during
 7 2010–2019 according to global DGVM models (Friedlingstein et al. 2020) 31% of total anthropogenic
 8 net emissions of CO₂ from all sectors. It is likely that the NGHIs and FAOSTAT implicitly cover some
 9 part of this sink and thus provide a net CO₂ AFOLU balance with some 5 GtCO₂ lower net emissions
 10 than according to bookkeeping models, with the overall net CO₂ value close to being neutral. Model
 11 results and atmospheric observations concur that, when combining both anthropogenic (AFOLU) and
 12 natural processes on the entire land surface (the total “land-atmosphere flux”), the land was a global net
 13 sink for CO₂ of -6.6 ± 4.6 GtCO₂ yr⁻¹ with a range for 2010 to 2019 from -4.4 to -8.4 GtCO₂ yr⁻¹. (Van
 14 Der Laan-Luijkx et al. 2017; Rödenbeck et al. 2003, 2018; Chevallier et al. 2005; Feng et al. 2016;
 15 Niwa et al. 2017; Patra et al. 2018). The natural land sink is *highly likely* to be affected by both future
 16 AFOLU activity and climate change (IPCC WGI Box 5.1 and IPCC WGI SPM Figure 7), whereby
 17 under more severe climate change, the amount of carbon stored on land would still increase although
 18 the relative share of the emissions that land takes up, declines.

7.2.2 Flux of CO₂ from AFOLU, and the non-anthropogenic land sink

7.2.2.1 Global net AFOLU CO₂ flux

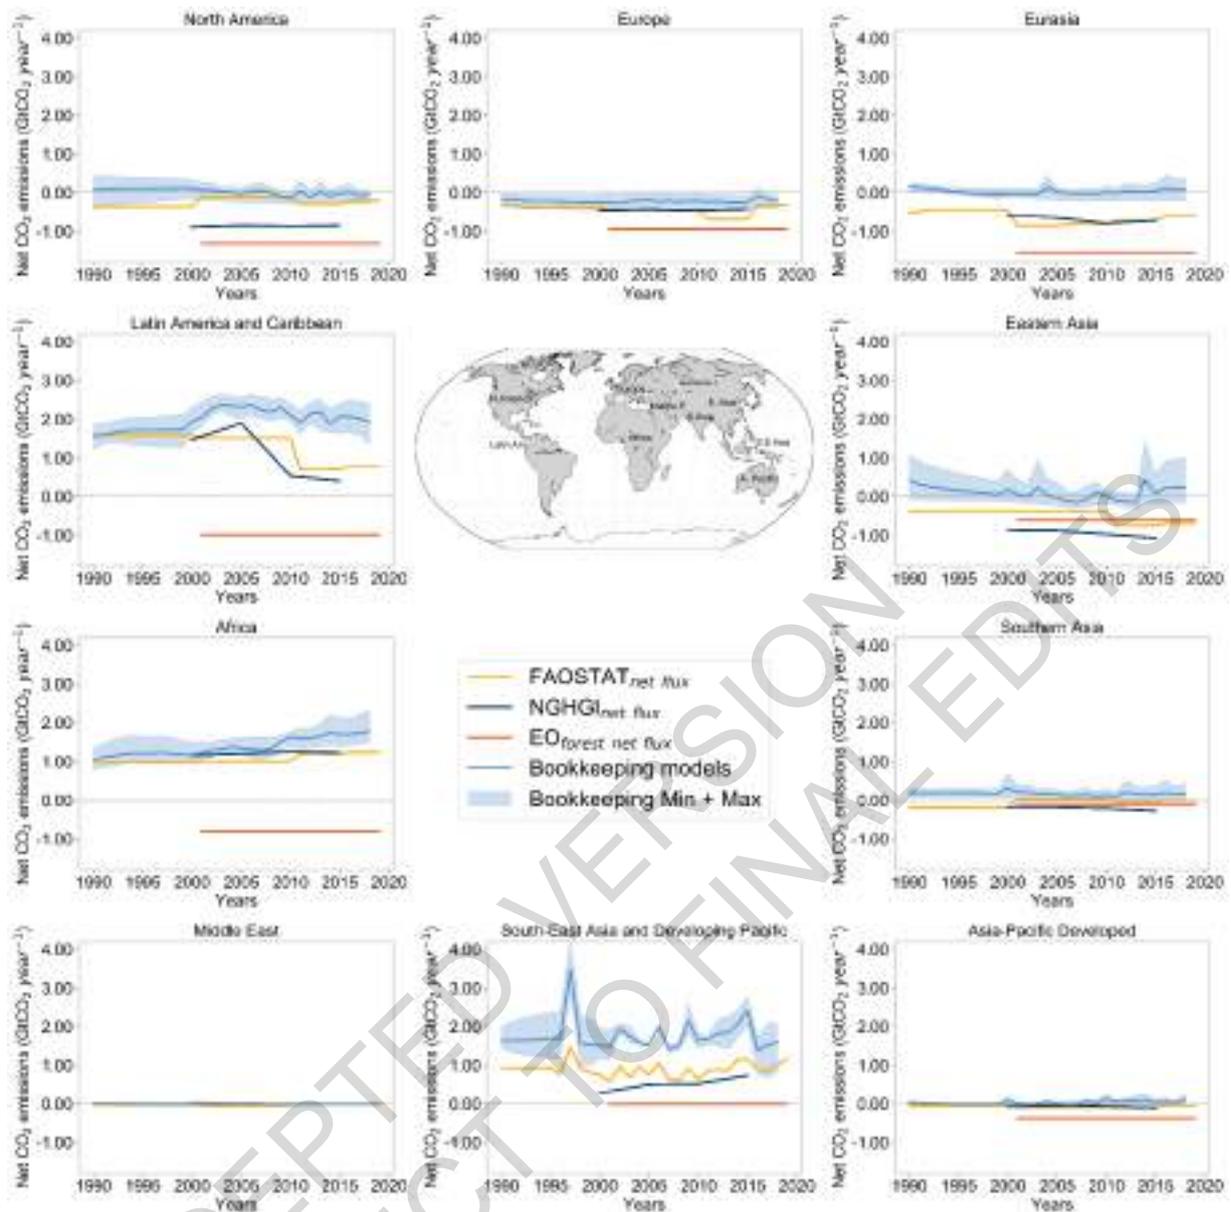

23
 24 **Figure 7.4 Global net CO₂ flux due to AFOLU estimated using different methods for the period 1960 to**
 25 **2019 (GtCO₂ yr⁻¹). Positive numbers represent emissions. (Grey line) The mean from 17 DGVMs all using**
 26 **the same driving data under TrendyV9 used within the Global Carbon Budget 2020 and including**
 27 **different degrees of management (Bastos et al. 2020; Friedlingstein et al. 2020). (Orange line) Data**
 28 **downloaded 6th June 2021 from FAOSTAT (FAO 2021b; <http://www.fao.org/faostat/>) comprising: net**
 29 **emissions from (i) forest land converted to other land, (ii) net emissions from organic soils in cropland,**
 30 **grassland and from biomass burning (including peat fires and peat draining (Prosperi et al. 2020) and (iii)**
 31 **net emissions from forest land remaining forest land, which includes managed forest lands (Tubiello et al.**
 32 **2020). (Dark blue line) Net flux estimate from National Greenhouse Gas Inventories (NGHGI) based on**

1 country reports to the UNFCCC for LULUCF (Grassi et al. 2021) which include land-use change, and
2 flux in managed lands. (Red (EO) line) The 2001 – 2019 average net CO₂ flux from non-intact forest-
3 related emissions and removals based on ground and Earth Observation data (EO) (Harris et al. 2021).
4 Data to mask non-intact forest were used in the tropics (Turubanova et al. 2018) and extra-tropics
5 (Potapov et al. 2017).

6 Light blue line: the mean estimate and minimum and maximum (blue shading) from three bookkeeping
7 models (Hansis et al. 2015; Houghton and Nassikas 2017; Gasser et al. 2020). These include land cover
8 change (e.g. deforestation, afforestation), forest management including wood harvest and land
9 degradation, shifting cultivation, regrowth of forests following wood harvest or abandonment of
10 agriculture, grassland management, agricultural management. Emissions from peat burning and
11 draining are added from external data sets (see text). Both the DGVM and Bookkeeping global data is
12 available at: <https://www.icos-cp.eu/science-and-impact/global-carbon-budget/2020> (Accessed on
13 04/010/2021). Data consistent with IPCC WGI Chapter 5. Dotted lines denote the linear regression from
14 2000 to 2019. Trends are statistically significant ($P < 0.05$) with exception for the NGHGI trend ($P < 0.01$).
15

16 Comparison of estimates of the global net AFOLU flux of CO₂ from diverse approaches (Figure 7.4)
17 show differences on the order of several GtCO₂ yr⁻¹. When considering the reasons for the differences,
18 and an approach to reconcile them (Section 7.2.2.3; Grassi et al. 2021), there is *medium confidence* in
19 the magnitude of the net AFOLU CO₂ flux. There is a discrepancy in the reported CO₂ AFOLU
20 emissions magnitude because alternative methodological approaches that incorporate different
21 assumptions are used (see 7.2.2.2). While the mean of the bookkeeping and DGVM model's show a
22 small increase in global CO₂ net emissions since year 2000, individual models suggest opposite trends
23 (Friedlingstein et al. 2020). The latest FAOSTAT and NGHGI estimates show a small reduction in net
24 emission. Overall, the trends are unclear.
25

1
2 **Figure 7.5 Regional net flux of CO₂ due to AFOLU estimated using different methods for the period 1990-**
3 **2019 (GtCO₂ yr⁻¹).** Positive numbers represent emissions. The upper-central panel depicts the world map
4 shaded according to the IPCC AR6 regions corresponding to the individual graphs. For each regional
5 panel; (Orange line) Total net flux data from FAOSTAT (Tubiello et al. 2020), (Dark blue line) Net
6 emissions estimates from National Greenhouse Gas Inventories based on country reports to the UNFCCC
7 for LULUCF (Grassi et al. 2021), (Light blue line) The mean estimate and minimum and maximum
8 (blue shading) from three bookkeeping models. (Hansis et al. 2015; Houghton and Nassikas 2017; Gasser
9 et al. 2020). Regional estimates from bookkeeping models are available at:
10 <https://zenodo.org/record/5548333#.YVwJB2LMJPY> (Minx et al. 2021). See the legend in Figure 7.4 for
11 a detailed explanation of flux components for each dataset.

12
13 Regionally (Figure 7.5), there is *high confidence* of net emissions linked to deforestation in Latin
14 America, Africa and South-East Asia from 1990 to 2019. There is *medium confidence* in trends
15 indicating a decrease in net emissions in Latin America since 2005 linked to reduced gross deforestation
16 emissions, and a small increase in net emissions related to increased gross deforestation emissions in

1 Africa since 2000 (Figure 7.5). There is *high confidence* regarding the net AFOLU CO₂ sink in Europe
2 due to forest regrowth and known other sinks in managed forests, and *medium confidence* of a net sink
3 in North America and Eurasia since 2010.

5 **7.2.2.2 Why do various methods deliver difference in results?**

6 The processes responsible for fluxes from land have been divided into three categories (IPCC 2006,
7 2010): (1) the *direct human-induced effects* due to changing land cover and land management; (2) the
8 *indirect human-induced effects* due to anthropogenic environmental change, such as climate change,
9 CO₂ fertilisation, nitrogen deposition, etc.; and (3) *natural effects*, including climate variability and a
10 background natural disturbance regime (e.g. wildfires, windthrows, diseases or insect outbreaks).

11 Global models estimate the anthropogenic land CO₂ flux considering only the impact of direct effects,
12 and only those areas that were subject to intense and direct management such as clear-cut harvest. It is
13 important to note, that DGVMs also estimate the non-anthropogenic land CO₂ flux (Land Sink) that
14 results from indirect and natural effects (Table 7.1). In contrast, estimates of the anthropogenic land
15 CO₂ flux in NGHGs (LULUCF) include the impact of direct effects and, in most cases, of indirect
16 effects on a much greater area considered “managed” than global models (Grassi et al. 2021).

17 The approach used by countries follows the IPCC methodological guidance for NGHGs (IPCC 2006,
18 2019a). Since separating direct, indirect and natural effects on the land CO₂ sink is impossible with
19 direct observation such as national forest inventories (IPCC 2010), upon which most NGHGs are
20 based, the IPCC adopted the ‘managed land’ concept as a pragmatic proxy to facilitate NGHGI
21 reporting. Anthropogenic land GHG fluxes (direct and indirect effects) are defined as all those occurring
22 on managed land, that is, where human interventions and practices have been applied to perform
23 production, ecological or social functions (IPCC 2006, 2019a). GHG fluxes from unmanaged land are
24 not reported in NGHGs because they are assumed to be non-anthropogenic. Countries report NGHGI
25 data with a range of methodologies, resolution and completeness, dependent on capacity and available
26 data, consistent with IPCC guidelines (IPCC 2006, 2019a) and subject to an international review or
27 assessment processes.

28 The FAOSTAT approach is conceptually similar to NGHGs. FAOSTAT data on forests are based on
29 country reports to FAO-FRA 2020 (FAO 2020a), and include changes in biomass carbon stock in
30 “forest land” and “net forest conversions” in five-year intervals. “Forest land” may include unmanaged
31 natural forest, leading to possible overall overestimation of anthropogenic fluxes for both sources and
32 sinks, though emissions from deforestation are likely underestimated (Tubiello et al. 2020). FAOSTAT
33 also estimate emissions from forest fires and other land uses (organic soils), following IPCC methods
34 (Prosperi et al. 2020). The FAO-FRA 2020 (FAO 2020b) update leads to estimates of larger sinks in
35 Russia since 1991, and in China and the USA from 2011, and larger deforestation emissions in Brazil
36 and smaller in Indonesia than FRA 2015 (FAO 2015;Tubiello et al. 2020).

37 The bookkeeping models by Houghton and Nassikas (2017), Hansis et al. (2015), and Gasser et al.
38 (2020) and the DGVMs used in the Global Carbon Budget (Friedlingstein et al. 2020) use either the
39 LUH2 data set (Hurtt et al. 2020) HYDE (Goldewijk et al. 2017) FRA 2015 (FAO 2015) or a
40 combination. The LUH2 dataset includes a new wood harvest reconstruction, new representation of
41 shifting cultivation, crop rotations, and management information including irrigation and fertilizer
42 application. The area of forest subject to harvest in LUH2 is much less than the area of forest considered
43 “managed” in the NGHGs (Grassi et al. 2018). The model datasets do not yet include the FAO FRA
44 2020 update (FAO 2020a). The DGVMs consider CO₂ fertilization effects on forest growth that are

1 sometimes confirmed from the groundbased forest inventory networks (Nabuurs et al. 2013) and
2 sometimes not at all (van der Sleen et al. 2015).

3 Further, the DGVMs and bookkeeping models do not include a wide range of practices which are
4 implicitly covered by the inventories; for example: forest dynamics (Pugh et al. 2019; Le Noë et al.
5 2020) forest management including wood harvest (Nabuurs, et al. 2013; Arneth et al. 2017) agricultural
6 and grassland practices (Pugh et al. 2015; Sanderman et al. 2017; Pongratz et al. 2018); or e.g. fire
7 management (Andela et al. 2017; Arora and Melton 2018).

8 Increasingly higher emissions estimates are expected from DGVMs compared to bookkeeping models,
9 because DGVMs include a loss of additional sink capacity of 3.3 ± 1.1 GtCO₂ yr⁻¹ on average over
10 2009-2018, which is increasing with larger climate and CO₂ impacts (Friedlingstein et al. 2020). This
11 arises because the DGVM methodological setup requires a reference simulation including climate and
12 environmental changes but without any land use change such as deforestation, so DGVMs implicitly
13 include the sink capacity forests would have developed in response to environmental changes on areas
14 that in reality have been cleared (Gitz and Ciais 2003; Pongratz et al. 2014)(IPCC WGI Chapter 5).

15 Carbon emissions from peat burning have been estimated based on the Global Fire Emission Database
16 (GFED4s; Van Der Werf et al. 2017). These were included in the bookkeeping model estimates and
17 added 2.0 Gt Carbon over 1960-2019 (e.g. causing the peak in South-East Asia in 1998, Figure 7.5).
18 Within the Global Carbon Budget (Friedlingstein et al. 2020), peat drainage from agriculture accounted
19 for an additional 8.6 Gt Carbon from 1960-2019 according to FAOSTAT (Conchedda and Tubiello,
20 2020) used by two of the bookkeeping models, (Hansis et al. 2015; Gasser et al. 2020).

21 Remote-sensing products provide valuable spatial and temporal land-use and biomass data globally
22 (including in remote areas), at potentially high spatial and temporal resolutions, that can be used to
23 calculate CO₂ fluxes, but have mostly been applied only to forests at the global or even regional scale.
24 While such data can strongly support monitoring reporting and verification, estimates of forest carbon
25 fluxes directly from Earth Observation (EO) data vary considerably in both their magnitude and sign
26 (i.e. whether forests are a net source or sink of carbon). For the period 2005 – 2017, net tropical forest
27 carbon fluxes were estimated as -0.4 GtCO₂ yr⁻¹ (Fan et al. 2019); 0.58 GtCO₂ yr⁻¹ (Grace et al. 2014);
28 1.6 GtCO₂yr⁻¹ (Baccini et al. 2017) and 2.87 GtCO₂ yr⁻¹ (Achard et al. 2014). Differences can in part
29 be explained by spatial resolution of the data sets, the definition of “forest” and the inclusion
30 of processes and methods used to determine degradation and growth in intact and secondary forests, or
31 the changes in algorithm over time (Palahí et al. 2021). A recent global study integrated ground
32 observations and remote sensing data to map forest-related GHG emissions and removals at a high
33 spatial resolution (30m spatial scale), although it only provides an average estimate of annual carbon
34 loss over 2001–2019 (Harris et al. 2021). The estimated net global forest carbon sink globally was -
35 7.66 GtCO₂ yr⁻¹, being -1.7 GtCO₂yr⁻¹ in the tropics only.

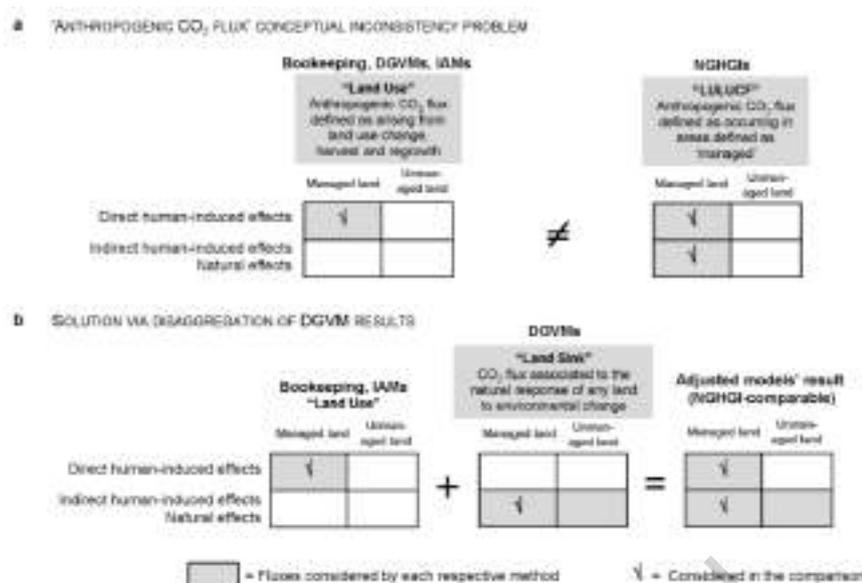

36 Remote sensing products can help to attribute changes to anthropogenic activity or natural inter-annual
37 climate variability (Fan et al. 2019; Wigneron et al. 2020). Products with higher spatial resolution make
38 it easier to determine forest and carbon dynamics in relatively small-sized managed forests (e.g. Wang
39 et al. 2020; Heinrich et al. 2021; Reiche et al. 2021). For example secondary forest regrowth in the
40 Brazilian Amazon offset 9 to 14% of gross emissions due to deforestation¹ (Silva Junior et al. 2021;
41 Aragão et al. 2018). Yet disturbances such as fire and repeated deforestation cycles due to shifting
42 cultivation over the period 1985 to 2017, were found to reduce the regrowth rates of secondary forests
43 by 8 to 55% depending on the climate region of regrowth (Heinrich et al. 2021).

1 **7.2.2.3 Implications of differences in AFOLU CO₂ fluxes between global models and National**
2 **Greenhouse Gas Inventories (NGHGIs), and reconciliation**

3 There is about 5.5 GtCO₂ yr⁻¹ difference in the anthropogenic AFOLU estimates between NGHGIs and
4 global models (this number relates to an IAMs comparison for the period 2005-2015 - see Cross-Chapter
5 Box 6 in this Chapter; for comparison with other models see Figure 7.4). Reconciling the differences
6 i.e. making estimates comparable, can build confidence in land-related CO₂ estimates, for example for
7 the purpose of assessing collective progress in the context of the Global Stocktake (Cross-Chapter Box
8 6 in this Chapter). The difference largely results from greater estimated CO₂ in NGHGIs, mostly
9 occurring in forests (Grassi et al. 2021). This difference is potentially a consequence of: (i) simplified
10 and/or incomplete representation of management in global models (Popp et al. 2017; Pongratz et al.
11 2018), e.g. concerning impacts of forest management in biomass expansion and thickening (Nabuurs et
12 al. 2013; Grassi et al. 2017) (ii) inaccurate and/or incomplete estimation of LULUCF fluxes in NGHGIs
13 (Grassi et al. 2017), especially in developing countries, primarily in non-forest land uses and in soils,
14 and (iii) conceptual differences in how global models and NGHGIs define ‘anthropogenic’ CO₂ flux
15 from land (Grassi et al. 2018). The impacts of (i) and (ii) are difficult to quantify and result in
16 uncertainties that will decrease slowly over time through improvements of both models and NGHGIs.
17 By contrast, the inconsistencies in (iii) and its resulting biases were assessed as explained below.

18 Since changing the NGHGIs’ approach is impractical, an interim method to translate and adjust the
19 output of global models was outlined for reconciling a bookkeeping model and NGHGIs (Grassi et al.
20 2018). More recently, an improved version of this approach has been applied to the future mitigation
21 pathways estimated by IAMs (Grassi et al. 2021), with the implications for the Global Stocktake
22 discussed in Cross-Chapter Box 6 in this Chapter. This method implies a post-processing of current
23 global models’ results that addresses two components of the conceptual differences in the
24 “anthropogenic” CO₂ flux; (i) how the impact of human-induced environmental changes (indirect
25 effects) are considered, and (ii) the extent of forest area considered ‘managed’. Essentially, this
26 approach adds DGVM estimates of CO₂ fluxes due to indirect effects from countries’ managed forest
27 area (using non-intact forest area maps as a proxy) to the original global models’ anthropogenic land
28 CO₂ fluxes (Figure 7.6).

29

1
2 **Figure 7.6 Main conceptual differences between global models (bookkeeping models, IAMs and**
3 **DGVMs) and NGHGs definitions of what is considered the 'anthropogenic' land CO₂ flux, and**
4 **proposed solution (from Grassi et al. 2021). (Panel a) Differences in defining the anthropogenic**
5 **land CO₂ flux by global models ('Land Use') and NGHGs ('LULUCF'), including the attribution**
6 **of processes responsible for land fluxes (IPCC 2006; 2010) in managed and unmanaged lands. The**
7 **anthropogenic land CO₂ flux by global models typically includes only the CO₂ flux due to 'direct**
8 **effects' (land-use change, harvest, regrowth). By contrast, most NGHGs consider anthropogenic**
9 **all fluxes occurring in areas defined as 'managed', including also the sink due to 'indirect effects'**
10 **(climate change, atmospheric CO₂ increase, N deposition etc.) and due to 'natural effects' (climate**
11 **variability, background natural disturbances). (Panel b) Proposed solution to the inconsistency, via**
12 **disaggregation of the 'Land Sink' flux from DGVMs into CO₂ fluxes occurring in managed and in**
13 **unmanaged lands. The sum of 'Land Use' flux (direct effects from bookkeeping models or IAMs)**
14 **and the 'Land Sink' (indirect effects from DGVMs) in managed lands produces an adjusted global**
15 **model CO₂ flux which is conceptually more comparable with LULUCF fluxes from NGHGs. Note**
16 **that the figure may in some cases be an oversimplification, e.g. not all NGHGs include all recent**
17 **indirect effects.**

18
19 **START CROSS-CHAPTER BOX 6 HERE**

20 **Cross-Chapter Box 6 Implications of reconciled anthropogenic land CO₂ fluxes for assessing**
21 **collective climate progress in the global stocktake**

22 Authors: Giacomo Grassi (Italy), Joeri Rogelj (Belgium/Austria), Joanna House (United Kingdom),
23 Alexander Popp (Germany), Detlef van Vuuren (The Netherlands), Katherine Calvin (The United States
24 of America), Shinichiro Fujimori (Japan), Petr Havlik (The Czech Republic), Gert-Jan Nabuurs (The
25 Netherlands)

26 The Global Stocktake aims to assess countries' collective progress towards the long-term goals of the
27 Paris Agreement in the light of the best available science. Historic progress is assessed based on
28 NGHGs, while expectations of future progress are based on country climate targets (e.g., NDCs for
29 2025 or 2030 and long-term strategies for 2050). Scenarios consistent with limiting warming well-

1 below 2°C and 1.5°C developed by IAMs (Chapter 3) are expected to play a key role as benchmarks
2 against which countries' aggregated future mitigation pledges will be assessed. This, however, implies
3 that estimates by IAMs and country data used to measure progress are comparable.

4 In fact, there is ~5.5 GtCO₂ yr⁻¹ difference during 2005-2015 between global anthropogenic land CO₂
5 net flux estimates of IAMs and aggregated NGHGs, due to different conceptual approaches to what is
6 "anthropogenic". This approach and its implications when comparing climate targets with global
7 mitigation pathways are illustrated in this Box Figure 1a-e.

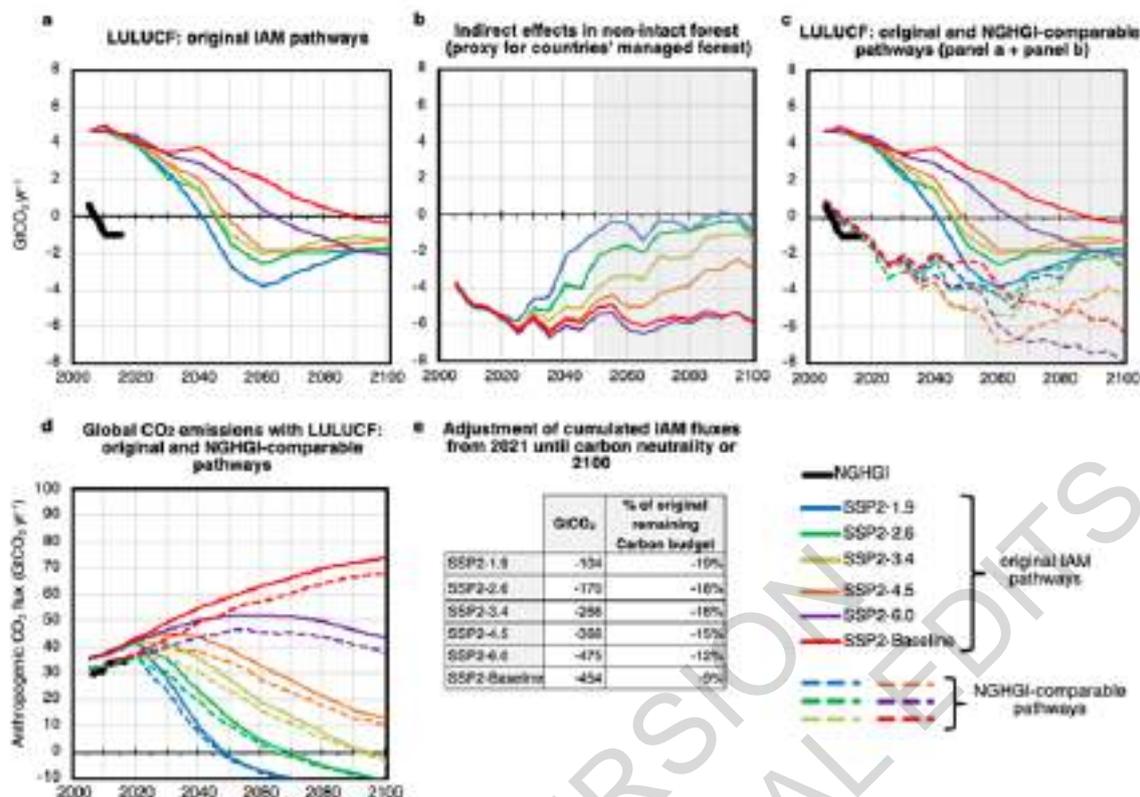

8 By adjusting the original IAM output (Cross-Chapter Box 6, Figure 1a) with the indirect effects from
9 countries' managed forest (Cross-Chapter Box 6, Figure 1b, estimated by DGVMs, see also Figure 7.6),
10 NGHGI-comparable pathways can be derived (Cross-Chapter Box 6, Figure 1c). The resulting apparent
11 increase in anthropogenic sink reflects simply a reallocation of a CO₂ flux previously labelled as natural,
12 and thus does not reflect a mitigation action. These changes do not affect non-LULUCF emissions.
13 However, since the atmosphere concentration is a combination of CO₂ emissions from LULUCF and
14 from fossil fuels, the proposed land-related adjustments also influence the NGHGI-comparable
15 economy-wide (all sector) CO₂ pathways (Cross-Chapter Box 6 Figure 1d).

16 This approach does not imply a change in the original decarbonisation pathways, nor does it suggest
17 that indirect effects should be considered in the mitigation efforts. It simply ensures that a like-with-
18 like comparison is made: if countries' climate targets use the NGHGI definition of anthropogenic
19 emissions, this same definition can be applied to derive NGHGI-comparable future CO₂ pathways. This
20 would have an impact on the NGHGI-comparable remaining carbon or GHG budget (i.e. the allowable
21 emissions until net zero CO₂ or GHG emissions consistent with a certain climate target). For example,
22 for SSP2-1.9 and SSP2-2.6 (representing pathways in line with 1.5°C and well-below 2°C limits under
23 SSP2 assumptions), carbon budget is lower by -170 carbon GtCO₂-eq than the original remaining
24 carbon budget according to the models' approach (Cross-Chapter Box 6, Figure 1e). Similarly, the
25 remaining carbon (or GHG) budgets in Chapter 3 (this report), as well as the net zero carbon (or GHG)
26 targets, could only be used in combination with the definition of anthropogenic emissions as used by
27 the IAMs (Cross-Chapter Box 3 in Chapter 3). In the absence of these adjustments, collective progress
28 would appear better than it is.

29 The UNEP's annual assessment of the global 2030 'emission gap' between aggregated country NDCs
30 and specific target mitigation pathways (UNEP 2020), is only affected to a limited degree. This is
31 because some estimates of global emissions under the NDCs already use the same land-use definitions
32 as the IAM mitigation pathways (Rogelj et al. 2017), and because historical data of global NDC
33 estimates is typically harmonised to the historical data of global mitigation pathway projections (Rogelj
34 et al. 2011). This latter procedure, however, is agnostic to the reasons for the observed mismatch, and
35 often uses a constant offset. The adjustment described here allows this mismatch to be resolved by
36 drawing on a scientific understanding of the underlying reasons, and thus provides a more informed and
37 accurate basis for estimating the emission gap.

38 The approach to deriving a NGHGI-comparable emission pathways presented here can be further
39 refined with improved estimates of the future forest sink. Its use would enable a more accurate
40 assessment of the collective progress achieved and of mitigation pledges under the Paris Agreement.

41

1
2
3 **Cross-Chapter Box 6, Figure 1. Impact on global mitigation pathways of adjusting the modelled**
4 **anthropogenic land CO₂ fluxes to be comparable with National Greenhouse Gas Inventories (NGHGIs)**
5 **(from Grassi et al. 2021). Panel a: The mismatch between global historical LULUCF CO₂ net flux from**
6 **NGHGIs (black), and the original (un-adjusted) modelled flux historically and under future mitigation**
7 **pathways for SSP2 scenarios from Integrated Assessment Models (IAMs, Chapter 3). Panel b: fluxes due**
8 **to indirect effects of environmental change on areas equivalent to countries' managed forest (i.e. those**
9 **fluxes generally considered 'anthropogenic' by countries and 'natural' by global models). Panel c:**
10 **original modelled (solid line) LULUCF mitigation pathways adjusted to be NGHGI-comparable (dashed**
11 **line) i.e. by adding the indirect effects in panel b. The indirect effects in panel b decline over time with**
12 **increasing mitigation ambition, mainly because of the weaker CO₂ fertilisation effect. In Panel c, the**
13 **dependency of the adjusted LULUCF pathways on the target becomes less evident after 2030, because the**
14 **indirect effects in countries' managed forest (which are progressively more uncertain with time, as**
15 **highlighted by the grey areas) compensate the effects of the original pathways. Panel d: NGHGI-**
16 **comparable pathways for global CO₂ emissions from all sectors including LULUCF (obtained by**
17 **combining global CO₂ pathways without LULUCF - where no adjustment is needed - and the NGHGI-**
18 **comparable CO₂ pathways for LULUCF (Gütschow et al. 2019; Grassi et al. 2017). Panel e: Cumulative**
19 **impact of the adjustments from 2021 until net zero CO₂ emissions or 2100 (whatever comes first) on the**
20 **remaining carbon budget.**

21 **END CROSS-CHAPTER BOX 6 HERE**

22 23 **7.2.3 CH₄ and N₂O flux from AFOLU**

24 Trends in atmospheric CH₄ and N₂O concentrations and the associated sources, including land and land
25 use are discussed in Sections 5.2.2 and 5.2.3 of the IPCC WGI sixth assessment report. Regarding
26 AFOLU, the SRCCL and AR5 (Jia et al. 2019; Smith et al. 2014) identified three global non-CO₂
27 emissions data sources; EDGAR (Crippa et al. 2021), FAOSTAT (FAO 2021a; Tubiello, 2019) and the
28 USA EPA (USEPA 2019). Methodological differences have been previously discussed (Jia et al. 2019).

1 In accordance with Chapter 2, this report, EDGAR data are used in Table 7.1 and Figure 7.3. It is
2 important to note that in terms of AFOLU sectoral CH₄ and N₂O emissions, only FAOSTAT provides
3 data on AFOLU emissions, while EDGAR and USEPA data consider just the agricultural component.
4 However, the mean of values across the three databases for both CH₄ and N₂O, fall within the assessed
5 uncertainty bounds (30 and 60% for CH₄ and N₂O respectively, Section 2.2.1, this report) of EDGAR
6 data. NGHGIS annually submitted to the UNFCCC (Section 7.2.2.3) provide national AFOLU CH₄ and
7 N₂O data, as included in the SRCCL (Jia et al. 2019). Aggregation of NGHGIS to indicate global
8 emissions must be considered with caution, as not all countries compile inventories, nor submit
9 annually. Additionally, NGHGIS may incorporate a range of methodologies for CH₄ and N₂O
10 accounting (e.g. Thakuri et al. 2020; Ndung'u et al. 2019; Van der Weerden et al. 2016), making
11 comparison difficult. The analysis of complete AFOLU emissions presented here, is based on
12 FAOSTAT data. For agricultural specific discussion, analysis considers EDGAR, FAOSTAT and
13 USEPA data.

14 7.2.3.1 Global AFOLU CH₄ and N₂O emissions

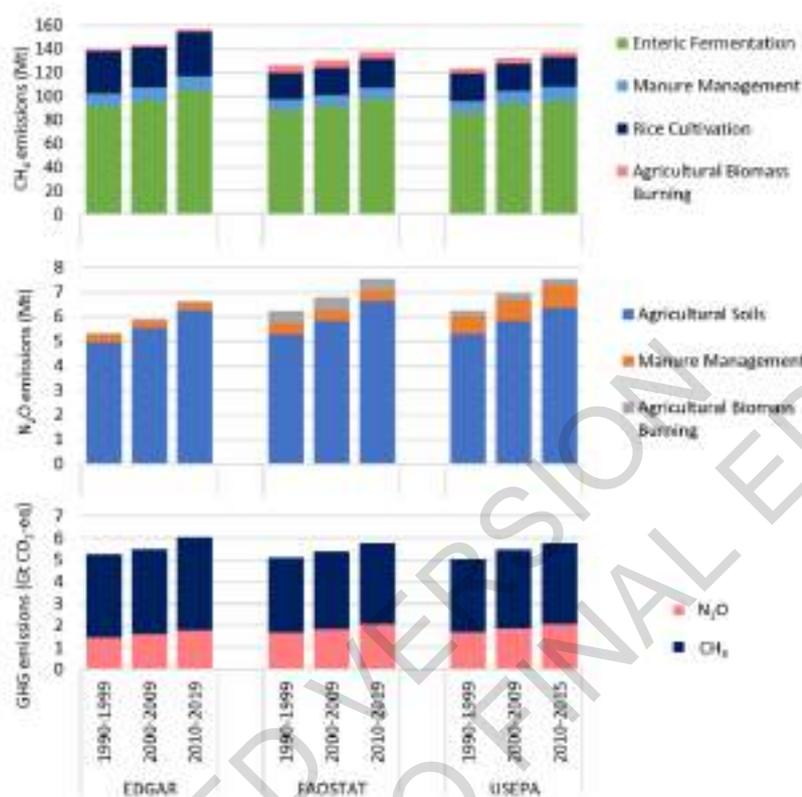

15 Using FAOSTAT data, the SRCCL estimated average CH₄ emissions from AFOLU to be 161.2 ± 43
16 Mt CH₄ yr⁻¹ for the period 2007-2016, representing 44% of total anthropogenic CH₄ emissions, with
17 agriculture accounting for 88% of the AFOLU component (Jia et al. 2019). The latest data (FAO 2021a,
18 2020b) highlight a trend of growing AFOLU CH₄ emissions, with a 10% increase evident between 1990
19 and 2019, despite year-to-year variation. Forestry and other land use (FOLU) CH₄ emission sources
20 include biomass burning on forest land and combustion of organic soils (peatland fires) (FAO 2020c).
21 The agricultural share of AFOLU CH₄ emissions remains relatively unchanged, with the latest data
22 indicating agriculture to have accounted for 89% of emissions on average between 1990 and 2019. The
23 SRCCL reported with *medium evidence* and *high agreement* that ruminants and rice production were
24 the most important contributors to overall growth trends in atmospheric CH₄ (Jia et al. 2019). The latest
25 data confirm this in terms of agricultural emissions, with agreement between databases that agricultural
26 CH₄ emissions continue to increase and that enteric fermentation and rice cultivation remain the main
27 sources (Figure 7.7). The proportionally higher emissions from rice cultivation indicated by EDGAR
28 data compared to the other databases, may result from the use of a Tier 2 methodology for this source
29 within EDGAR (Janssens-Maenhout et al. 2019).

30 The SRCCL also noted a trend of increasing atmospheric N₂O concentration, with *robust evidence* and
31 *high agreement* that agriculture accounted for approximately two-thirds of overall global anthropogenic
32 N₂O emissions. Average AFOLU N₂O emissions were reported to be 8.7 ± 2.5 Mt N₂O yr⁻¹ for the
33 period 2007-2016, accounting for 81% of total anthropogenic N₂O emissions, with agriculture
34 accounting for 95% of AFOLU N₂O emissions (Jia et al. 2019). A recent comprehensive review
35 confirms agriculture as the principal driver of the growing atmospheric N₂O concentration (Tian et al.
36 2020). The latest FAOSTAT data (FAO 2020b, 2021a) document a 25% increase in AFOLU N₂O
37 emissions between 1990 and 2019, with the average share from agriculture remaining approximately
38 the same (96%). Agricultural soils were identified in the SRCCL and in recent literature as a dominant
39 emission source, notably due to nitrogen fertiliser and manure applications to croplands, and manure
40 production and deposition on pastures (Jia et al. 2019; Tian et al. 2020). There is agreement within latest
41 data that agricultural soils remain the dominant source (Figure 7.7).

42 Aggregation of CH₄ and N₂O to CO₂ equivalence (using GWP₁₀₀ IPCC AR6 values), suggests that
43 AFOLU emissions increased by 15% between 1990 and 2019, though emissions showed trend
44 variability year to year. Agriculture accounted for 91% of AFOLU emissions on average over the period
45 (FAO 2020b, 2021a). EDGAR (Crippa et al. 2021), FAOSTAT (FAO 2021a) and USEPA (USEPA
46 2019) data suggest aggregated agricultural emissions (CO₂-eq) to have increased since 1990, by 19

1 (1990-2019), 15 (1990-2019) and 21 (1990-2015) % respectively, with all databases identifying enteric
 2 fermentation and agricultural soils as the dominant agricultural emissions sources.

3

4

5 **Figure 7.7** Estimated global mean agricultural CH₄ (Top), N₂O (Middle) and aggregated CH₄ and
 6 N₂O (using CO₂-eq according to GWP₁₀₀ AR6 values) (Bottom) emissions for three decades
 7 according to EDGARv6.0 (Crippa et al. 2021), FAOSTAT (FAO 2021a) and USEPA (USEPA 2019)
 8 databases. Latest versions of databases indicate historic emissions to 2019, 2019 and 2015
 9 respectively, with average values for the post-2010 period calculated accordingly. For CH₄,
 10 emissions classified as ‘Other Ag.’ within USEPA data, are re-classified as ‘Agricultural Biomass
 11 Burning’. Despite CH₄ emissions from agricultural soils also being included, this category was
 12 deemed to principally concern biomass burning on agricultural land and classified accordingly. For
 13 N₂O, emissions classified within EDGAR as direct and indirect emissions from managed soils, and
 14 indirect emissions from manure management are combined under ‘Agricultural Soils’. Emissions
 15 classified by FAOSTAT as from manure deposition and application to soils, crop residues, drainage
 16 of organic soils and synthetic fertilisers are combined under ‘Agricultural Soils’, while emissions
 17 reported as ‘Other Ag.’ under USEPA data are re-classified as ‘Agricultural Biomass Burning’.

18

19 7.2.3.2 Regional AFOLU CH₄ and N₂O emissions

20 FAOSTAT data (FAO 2020b, 2021a) indicate Africa (+ 44%), followed by Southern Asia (+ 29%) to
 21 have the largest growth in AFOLU CH₄ emissions between 1990 and 2019 (Figure 7.8). Eurasia was
 22 characterised by notable emission reductions (–58%), principally as a result of a sharp decline (–63%)

1 between 1990 and 1999. The average agricultural share of AFOLU emissions between 1990 and 2019
2 ranged from 66% in Africa to almost 100% in the Middle East.

3 In agreement with AR5 (Smith et al. 2014), the SRCCL identified Asia as having the largest share
4 (37%) of emissions from enteric fermentation and manure management since 2000, but Africa to have
5 the fastest growth rate. Asia was identified as responsible for 89% of rice cultivation emissions, which
6 were reported as increasing (Jia et al. 2019). Considering classification by ten IPCC regions, data
7 suggest enteric fermentation to have dominated emissions in all regions since 1990, except in South-
8 east Asia and Developing Pacific, where rice cultivation forms the principal source (FAO 2021; USEPA
9 2019). The different databases broadly indicate the same regional CH₄ emission trends, though the
10 indicated absolute change differs due to methodological differences (Section 7.2.3.1). All databases
11 indicate considerable emissions growth in Africa since 1990 and that this region recorded the greatest
12 regional increases in emissions from both enteric fermentation and rice cultivation since 2010.
13 Additionally, FAOSTAT data suggest that emissions from agricultural biomass burning account for a
14 notably high proportion of agricultural CH₄ emissions in Africa (Figure 7.8).

15 The latest data suggest growth in AFOLU N₂O emissions in most regions between 1990 and 2019, with
16 Southern Asia demonstrating highest growth (+ 74%) and Eurasia, greatest reductions (- 51%), the latter
17 mainly a result of a 61% reduction between 1990 and 2000 (FAO 2020b, 2021a). Agriculture was the
18 dominant emission source in all regions, its proportional average share between 1990 and 2019 ranging
19 from 87% in Africa, to almost 100% in the Middle East (Figure 7.8).

20 The SRCCL provided limited discussion on regional variation in agricultural N₂O emissions but
21 reported with *medium confidence* that certain regions (North America, Europe, East & South Asia) were
22 notable sources of grazing land N₂O emissions (Jia et al. 2019). AR5 identified Asia as the largest
23 source and as having the highest growth rate of N₂O emissions from synthetic fertilisers between 2000
24 and 2010 (Smith et al. 2014). Latest data indicate agricultural N₂O emission increases in most regions,
25 though variation between databases prevents definitive conclusions on trends, with Africa, Southern
26 Asia, and Eastern Asia suggested to have had greatest growth since 1990 according to EDGAR (Crippa
27 et al. 2021), FAOSTAT (FAO 2021a) and USEPA (USEPA 2019) data respectively. However, all
28 databases indicate that emissions declined in Eurasia and Europe from 1990 levels, in accordance with
29 specific environmental regulations put in place since the late 1980s (Tubiello 2019; European
30 Environment Agency 2020; Tian et al. 2020), but generally suggest increases in both regions since
31 2010.

32

1
2 **Figure 7.8** Estimated average AFOLU CH₄ (Top) and N₂O (Bottom) emissions for three decades
3 according to FAOSTAT data by ten global regions, with disaggregation of agricultural emissions
4 (FAO 2020b; 2021a). Note for N₂O, emissions from manure deposition and application to soils,
5 crop residues and synthetic fertilisers are combined under ‘Agricultural Soils’.

7 7.2.4 Biophysical effects and short-lived climate forcers

8 Despite new literature, general conclusions from the SRCCL and WGI-AR6 on biophysical effects and
9 short-lived climate forcers remain the same. Changes in land conditions from land cover change or land
10 management jointly affect water, energy, and aerosol fluxes (biophysical fluxes) as well as GHG fluxes
11 (biogeochemical fluxes) exchanged between the land and atmosphere (*high agreement, robust*
12 *evidence*) (Erb et al. 2017; Alkama and Cescatti 2016; Naudts et al. 2016; O’Halloran et al. 2012;
13 Anderson et al. 2011). There is *high confidence* that changes in land condition do not just have local
14 impacts but also have non-local impacts in adjacent and more distant areas (Mahmood et al. 2014;
15 Pielke et al. 2011) which may contribute to surpassing climate tipping points (Brando et al. 2014;
16 Nepstad et al. 2008). Non-local impacts may occur through: GHG fluxes and subsequent changes in
17 radiative transfer, changes in atmospheric chemistry, thermal, moisture and surface pressure gradients
18 creating horizontal transport (advection) (De Vrese et al. 2016; Davin and de Noblet-Ducoudre 2010)
19 and vertical transport (convection and subsidence) (Devaraju et al. 2018). Although regional and global
20 biophysical impacts emerge from model simulations (Devaraju et al. 2018; De Vrese et al. 2016; Davin
21 and de Noblet-Ducoudre 2010), especially if the land condition has changed over large areas, there is
22 *very low agreement* on the location, extent and characteristics of the non-local effects across models.

1 Recent methodological advances, empirically confirmed changes in temperature and precipitation
2 owing to distant changes in forest cover (Meier et al. 2021; Cohn et al. 2019).

3 Following changes in land conditions, CO₂, CH₄ and N₂O fluxes are quickly mixed into the atmosphere
4 and dispersed, resulting in the biogeochemical effects being dominated by the biophysical effects at
5 local scales (*high confidence*) (Alkama and Cescatti 2016; Li et al. 2015). Afforestation/reforestation
6 (Strandberg and Kjellström 2019; Lejeune et al. 2018), urbanisation (Li and Bou-Zeid 2013) and
7 irrigation (Thiery et al. 2017; Mueller et al. 2016) modulate the likelihood, intensity, and duration of
8 many extreme events including heatwaves (*high confidence*) and heavy precipitation events (*medium*
9 *confidence*) (Haberlie et al. 2015). There is *high confidence and high agreement* that afforestation in
10 the tropics (Perugini et al. 2017), irrigation (Mueller et al. 2016; Alter et al. 2015) and urban greening
11 result in local cooling, *high agreement and medium confidence* on the impact of tree growth form
12 (deciduous vs. evergreen) (Schwaab et al. 2020; Luysaert et al. 2018; Naudts et al. 2016), and *low*
13 *agreement* on the impact of wood harvest, fertilisation, tillage, crop harvest, residue management,
14 grazing, mowing, and fire management on the local climate.

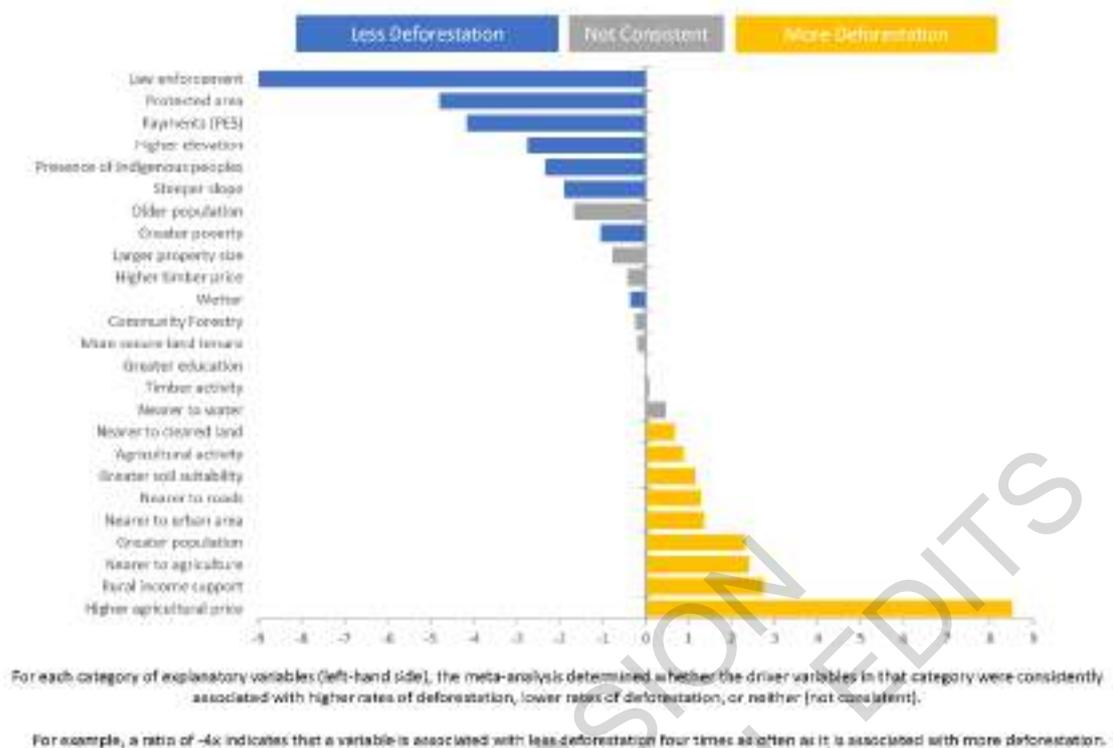

15 Studies of biophysical effects have increased since AR5 reaching *high agreement* for the effects of
16 changes in land condition on surface albedo (Leonardi et al. 2015). *Low confidence* remains in
17 proposing specific changes in land conditions to achieve desired impacts on local, regional and global
18 climates due to: a poor relationship between changes in surface albedo and changes in surface
19 temperature (Davin and de Noblet-Ducoudre 2010), compensation and feedbacks among biophysical
20 processes (Kalliokoski et al. 2020; Bonan 2016), climate and seasonal dependency of the biophysical
21 effects (Bonan 2016), omission of short-lived chemical forcers (Kalliokoski et al. 2020; Unger 2014),
22 and study domains often being too small to document possible conflicts between local and non-local
23 effects (Hirsch et al. 2018; Swann et al. 2012).

24

25 7.3 Drivers

26 Since AR5 several global assessments (IPBES 2018; NYDF Assessment Report. 2019; UN
27 Environment 2019; IPCC 2019) and studies (e.g. Tubiello 2019; Tian et al. 2020) have reported on
28 drivers (natural and anthropogenic factors that affect emissions and sinks of the land use sector) behind
29 AFOLU emissions trends, and associated projections for the coming decades. The following analysis
30 aligns with the drivers typology used by (IPBES (2019) and the Global Environmental Outlook (UN
31 Environment 2019). Drivers are divided into direct drivers resulting from human decisions and actions
32 concerning land use and land-use change, and indirect drivers that operate by altering the level or rate
33 of change of one or more direct drivers. Although drivers of emissions in Agriculture and FOLU are
34 presented separately, they are interlinked, operating in many complex ways at different temporal and
35 spatial scales, with outcomes depending on their interactions. For example, deforestation in tropical
36 forests is a significant component of sectorial emissions. A review of deforestation drivers' studies
37 published between 1996 and 2013, indicated a wide range of factors associated with deforestation rates
38 across many analyses and studies, covering different regions (Figure 7.9; Busch and Ferretti-Gallon
39 2017). Higher agricultural prices were identified as a key driver of deforestation, while law
40 enforcement, area protection, and ecosystem services payments were found to be important drivers of
41 reduced deforestation, while timber activity did not show a consistent impact

42

4 **7.3.1 Anthropogenic direct drivers – Deforestation, conversion of other ecosystems, and** 5 **land degradation**

6 The global forest area in 2020 is estimated at 4.1 billion ha, representing 31% of the total land area
7 (FAO 2020a). Most forests are situated in the tropics (45%), followed by boreal (27%), temperate (16%)
8 and subtropical (11%) domains. Considering regional distribution of global forest area, Europe and the
9 Russian Federation accounts for 25%, followed by South America (21%), North and Central America
10 (19%), Africa (16%), Asia (15%) and Oceania (5%). However, a significant share (54%) of the world's
11 forest area concerns five countries – the Russian Federation, Brazil, Canada, the USA and China (FAO
12 2020a). Forest loss rates differ among regions though the global trend is towards a net forest loss (UN
13 Environment 2019). The global forest area declined by about 178 Mha in the 30 years from 1990 to
14 2020 (FAO 2020a). The rate of net forest loss has decreased since 1990, a result of reduced deforestation
15 in some countries and forest gains in others. The annual net loss of forest area declined from 7.8 Mha
16 in 1990–2000, to 5.2 Mha in 2000–2010, to 4.7 Mha in 2010–2020, while the total growing stock in
17 global forests increased (FAO 2020a). The rate of decline in net forest loss during the last decade was
18 due mainly to an increase in the rate of forest gain (i.e. afforestation and the natural expansion of
19 forests).

20 Globally, the area of the more open, other wooded land is also of significant importance, with almost 1
21 billion hectares (FAO 2020a). The area of other wooded land decreased by 30.6 Mha between 1990
22 and 2020 with larger declines between 1990–2000 (FAO 2020a). There are still significant challenges
23 in monitoring the area of other wooded land, largely associated with difficulties in measuring tree-
24 canopy cover in the range of 5–10%. The global area of mangroves, one of the most productive terrestrial
25 ecosystems (Neogi 2020a), has also experienced a significant decline (Thomas et al. 2017; Neogi
26 2020b), with a decrease of 1.0 Mha between 1990 and 2020 (FAO 2020a) due to agriculture and

1 aquaculture (Bhattarai 2011; Ajonina et al. 2014; Webb et al. 2014; Giri et al. 2015; Fauzi et al. 2019;
2 Thomas et al. 2017). Some relevant direct drivers affecting emissions and removal in forests and other
3 ecosystems are discussed in proceeding sections.

4 **7.3.1.1. Conversion of natural ecosystems to agriculture**

5 Previous IPCC reports identify land use change as an important driver of emissions and agriculture as
6 a key driver of land use change, causing both deforestation and wetland drainage (Smith et al. 2019d).
7 AR5 reported a trend of declining global agricultural land area since 2000 (Smith et al. 2014). The latest
8 data (FAO 2021b) indicate a 2% reduction in the global agricultural area between 2000 and 2019
9 (Figure 7.10). This area includes (though is not limited to) land under permanent and temporary crops
10 or pasture, temporary fallow and natural meadows and pasture utilized for grazing or agricultural
11 purposes (FAO 2021b), although the extent of land used for grazing may not be fully captured (Fetzel
12 et al. 2017). Data indicate changes in how agricultural land is used. Between 2000 and 2019, the area
13 classified as permanent meadow and pasture decreased (- 6%) while cropland area (under arable
14 production and temporary crops) increased (+ 2%). A key driver of this change has been a general trend
15 of intensification, including in livestock production (Barger et al. 2018; OECD/FAO 2019; UN
16 Environment 2019), whereby less grazing land is supporting increasing livestock numbers in
17 conjunction with greater use of crops as livestock feed (Barger et al. 2018). The share of feed crops,
18 such as maize and soybean, of global crop production is projected to grow as the demand for animal
19 feed increases with further intensification of livestock production (OECD/FAO 2019). Despite
20 increased demand for food, feed, fuel and fibre from a growing human population (FAO 2019b), global
21 agricultural land area is projected to remain relatively stable during the next decade, with increases in
22 production expected to result from agricultural intensification (OECD/FAO 2019).

23 Despite a decline in global agricultural area, the latest data document some regional expansion between
24 2000 and 2019, specifically in Africa (+ 3%) and Asia and the Developing Pacific (+ 1%). Agricultural
25 area declined in all other regions, notably in developed countries (- 9%), due to multiple factors
26 including among others, urbanisation (see Section 7.3.1.2).

27 **7.3.1.2. Infrastructure development and urbanisation**

28 Although built-up areas (defined as cities, towns, villages and human infrastructure) occupy a relatively
29 small fraction of land (around 1% of global land), since 1975 urban clusters (i.e. urban centres as well
30 as surrounding suburbs) have expanded approximately 2.5 times (UN Environment 2019; Chapter 8,
31 this report). Regional differences are striking. Between 1975 and 2015, built-up areas doubled in size
32 in Europe while urban population remained relatively constant. In Africa built-up areas grew
33 approximately fourfold, while urban population tripled (UN Environment 2019). Trends indicate that
34 rural-to-urban migration will continue and accelerate in developing countries increasing environmental
35 pressure in spite of measures to mitigate some of the impacts (e.g. by preserving or enhancing natural
36 systems within cities for example lakes or natural and urban green infrastructures (UN Environment
37 2019). If current population densities within cities remain stable, the extent of built-up areas in
38 developed countries is expected to increase by 30% and triple in developing countries between 2000
39 and 2050 (Barger et al. 2018).

40 Urban expansion leads to landscape fragmentation and urban sprawl with effects on forest resources
41 and land use (Ünal et al. 2019) while interacting with other drives. For example, in the Brazilian
42 Amazon, the most rapid urban growth occurs within cities that are located near rural areas that produce
43 commodities (minerals or crops) and are connected to export corridors (Richards and VanWey 2015).
44 Urbanisation, coastal development and industrialisation also play crucial roles in the significant loss of
45 mangrove forests (Richards and Friess 2016; Hiraes-Cota 2010; Rivera-Monroy et al. 2017). Among
46 infrastructural developments, roads are one of the most consistent and most considerable factors in

1 deforestation, particularly in tropical frontiers (Pfaff et al. 2007; Rudel et al. 2009; Ferretti-Gallon and
2 Busch 2014). The development of roads may also bring subsequent impacts on further development
3 intensity due to increasing economic activities (see Chapter 8) mostly in the tropics and subtropics,
4 where the expansion of road networks increases access to remote forests that act as refuges for
5 biodiversity (Campbell et al. 2017) (Box 7.1). Logging is one of the main drivers of road construction
6 in tropical forests (Kleinschroth and Healey 2017) which leads to more severe long term impacts that
7 include increased fire incidence, soil erosion, landslides, and sediment accumulation in streams,
8 biological invasions, wildlife poaching, illicit land colonisation, illegal logging and mining, land
9 grabbing and land speculation (Laurance et al. 2009; Alamgir et al. 2017).

10

11 **[START BOX 7.1 HERE]**12 **Box 7.1 Case study: Reducing the impacts of roads on deforestation**13 **Summary**

14 Rapidly expanding roads, particularly in tropical regions, are linked to forest loss, degradation, and
15 fragmentation because the land becomes more generally accessible. Increase of land values of areas
16 adjacent to roads also drives speculation and deforestation related to land tenure (Fearnside 2015). If
17 poorly planned, infrastructure can facilitate fires, illegal mining, and wildlife poaching with
18 consequences for GHG emissions and biodiversity conservation. However, some initiatives are
19 providing new approaches for better planning and then limit environmental and societal impacts.

20 **Background**

21 Although the number and extent of protected areas has increased markedly in recent decades (Watson
22 et al. 2014), many other indicators reveal that nature is in broad retreat. For example, the total area of
23 intact wilderness is declining rapidly worldwide (Watson et al. 2016), 70% of the world's forests are
24 now less than 1 km from a forest edge (Haddad et al. 2015), the extent of tropical forest fragmentation
25 is accelerating exponentially (Taubert et al. 2018). One of the most direct and immediate driver of
26 deforestation and biodiversity decline is the dramatic expansion of roads and other transportation
27 infrastructure (Laurance et al. 2014a; Laurance and Arrea 2017; Alamgir et al. 2017).

28 **Case description**

29 From 2010 to 2050, the total length of paved roads is projected to increase by 25 million km (Dulac
30 2013) including large infrastructure-expansion schemes in Asia (Lechner et al. 2018; Laurance and
31 Arrea 2017) and in South America (Laurance et al. 2001; Killeen 2007)—as well as widespread illegal
32 or unplanned road building (Barber et al. 2014; Laurance et al. 2009). For example, in the Amazon,
33 95% of all deforestation occurs within 5.5 km of a road, and for every km of legal road there are nearly
34 three km of illegal roads (Barber et al. 2014).

35 **Interactions and limitations**

36 More than any other proximate factor, the dramatic expansion of roads is determining the pace and
37 patterns of habitat disruption and its impacts on biodiversity (Laurance et al. 2009; Laurance and Arrea
38 2017). Much road expansion is poorly planned. Environmental Impact Assessments (EIAs) for roads
39 and other infrastructure are typically too short-term and superficial to detect rare species or assess long-
40 term or indirect impacts of projects (Flyvbjerg 2009; Laurance and Arrea 2017). Another limitation is
41 the consideration of each project in isolation from other existing or planned developments (Laurance et
42 al. 2014b). Hence, EIAs alone are inadequate for planning infrastructure projects and assessing their

1 broader environmental, social, and financial impacts and risks (Laurance et al. 2015a; Alamgir et al.
2 2018, 2017).

3 **Lessons**

4 The large-scale, proactive land-use planning is an option for managing the development of modern
5 infrastructure. Approaches such as the “Global Roadmap” scheme (Laurance and Balmford 2013;
6 Laurance et al. 2014a) Strategic Environmental Assessments (Fischer 2007) can be used to evaluate the
7 relative costs and benefits of infrastructure projects, and to spatially prioritise land-uses to optimise
8 human benefits while limited new infrastructure in areas of intact or critical habitats. For example, the
9 Global Roadmap strategy has been used in parts of Southeast Asia (Sloan et al. 2018), Indochina
10 (Balmford et al. 2016), and sub-Saharan Africa (Laurance et al. 2015b) to devise land-use zoning that
11 can help optimise the many risks and rewards of planned infrastructure projects.

12 **[END BOX 7.1 HERE]**

13

14 **7.3.1.3. Extractive industry development**

15 The extent and scale of mining is growing due to increased global demand (UN Environment 2019).
16 Due to declining ore grades, more ore needs to be processed to meet demand, with extensive use of
17 open cast mining. A low-carbon future may be more mineral intensive with for example, clean energy
18 technologies requiring greater inputs in comparison to fossil-fuel-based technologies (Hund et al. 2020).
19 Mining presents cumulative environmental impacts, especially in intensively mined regions (UN
20 Environment 2019). The impact of mining on deforestation varies considerably across minerals and
21 countries. Mining causes significant changes to the environment, for example through mining
22 infrastructure establishment, soil erosion, urban expansion to support a growing workforce and
23 development of mineral commodity supply chains (Sonter et al. 2015). The increasing consumption of
24 gold in developing countries, increased prices, and uncertainty in financial markets is identified as
25 driving gold mining and associated deforestation in the Amazon region (Alvarez-Berrios and Mitchell
26 Aide 2015; Dezécache et al. 2017; Asner and Tupayachi 2017; Espejo et al. 2018). The total estimated
27 area of gold mining throughout the region increased by about 40% between 2012 and 2016 (Asner and
28 Tupayachi 2017). In the Brazilian Amazon, mining significantly increased forest loss up to 70 km
29 beyond mining lease boundaries, causing 11,670 km² of deforestation between 2005 and 2015,
30 representing 9% of all Amazon forest loss during this time (Sonter et al. 2015).

31 Mining is also an important driver of deforestation in African and Asian countries. In the Democratic
32 Republic of Congo, where the second-largest area of tropical forest in the world occurs, mining-related
33 deforestation exacerbated by violent conflict (Butsic et al. 2015). In India, mining has contributed to
34 deforestation at a district level, with coal, iron and limestone having had the most adverse impact on
35 forest area loss (Ranjan 2019). Gold mining is also identified as a driver of deforestation in Myanmar
36 (Papworth et al. 2017).

37 **7.3.1.4. Fire regime changes**

38 Wildland fires account for approximately 70% of the global biomass burned annually (Van Der Werf
39 et al. 2017) and constitute a large global source of atmospheric trace gases and aerosols (Gunsch et al.
40 2018; IPCC WGI AR6). Although fires are part of the natural system, the frequency of fires has
41 increased in many areas, exacerbated by decreases in precipitation, including in many regions with
42 humid and temperate forests that rarely experience large-scale fires naturally. Natural and human-
43 ignited fires affect all major biomes, from peatlands through shrublands to tropical and boreal forests,
44 altering ecosystem structure and functioning (Argañaraz et al. 2015; Engel et al. 2019; Mancini et al.
45 2018; Remy et al. 2017; Nunes et al. 2016; Aragão et al. 2018; (Rodríguez Vásquez et al. 2021).

1 However, the degree of incidence and regional trends are quite different and a study over 14 year
2 indicated, on average, the largest fires in Australia, boreal North America and Northern Hemisphere
3 Africa (Andela et al. 2019). More than half of the terrestrial surface of the Earth has fire regimes outside
4 the range of natural variability, with changes in fire frequency and intensity posing major challenges
5 for land restoration and recovery (Barger et al. 2018). In some ecosystems, fire prevention might lead
6 to accumulation of large fuel loads that enable wildfires (Moreira et al. 2020a).

7 About 98 Mha of forest and savannahs are estimated to have been affected by fire in 2015 (FAO and
8 UNEP 2020). Fire is a prevalent forest disturbance in the tropics where about 4% of the total forest and
9 savannah area in that year was burned and more than two-thirds of the total area affected was in Africa
10 and South America; mostly open savanna types (FAO and UNEP 2020). Fires have many different
11 causes, with land clearing for agriculture the primary driver in tropical regions, for example, clearance
12 for industrial oil-palm and paper-pulp plantations in Indonesia (Chisholm et al. 2016), or for pastures
13 in the Amazon (Barlow et al. 2020). Other socioeconomic factors are also associated with wildfire
14 regimes such as land-use conflict and socio-demographic aspects (Nunes et al. 2016; Mancini et al.
15 2018). Wildfire regimes are also changing by the influence of climate change, with wildfire seasons
16 becoming longer, wildfire average size increases in many areas and wildfires occurring in areas where
17 they did not occur before (Jolly et al. 2015; Artés et al. 2019). Human influence has likely increased
18 fire weather in some regions of all inhabited continents (IPCC WGI AR6 Technical Summary) and, in
19 the last years, fire seasons of unprecedented magnitude occurred in diverse regions as California (Goss
20 et al. 2020), the Mediterranean basin (Ruffault et al. 2020), Canada (Kirchmeier-Young et al. 2019)
21 with unprecedented fires in British Columbia in 2021, the Arctic and Siberia (McCarty et al. 2020),
22 Brazilian Amazon (Silva et al. 2021b) and Pantanal (Leal Filho et al. 2021), Chile (Bowman et al. 2019)
23 and Australia (Gallagher et al. 2021; Ward et al. 2020). Lightning plays an important role in the ignition
24 of wildfires, with the incidence of lightning igniting wildfires predicted to increase with rises in global
25 average air temperature (Worden et al. 2017).

26 **7.3.1.5. Logging and fuelwood harvest**

27 The area of forest designated for production has been relatively stable since 1990. Considering forest
28 uses, about 30% (1.2 billion ha) of all forests is used primarily for production (wood and non-wood
29 forest products), about 10% (424 Mha) is designated for biodiversity conservation, 398 Mha for the
30 protection of soil and water, and 186 Mha is allocated for social services (recreation, tourism, education
31 research and the conservation of cultural and spiritual sites) (FAO and UNEP 2020). While the rate of
32 increase in the area of forest allocated primarily for biodiversity conservation has slowed in the last ten
33 years, the rate of increase in the area of forest allocated for soil and water protection has grown since
34 1990, and notably in the last ten years. Global wood harvest (including from forests, other wooded land
35 and trees outside forests) was estimated to be almost 4.0 billion m³ in 2018 (considering both industrial
36 roundwood and fuelwood) (FAO, 2019). Overall, wood removals are increasing globally as demand
37 for, and the consumption of wood products grows annually by 1% in line with growing populations and
38 incomes with this trend expected to continue in coming decades. When done in a sustainable way, more
39 regrowth will occur and is stimulated by management, resulting in a net sink. However illegal and
40 unsustainable logging (i.e. harvesting of timber in contravention of the laws and regulations of the
41 country of harvest) is a global problem with significant negative economic (e.g. lost revenue),
42 environmental (e.g. deforestation, forest degradation, GHG emissions and biodiversity losses) and
43 social impact (e.g. conflicts over land and resources, disempowerment of local and indigenous
44 communities) (World Bank 2019). Many countries around the world have introduced regulations for
45 the international trade of forest products to reduce illegal logging, with significant and positive impacts
46 (Guan et al. 2018).

1 Over-extraction of wood for timber and fuelwood) is identified as an important driver of mangrove
2 deforestation and degradation (Fauzi et al. 2019; Bhattarai 2011; Ajonina et al. 2014; Webb et al. 2014;
3 Giri et al. 2015; Thomas et al. 2017; Bhattarai 2011; Ajonina et al. 2014; Webb et al. 2014; Giri et al.
4 2015; Thomas et al. 2017; Fauzi et al. 2019). Unsustainable selective logging and over-extraction of
5 wood is a substantial form of forest and mangrove degradation in many tropical and developing
6 countries, with emissions associated with the extracted wood, incidental damage to the surrounding
7 forest and from logging infrastructure (Pearson et al. 2014, (Fauzi et al. 2019; Bhattarai 2011; Ajonina
8 et al. 2014; Webb et al. 2014; Giri et al. 2015; Thomas et al. 2017).). Traditional fuelwood and charcoal
9 continue to represent a dominant share of total wood consumption in low-income countries (Barger et
10 al. 2018). Regionally, the percentage of total wood harvested used as fuelwood varies from 90% in
11 Africa, 62 % in Asia, 50% in South America to less than 20 % in Europe, North America and Oceania.
12 Under current projections, efforts to intensify wood production in plantation forests, together with
13 increases in fuel-use efficiency and electrification, are suggested to only partly alleviate the pressure on
14 native forests (Barger et al. 2018). Nevertheless, the area of forest under management plans has
15 increased in all regions since 2000 by 233 Mha (FAO-FRA 2020). In regions representing the majority
16 of industrial wood production, forests certified under sustainable forest management programs
17 accounted for 51% of total managed forest area in 2017, an increase from 11% in 2000 (ICFPA 2021).

18 **7.3.2. Anthropogenic direct drivers – Agriculture**

19 **7.3.2.1. Livestock populations and management**

20 Enteric fermentation dominates agricultural CH₄ emissions (Section 7.2.3) with emissions being a
21 function of both ruminant animal numbers and productivity (output per animal). In addition to enteric
22 fermentation, both CH₄ and N₂O emissions from manure management (i.e. manure storage and
23 application) and deposition on pasture, make livestock the main agricultural emissions source (Tubiello
24 2019). AR5 reported increases in populations of all major livestock categories between the 1970s and
25 2000s, including ruminants, with increasing numbers directly linked with increasing CH₄ emissions
26 (Smith et al. 2014). The SRCCL identified managed pastures as a disproportionately high N₂O
27 emissions source within grazing lands, with *medium confidence* that increased manure production and
28 deposition was a key driver (Jia et al. 2019). The latest data (FAO 2021c) indicate continued global
29 livestock population growth between 1990 and 2019 (Figure 7.10), including increases of 18% in cattle
30 and buffalo numbers, and 30% in sheep and goat numbers, corresponding with CH₄ emission trends.
31 Data also indicate increased productivity per animal for example, average increases of 16% in beef,
32 17% in pig meat and 70% in whole (cow) milk per respective animal between 1990 and 2019 (FAO
33 2021c). Despite these advances leading to reduced emissions per unit of product (calories, meat and
34 milk) (FAO 2016; Tubiello 2019), increased individual animal productivity generally requires increased
35 inputs (e.g. feed) and this generates increased emissions (Beauchemin et al. 2020). Manipulation of
36 livestock diets, or improvements in animal genetics or health may counteract some of this. In addition,
37 the production of inputs to facilitate increased animal productivity, may indirectly drive further absolute
38 GHG emissions along the feed supply chain.

39 Although there are several potential drivers (McDermott et al. 2010; Alary V. 2015), increased livestock
40 production is principally in response to growth in demand for animal-sourced food, driven by a growing
41 human population (FAO, 2019) and increased consumption resulting from changes in affluence, notably
42 in middle-income countries (Godfray et al. 2018). Available data document increases in total meat and
43 milk consumption by 24 and 22% respectively between 1990 and 2013, as indicated by average annual
44 per capita supply (FAO 2017a). Updated data indicate that trends of increasing consumption continued
45 between 2014 and 2018 (FAO 2021d). Sustained demand for animal-sourced food is expected to drive

1 further livestock sector growth, with global production projected to expand by 14% by 2029, facilitated
2 by maintained product prices and lower feed prices (OECD/FAO 2019).

3 **7.3.2.2. Rice cultivation**

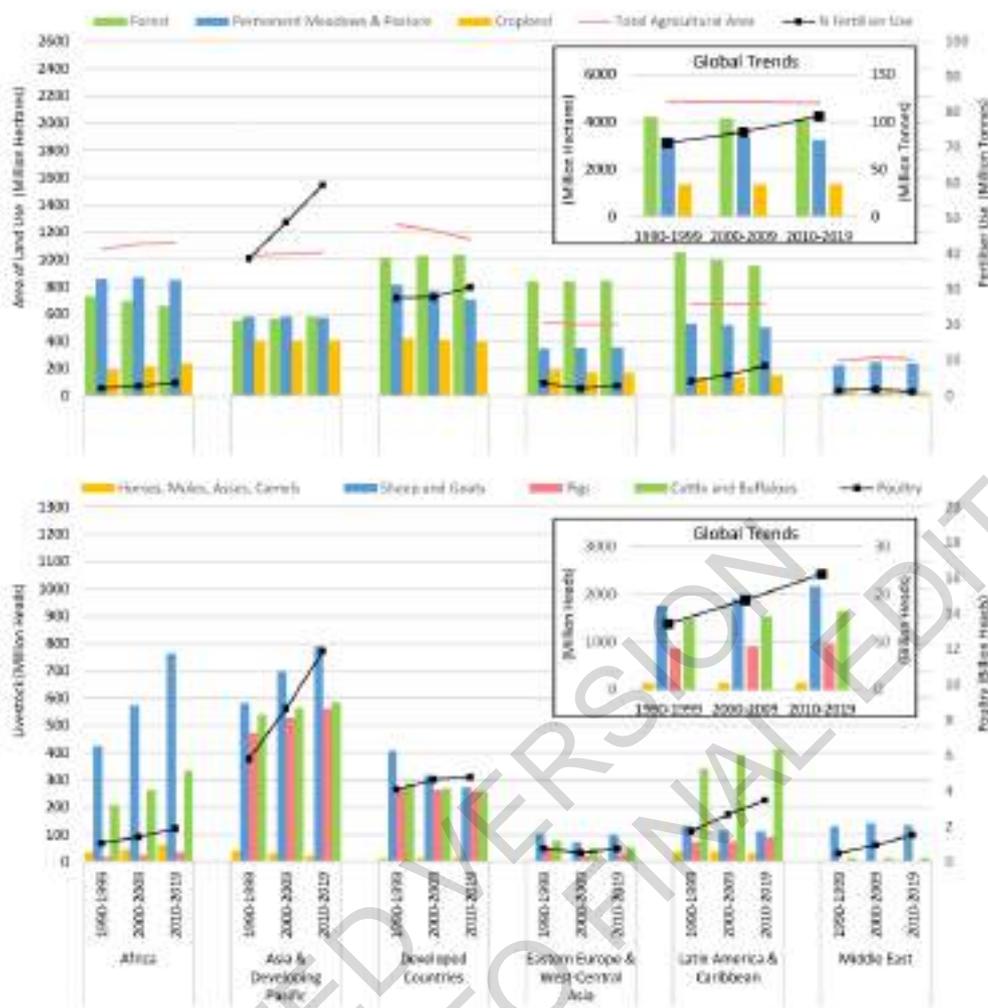

4 In addition to livestock, both AR5 and the SRCCL identified paddy rice cultivation as an important
5 emissions source (Smith et al. 2014), with *medium evidence* and *high agreement* that its expansion is a
6 key driver of growing trends in atmospheric CH₄ concentration (Jia et al. 2019). The latest data indicate
7 the global harvested area of rice to have grown by 11% between 1990 and 2019, with total paddy
8 production increasing by 46%, from 519 Mt to 755 Mt (FAO 2021c). Global rice production is projected
9 to increase by 13% by 2028 compared to 2019 levels (OECD/FAO 2019). However, yield increases are
10 expected to limit cultivated area expansion, while dietary shifts from rice to protein as a result of
11 increasing per capita income, is expected to reduce demand in certain regions, with a slight decline in
12 related emissions projected to 2030 (USEPA 2019).

13 Between 1990 and 2019, Africa recorded the greatest increase (+160%) in area under rice cultivation,
14 followed by Asia and the Developing Pacific (+6%), with area reductions evident in all other regions
15 (FAO 2021c) broadly corresponding with related regional CH₄ emission (Figures 7.3 and 7.8). Data
16 indicate the greatest growth in consumption (average annual supply per capita) between 1990 and 2013
17 to have occurred in Eastern Europe and West Central Asia (+ 42%) followed by Africa (+ 25%), with
18 little change (+ 1%) observed in Asia and the Developing Pacific (FAO 2017a). Most of the projected
19 increase in global rice consumption is in Africa and Asia (OECD/FAO 2019).

20 **7.3.2.3. Synthetic fertiliser use**

21 Both AR5 and the SRCCL described considerable increases in global use of synthetic nitrogen fertilisers
22 since the 1970s, which was identified to be a major driver of increasing N₂O emissions (Jia et al. 2019).
23 The latest data document a 41% increase in global nitrogen fertiliser use between 1990 and 2019 (FAO
24 2021e) corresponding with associated increased N₂O emissions (Figure 7.3). Increased fertiliser use has
25 been driven by pursuit of increased crop yields, with for example, a 61% increase in average global
26 cereal yield per hectare observed during the same period (FAO 2021c), achieved through both increased
27 fertiliser use and varietal improvements. Increased yields are in response to increased demand for food,
28 feed, fuel and fibre crops which in turn has been driven by a growing human population (FAO, 2019),
29 increased demand for animal-sourced food and bioenergy policy (OECD/FAO 2019). Global crop
30 production is projected to increase by almost 15% over the next decade, with low income and emerging
31 regions with greater availability of land and labour resources expected to experience the strongest
32 growth, and account for about 50% of global output growth (OECD/FAO 2019). Increases in global
33 nitrogen fertiliser use are also projected, notably in low income and emerging regions (USEPA 2019).

34

1
 2 **Figure 7.10 Trends in average global and regional land area under specific land uses (FAO 2021b),**
 3 **inorganic nitrogen fertiliser use (FAO 2021e) (Top) and number of livestock (FAO 2021c) (Bottom) for**
 4 **three decades. For land use classification ‘cropland’ represents the FAOSTAT category ‘arable land’**
 5 **which includes land under temporary crops, meadow, pasture and fallow. ‘Forest’ and ‘permanent**
 6 **meadow and pasture’ follow FAOSTAT categories.**

7 **7.3.3. Indirect drivers**

8 The indirect drivers behind how humans both use and impact natural resources are outlined in Table
 9 7.2, specifically; demographic, economic and cultural, scientific and technological, and institutional
 10 and governance drivers. These indirect drivers not only interact with each other at different temporal
 11 and spatial scales but are also subject to impacts and feedbacks from the direct drivers (Barger et al.
 12 2018).

13

14 **Table 7.2 Indirect drivers of anthropogenic land and natural resource use patterns**

Demography	<i>Global and regional trends in population growth:</i> There was a 43% increase in global population between 1990 and 2018. The greatest growth was observed in Africa and the
-------------------	--

	<p>Middle East (+ 104%) and least growth in Eastern Europe and West-Central Asia (+ 7%) (FAO 2019b).</p> <p><i>Global and regional projections:</i> Population is projected to increase by 28% between 2018 and 2050 reaching 9.7 billion (FAO 2019). The world's population is expected to become older, more urbanised and live in smaller households (UN Environment 2019). <i>Human migration:</i> Growing mobility and population are linked to human migration, a powerful driver of changes in land and resource use patterns at decadal timescales, with the dominant flow of people being from rural areas to urban settlements over the past few decades, notably in the developing world (Adger et al. 2015; Barger et al. 2018).</p>
<p>Economic development and cultural factors</p>	<p>Changes in land use and management come from individual and social responses to economic opportunities (e.g. demand for a particular commodity or improved market access), mediated by institutions and policies (e.g. agricultural subsidies and low-interest credit or government-led infrastructure projects) (Barger et al. 2018).</p> <p><i>Projections on consumption:</i> If the future global population adopts a per capita consumption rate similar to that of the developed world, the global capacity to provide land-based resources will be exceeded (Barger et al. 2018). Economic growth in the developing world is projected to double the global consumption of forest and wood products by 2030, with demand likely to exceed production in many developing and emerging economies in Asia and Africa within the next decade (Barger et al. 2018).</p> <p><i>Global trade:</i> Market distorting agricultural subsidies and globalisation increases pressure on land systems and functions, with global trade and capital flow influencing land use, notably in developing countries (Yao et al. 2018; Furumo and Aide 2017; Pendrill et al. 2019a; UN Environment 2019), OECD/FAO 2019). Estimates suggest that between 29 and 39% of emissions from deforestation in the tropics resulted from the international trade of agricultural commodities (Pendrill et al. 2019a).</p>
<p>Science and technology</p>	<p>Technological factors operates in conjunction with economic drivers of land use and management, whether through intensified farming techniques and biotechnology, high-input approaches to rehabilitating degraded land (e.g. Lin et al. 2017; Guo et al. 2020) or through new forms of data collection and monitoring (e.g. Song et al. 2018; Thyagarajan and Vignesh 2019; Arévalo et al. 2020).</p> <p><i>Changes in farming and forestry systems:</i> Changes can have both positive and negative impacts regarding multiple factors, including GHG emission trends. Fast advancing technologies shape production and consumption, and drive land-use patterns and terrestrial ecosystems at various scales. Innovation is expected to help drive increases in global crop production during the next decade (OECD/FAO 2019). For example, emerging gene editing technologies, may advance crop breeding capabilities, though are subject to biosafety, public acceptance and regulatory approval (Jaganathan et al. 2018; Chen et al. 2019; Schmidt et al. 2020). Technological changes were significant for the expansion of soybean in Brazil by adapting to different soils and photoperiods (Abrahão and Costa 2018). In Asia, technological development changed agriculture with significant improvements in production and adaptation to climate change (Thomson et al. 2019; Giller and Ewert 2019; Anderson et al. 2020; Cassman and Grassini 2020). Developments such as precision agriculture and drip irrigation have facilitated more efficient agrochemical and water use (UN Environment 2019).</p> <p>Research and development are central to forest restoration strategies that have become increasingly important around the world as costs vary depending on methods used, from natural regeneration with native tree species to active restoration using site preparation and planting (Löf et al. 2019). In addition, climate change poses the challenge about tree species selection in the future. Innovations in the forest sector innovations also form the basis of a bioeconomy associated with bioproducts and new processes (Verkerk et al. 2020; Cross-Working Group Box 3 in Chapter 12).</p>

	<p><i>Emerging mitigation technologies:</i> Chemically synthesised methanogen inhibitors for ruminants are expected to be commercially available in some countries within the next two years and have considerable CH₄ mitigation potential (McGinn et al. 2019; Melgar et al. 2020; Beauchemin et al. 2020; Reisinger et al. 2021) (Section 7.4.3). There is growing literature (in both academic and non-academic sphere) on the biological engineering of protein. Although in its infancy and subject to investment, technological development, regulatory approval and consumer acceptance, it is suggested to have the potential to disrupt current livestock production systems and land use (Stephens et al. 2018; Ben-Arye and Levenberg 2019; Post et al. 2020; RethinkX 2019). The extent to which this is possible and the overall climate benefits are unclear (Lynch and Pierrehumbert 2019; Chriki and Hocquette 2020).</p>
<p>Institutions and governance</p>	<p>Institutional factors often moderate the relevance and impact of changes in economic and demographic variables related to resource exploitation and use. Institutions encompass the rule of law, legal frameworks and other social structures (e.g. civil society networks and movements) determining land management (e.g. formal and informal property rights, regimes and their enforcement); information and knowledge exchange systems; local and traditional knowledge and practice systems (Barger et al. 2018).</p> <p><i>Land rights:</i> Land tenure often allows communities to exercise traditional governance based on traditional ecological knowledge, devolved and dynamic access rights, judicious use, equitable distribution of benefits (Mantyka-Pringle et al. 2017; Wynberg 2017; Thomas et al. 2017), biodiversity (Contreras-Negrete et al. 2014) and fire and grazing management (Levang et al. 2015; Varghese et al. 2015).</p> <p><i>Agreements and Finance:</i> Since AR5, global agreements were reached on climate change, sustainable development goals, and the mobilisation of finance for development and climate action. Several countries adopted policies and commitments to restore degraded land (Barger et al. 2018). The UN Environment Programme (UNEP) and the Food and Agriculture Organization of the UN (FAO), launched the UN Decade on Ecosystem Restoration (https://www.decadeonrestoration.org/).</p> <p>Companies have also made pledges to reduce impacts on forests and on the rights of local communities as well as eliminating deforestation from their supply chains. The finance sector, a crucial driver behind action (Section 7.6, Box 7.12), has also started to make explicit commitments to avoiding environmental damage (Barger et al. 2018) and net zero targets (Forest Trends Ecosystem Marketplace 2021), though investment is sensitive to market outlook.</p>

1

2

7.4. Assessment of AFOLU mitigation measures including trade-offs and synergies

AFOLU mitigation or land-based climate change mitigation (used in this chapter interchangeably) are a variety of land management or demand management practices that reduce GHG emissions and/or enhance carbon sequestration within the land system (i.e. in forests, wetlands, grasslands, croplands and pasturelands). If implemented with benefits to human well-being and biodiversity, land-based mitigation measures are often referred to as nature-based solutions and/or natural climate solutions (Glossary). Measures that result in a net removal of GHGs from the atmosphere and storage in either living or dead organic material, or in geological stores, are known as CDR, and in previous IPCC reports were sometimes referred to as greenhouse gas removal (GGR) or negative emissions technologies (NETs) (Rogelj et al. 2018a; Jia et al. 2019). This section evaluates current knowledge and latest scientific literature on AFOLU mitigation measures and potentials, including land-based CDR measures. Section 7.4.1 provides an overview of the approaches for estimating mitigation potential, the co-benefits and risks from land-based mitigation measures, estimated global and regional mitigation potential and associated costs according to literature published over the last decade. Subsequent subsections assess literature on 20 key AFOLU mitigation measures specifically providing:

- A description of activities, co-benefits, risks and implementation opportunities and barriers
- A summary of conclusions in AR5 and IPCC Special Reports (SR15, SROCCC and SRCCL)
- An overview of literature and developments since the AR5 and IPCC Special Reports
- An assessment and conclusion based on current evidence

Measures are categorised as supply-side activities in: (1) forests and other ecosystems (Section 7.4.2), (2) agriculture (Section 7.4.3), (3) bioenergy and other land-based energy technologies (Section 7.4.4); as well as (4) demand-side activities (Section 7.4.5) (Figure 7.11). Several information boxes are dispersed within the section and provide supporting material, including case studies exploring a range of topics from climate-smart forestry in Europe (Box 7.2), agroforestry in Brazil (Box 7.3), climate-smart village approaches (Box 7.4), farm systems approaches (Box 7.5), mitigation within Indian agriculture (Box 7.6), and bioenergy and BECCS mitigation calculations (Box 7.7). Novel measures, including enhanced weathering and novel foods are covered in Chapter 12, this report. In addition, as mitigation within AFOLU concerns land management and use of land resources, AFOLU measures impact other sectors. Accordingly, AFOLU measures are also discussed in other sectoral chapters within this report, notably demand-side solutions (Chapter 5), bioenergy and Bioenergy with Carbon Capture and Storage (BECCS) (Chapter 6), the use of wood products and biomass in buildings (Chapter 9), and CDR measures, food systems and land related impacts, risks and opportunities of mitigation measures (Chapter 12).

7.4.1. Introduction and overview of mitigation potential

7.4.1.1. Estimating mitigation potentials

Mitigation potentials for AFOLU measures are estimated by calculating the scale of emissions reductions or carbon sequestration against a counterfactual scenario without mitigation activities. The types of mitigation potential estimates in recent literature include: (1) technical potential (the biophysical potential or amount possible with current technologies), (2) economic potential (constrained by costs, usually by a given carbon price (Table 7.3), (3) sustainable potential (constrained by environmental safeguards and/or natural resources, e.g. limiting natural forest conversion), and (4) feasible potential (constrained by environmental, socio-cultural, and/or institutional barriers), however, there are no set definitions used in literature. In addition to types of mitigation estimates, there are two

1 AFOLU mitigation categories often calculated: supply-side measures (land management interventions)
2 and demand-side measures (interventions that require a change in consumer behaviour).

3 Two main approaches to estimating mitigation potentials include: 1) studies on individual measures
4 and/or sectors – henceforth referred to as sectoral assessments, and 2) integrated assessment models
5 (IAM). Sectoral assessments include studies focusing on one activity (e.g. agroforestry) based on spatial
6 and biophysical data, as well as econometric and optimisation models for a sector, e.g. the forest or
7 agriculture sector, and therefore cover a large suite of practices and activities while representing a broad
8 body of literature. Sectoral assessments however, rarely capture cross-sector interactions or impacts,
9 making it difficult to completely account for land competition, trade-offs, and double counting when
10 aggregating sectoral estimates across different studies and methods (Smith et al. 2014; Jia et al. 2019).
11 On the other hand, IAMs assess the climate impact of multiple and interlinked practices across sectors
12 and therefore, can account for interactions and trade-offs (including land competition, use of other
13 resources and international trade) between them. However, the number of land-based measures used in
14 IAMs are limited compared with the sectoral portfolio (Figure 7.11). The resolution of land-based
15 measures in IAMs are also generally coarser compared to some sectoral estimates, and as such, may be
16 less robust for individual measures (Roe et al. 2021). Given the differences between and strengths and
17 weaknesses of the two approaches, it is helpful to compare the estimates from both. We combine
18 estimates from both approaches to establish an updated range of global land-based mitigation potential.

19 For the 20 land-based mitigation measures outlined in this section, the mitigation potential estimates
20 are largely derived from sectoral approaches, and where data is available, are compared to IAM
21 estimates. Integrated assessment models and the emissions trajectories, cost-effectiveness and trade-
22 offs of various mitigation pathways are detailed in Section 7.5. It should be noted that the underlying
23 literature for sectoral as well as IAM mitigation estimates consider GWP₁₀₀ IPCC AR5 values (CH₄ =
24 28, N₂O = 265) as well as GWP₁₀₀ IPCC AR4 values (CH₄ = 25, N₂O = 298) to convert CH₄ and N₂O
25 to CO₂-eq. Where possible, we note the various GWP₁₀₀ values (in IAM estimates, and the wetlands and
26 agriculture sections), however in some instances, the varying GWP₁₀₀ values used across studies
27 prevents description of non-CO₂ gases in native units as well as conversion to AR6 GWP₁₀₀ (CH₄ = 27,
28 N₂O = 273) CO₂-eq values to aggregate sectoral assessment estimates.

29 **7.4.1.2. Co-benefits and risks**

30 Land interventions have interlinked implications for climate mitigation, adaptation, food security,
31 biodiversity, ecosystem services, and other environmental and societal challenges (Section 7.6.5).
32 Therefore, it is important to consider the net effect of mitigation measures for achieving both climate
33 and non-climate goals (Section 7.1).

34 While it is helpful to assess the general benefits, risks and opportunities possible for land-based
35 mitigation measures (Smith et al. 2019a), their efficacy and scale of benefit or risk largely depends on
36 the type of activity undertaken, deployment strategy (e.g. scale, method), and context (e.g. soil, biome,
37 climate, food system, land ownership) that vary geographically and over time (Smith et al. 2019a,b;
38 Hurlbert et al. 2019; Chapter 12, Section 12.5) (*robust evidence, high agreement*). Impacts of land-
39 based mitigation measures are therefore highly context specific and conclusions from specific studies
40 may not be universally applicable. If implemented at appropriate scales and in a sustainable manner,
41 land-based mitigation practices have the capacity to reduce emissions and sequester billions of tonnes
42 of carbon from the atmosphere over coming decades, while also preserving or enhancing biodiversity,
43 water quality and supply, air quality, soil fertility, food and wood security, livelihoods, resilience to
44 droughts, floods and other natural disasters, and positively contributing to ecosystem health and human
45 wellbeing (*high confidence*) (Toensmeier 2016; Karlsson et al. 2020).

46 Overall, measures in the AFOLU sector are uniquely positioned to deliver substantial co-benefits.

1 However, the negative consequences of inappropriate or misguided design and implementation of
2 measures may be considerable, potentially impacting for example, mitigation permanence, longevity,
3 and leakage, biodiversity, wider ecosystem functioning, livelihoods, food security and human well-
4 being (Section 7.6; WGII, Box 2.2. ‘Risks of maladaptive mitigation’. Land-based mitigation may also
5 face limitations and trade-offs in achieving sustained emission reductions and/or removals due to other
6 land challenges including climate change impacts. It is widely recognised that land-use planning that is
7 context-specific, considers other sustainable development goals, and is adaptable over time can help
8 achieve land-based mitigation that maximises co-benefits, avoids or limits trade-offs, and delivers on
9 international policy goals including the SDGs, Land Degradation Neutrality, and Convention on
10 Biological Diversity (Section 7.6; Chapter 12).

11 Potential co-benefits and trade-offs are outlined for each of the 20 land-based mitigation measures in
12 the proceeding sub-sections and summarised in Figure 7.12. Section 7.6.5. discusses general links with
13 ecosystem services, human well-being and adaptation, while Chapter 12 (Section 12.5) provides an in-
14 depth assessment of the land related impacts, risks and opportunities associated with mitigation options
15 across sectors, including positive and negative effects on land resources, water, biodiversity, climate,
16 and food security.

17 **7.4.1.3. Overview of global and regional technical and economic potentials in AFOLU**

18 **IPCC AR5 (2014).** In the AR5, the economic mitigation potential of supply-side measures in the
19 AFOLU sector was estimated at 7.18–10.60 GtCO₂-eq yr⁻¹ in 2030 with carbon prices up to USD100
20 tCO₂-eq⁻¹, about a third of which could be achieved at < USD20 tCO₂-eq⁻¹ (*medium evidence; medium*
21 *agreement*) (Smith et al. 2014). AR5 provided a summary table of individual AFOLU mitigation
22 measures, but did not conduct a detailed assessment for each.

23 **IPCC SRCCL (2019).** The SRCCL assessed the full range of technical, economic and sustainability
24 mitigation potentials in AFOLU for the period 2030-2050 and identified reduced deforestation and
25 forest degradation to have greatest potential for reducing supply-side emissions (0.4–5.8 GtCO₂-eq yr⁻¹
26 ¹) (*high confidence*) followed by combined agriculture measures, 0.3–3.4 GtCO₂-eq yr⁻¹ (*medium*
27 *confidence*) (Jia et al. 2019). For the demand-side estimates, shifting towards healthy, sustainable diets
28 (0.7–8.0 GtCO₂-eq yr⁻¹) (*high confidence*) had the highest potential, followed by reduced food loss and
29 waste (0.8–4.5 GtCO₂-eq yr⁻¹) (*high confidence*). Measures with greatest potential for CDR were
30 afforestation/reforestation (0.5–10.1 GtCO₂-eq yr⁻¹) (*medium confidence*), soil carbon sequestration in
31 croplands and grasslands (0.4–8.6 GtCO₂-eq yr⁻¹) (*medium confidence*) and BECCS (0.4–11.3 GtCO₂-
32 eq yr⁻¹) (*medium confidence*). The SRCCL did not explore regional potential, associated feasibility nor
33 provide detailed analysis of costs.

34 **IPCC AR6.** This assessment concludes the likely range of global land-based mitigation potential is
35 approximately 8 – 14 GtCO₂-eq yr⁻¹ between 2020-2050 with carbon prices up to USD100 tCO₂-eq⁻¹,
36 about half of the technical potential (*medium evidence; medium agreement*). About 30-50% could be
37 achieved < USD20 tCO₂-eq⁻¹ (Table 7.3). The global economic potential estimates in this assessment
38 are slightly higher than the AR5 range. Since AR5, there have been numerous new global assessments
39 of sectoral land-based mitigation potential (Fuss et al. 2018; Griscom et al. 2017, 2020; Roe et al. 2019;
40 Jia et al. 2019; Griscom et al. 2020; Roe et al. 2021) as well as IAM estimates of mitigation potential
41 (Frank et al. 2019; Johnston and Radeloff 2019; Riahi et al. 2017; Baker et al. 2019; Popp et al. 2017;
42 Rogelj et al. 2018a), expanding the scope of AFOLU mitigation measures included and substantially
43 improving the robustness and spatial resolution of mitigation estimates. A recent development is an
44 assessment of country-level technical and economic (USD100 tCO₂-eq⁻¹) mitigation potential for 20
45 AFOLU measures, including for demand-side and soil organic carbon sequestration in croplands and
46 grasslands, not estimated before (Roe et al. 2021). Estimates on costs, feasibility, sustainability,

1 benefits, and risks have also been developed for some mitigation measures, and they continue to be
2 active areas of research. Developing more refined sustainable potentials at a country-level will be an
3 important next step. Although most mitigation estimates still do not consider the impact of future
4 climate change, there are some emerging studies that do (Doelman et al. 2019; Sonntag et al. 2016).
5 Given the IPCC WG1 finding that the land sink is continuing to increase although its efficiency is
6 decreasing with climate change, it will be critical to better understand how future climate will affect
7 mitigation potentials, particularly from CDR measures.

8 Across global sectoral studies, the economic mitigation potential (up to USD100 tCO₂-eq⁻¹) of supply-
9 side measures in AFOLU for the period 2020-2050 is 11.4 mean (5.6–19.8 full range) GtCO₂-eq yr⁻¹,
10 about 50% of the technical potential of 24.2 (4.9 - 58) GtCO₂-eq yr⁻¹ (Table 7.3). Adding 2.1 GtCO₂-eq
11 yr⁻¹ from demand-side measures (accounting only for diverted agricultural production to avoid double
12 counting with land-use change effects), total land-based mitigation potential up to USD100 tCO₂-eq⁻¹
13 is 13.6 (6.7 – 23.4) GtCO₂-eq yr⁻¹. This estimate aligns with the most recent regional assessment (Roe
14 et al. 2021), which found the aggregate global mitigation potential of supply and demand-side measures
15 to be 13.8 ± 3.1 GtCO₂-eq yr⁻¹ up to USD100 tCO₂-eq⁻¹ for the period 2020-2050. Across integrated
16 assessment models (IAMs), the economic potential for land-based mitigation (Agriculture, LULUCF
17 and BECCS) for USD100 tCO₂-eq⁻¹ is 7.9 mean (4.1–17.3 range) GtCO₂-eq yr⁻¹ in 2050 (Table 7.3).
18 We add the estimate for BECCS here to provide the full land-based potential, as IAMs optimize land
19 allocation based on costs, which displaces land-based CDR activities for BECCS. Combining both IAM
20 and sectoral approaches, the likely range is therefore 7.9–13.6 (rounded to 8–14) GtCO₂-eq yr⁻¹ up to
21 USD100 tCO₂-eq⁻¹ between 2020-2050. Considering both IAM and sectoral economic potential
22 estimates, land-based mitigation could have the capacity to make the AFOLU sector net negative GHG
23 emissions from 2036 (Figure 7.12), although there are highly variable mitigation strategies for how
24 AFOLU potential can be deployed for achieving climate targets (Illustrative Mitigation Pathways in
25 7.5.5). Economic potential estimates, which reflect a public willingness to pay, may be more relevant
26 for policy making compared with technical potentials which reflect a theoretical maximum that may
27 not be feasible or sustainable.

28 Among the mitigation options, the protection, improved management, and restoration of forests and
29 other ecosystems (wetlands, savannas and grasslands) have the largest potential to reduce emissions
30 and/or sequester carbon at 7.3 (3.9–13.1) GtCO₂-eq yr⁻¹ (up to USD100 tCO₂-eq⁻¹), with measures that
31 ‘protect’ having the single highest total mitigation and mitigation densities (mitigation per area) in
32 AFOLU (Table 7.3, Figure 7.11). Agriculture provides the second largest share of mitigation, with 4.1
33 (1.7–6.7) GtCO₂-eq yr⁻¹ potential (up to USD100 tCO₂-eq⁻¹), from soil carbon management in croplands
34 and grasslands, agroforestry, biochar, rice cultivation, and livestock and nutrient management Table
35 7.3, Figure 7.11. Demand-side measures including shifting to sustainable healthy diets, reducing food
36 waste, and improving wood products can mitigate 2.2 (1.1 - 3.6) GtCO₂-eq yr⁻¹ when accounting only
37 for diverted agricultural production from diets and food waste to avoid double counting with measures
38 in forests and other ecosystems (Table 7.3, Figure 7.11). The potential of demand-side measures
39 increases three-fold, to 6.5 (4 – 9.5) GtCO₂-eq yr⁻¹ when accounting for the entire value chain including
40 land-use effects, but would overlap with other measures and is therefore not additive.

41 Most mitigation options are available and ready to deploy. Emissions reductions can be unlocked
42 relatively quickly, whereas CDR need upfront investment to generate sequestration over time. The
43 protection of natural ecosystems, carbon sequestration in agriculture, sustainable healthy diets and
44 reduced food waste have especially high co-benefits and cost efficiency. Avoiding the conversion of
45 carbon-rich primary peatlands, coastal wetlands and forests is particularly important as most carbon lost
46 from those ecosystems are irrecoverable through restoration by the 2050 timeline of achieving net zero
47 carbon emissions (Goldstein et al. 2020). Sustainable intensification, shifting diets, reducing food waste

1 could enhance efficiencies and reduce agricultural land needs, and are therefore critical for enabling
2 supply-side measures such as reduced deforestation, restoration, as well as reducing N₂O and CH₄
3 emissions from agricultural production - as seen in the Illustrative Mitigation Pathway IMP-SP (Section
4 7.5.6). Although agriculture measures that reduce non-CO₂, particularly of CH₄, are important for near-
5 term emissions reductions, they have less economic potential due to costs. Demand-side measures may
6 be able to deliver non-CO₂ emissions reductions more cost efficiently.

7 Regionally, economic mitigation potential up to USD100 tCO₂-eq⁻¹ is estimated to be greatest in tropical
8 countries in Asia and developing Pacific (34%), Latin America and the Caribbean (24%), and Africa
9 and the Middle East (18%) because of the large potential from reducing deforestation and sequestering
10 carbon in forests and agriculture (Figure 7.11). However, there is also considerable potential in
11 Developed Countries (18%) and more modest potential in Eastern Europe and West-Central Asia (5%).
12 These results are in line with the IAM regional mitigation potentials (Figure 7.11). The protection of
13 forests and other ecosystems is the dominant source of mitigation potential in tropical regions, whereas
14 carbon sequestration in agricultural land and demand-side measures are important in Developed
15 Countries and Asia and developing Pacific. The restoration and management of forests and other
16 ecosystems is more geographically distributed, with all regions having significant potential. Regions
17 with large livestock herds (Developed Countries, Latin America) and rice paddy fields (Asia and
18 developing Pacific) have potential to reduce CH₄. As expected, the highest total potential is associated
19 with countries and regions with large land areas, however when considering mitigation density (total
20 potential per hectare), many smaller countries, particularly those with wetlands have disproportionately
21 high levels of mitigation for their size (Roe et al. 2021). As global commodity markets connect regions,
22 AFOLU measures may create synergies and trade-offs across the world, which could make national
23 demand-side measures for example, important in mitigating supply-side emissions elsewhere (Kallio &
24 Solberg 2018).

25 Although economic potentials provide more realistic, near-term climate mitigation compared to
26 technical potentials, they still do not account for feasibility barriers and enabling conditions that vary
27 by region and country. For example, according to most models, including IAMs, avoided deforestation
28 is the cheapest land-based mitigation option (Table 7.3, Sections 7.5.3 and 7.5.4), however
29 implementing interventions aimed at reducing deforestation (including REDD+) often have higher
30 transaction and implementation costs than expected due to various barriers and enabling conditions
31 (Luttrell et al. 2018; Section 7.6). The feasibility of implementing AFOLU mitigation measures,
32 including those with multiple co-benefits, depends on varying economic, technological, institutional,
33 socio-cultural, environmental and geophysical barriers (*high confidence*) (Smith et al. 2019a). The
34 section for each individual mitigation measure provides an overview of co-benefits and risks associated
35 with the measure and Section 7.6.6 outlines key enabling factors and barriers for implementation.

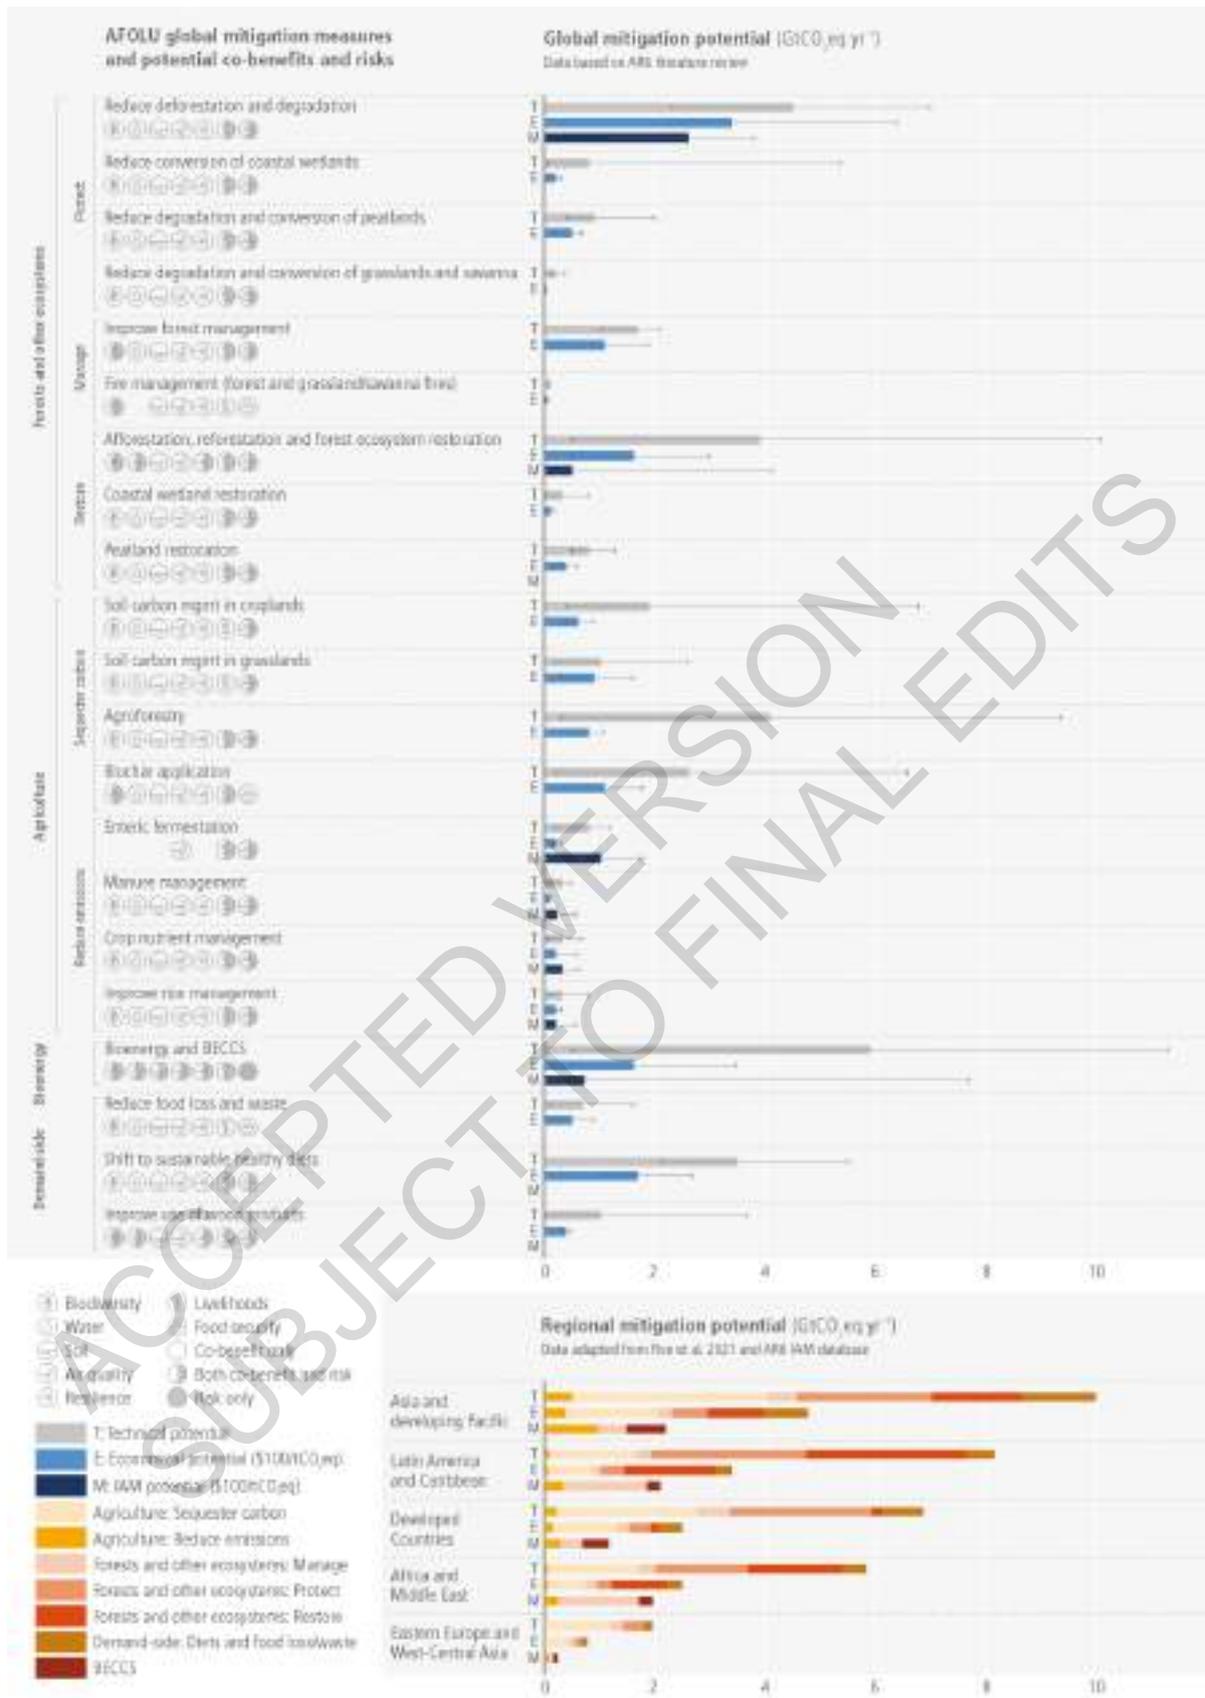

36
37 **Table 7.3 Estimated annual mitigation potential (GtCO₂-eq yr⁻¹) in 2020-2050 of AFOLU mitigation**
38 **options by carbon price. Estimates reflect sectoral studies based on a comprehensive literature review**
39 **updating data from (Roe et al. 2019) and integrated assessment models using the IPCC AR6 database**
40 **(Section 7.5). Values represent the mean, and full range of potential. Sectoral mitigation estimates are**
41 **averaged for the years 2020-2050 to capture a wider range of literature, and the IAM estimates are given**
42 **for 2050 as many model assumptions delay most land-based mitigation to mid-century. The sectoral**
43 **potentials are the sum of global estimates for the individual measures listed for each option. IAM**
44 **potentials are given for mitigation options with available data; e.g., net land-use CO₂ for total forests &**
45 **other ecosystems, and land sequestration from A/R, but not reduced deforestation (protect). Sectoral**
46 **estimates predominantly use GWP₁₀₀ IPCC AR5 values (CH₄ = 28, N₂O = 265), although some use**
47 **GWP₁₀₀ IPCC AR4 values (CH₄ = 25, N₂O = 298); and the IAMs use GWP₁₀₀ IPCC AR6 values (CH₄ =**

1 27, N₂O = 273). The sectoral and IAM estimates reflected here do not account for the substitution effects
 2 of avoiding fossil fuel emissions nor emissions from other more energy intensive resources/materials. For
 3 example, BECCS estimates only consider the carbon dioxide removal (CDR) via geological storage
 4 component and not potential mitigation derived from the displacement of fossil fuel use in the energy
 5 sector. Mitigation potential from substitution effects are included in the other sectoral chapters like
 6 energy, transport, buildings and industry. The total AFOLU sectoral estimate aggregates potential from
 7 agriculture, forests & other ecosystems, and diverted agricultural production from avoided food waste
 8 and diet shifts (excluding land-use impacts to avoid double counting). Because of potential overlaps
 9 between measures, sectoral values from BECCS and the full value chain potential from demand-side
 10 measures are not summed with AFOLU. IAMs account for land competition and resource optimization
 11 and can therefore sum across all available categories to derive the total AFOLU potential. Key: ND = no
 12 data; Sectoral = as assessed by sectoral literature review; IAM = as assessed by integrated assessment
 13 models; EJ = ExaJoule primary energy.

Mitigation option	Estimate type	< USD20 tCO ₂ -eq ⁻¹	< USD50 tCO ₂ -eq ⁻¹	< USD100 tCO ₂ -eq ⁻¹	Technical
Agriculture total	Sectoral	0.9 (0.5 - 1.4)	1.6 (1 - 2.4)	4.1 (1.7 - 6.7)	11.2 (1.6 - 28.5)

Figure 7.11 Global and regional mitigation potential (GtCO₂-eq yr⁻¹) in 2020–20250 for 20 land-based measures. (a) Global estimates represent the mean (bar) and full range (error bars) of the economic

1 potential (up to USD100 tCO₂-eq⁻¹) based on a comprehensive literature review of sectoral studies
 2 (references are outlined in the sub-section for each measure in 7.4.2–7.4.5). Potential co-benefits and
 3 trade-offs for each of the 20 measures are summarized in icons. (b) Regional estimates illustrate the
 4 mean technical (T) and economic (E) (up to USD100 tCO₂-eq⁻¹) sectoral potential based on data from
 5 (Roe et al. 2021). IAM economic potential (M) (USD100 tCO₂-eq⁻¹) data is from the IPCC AR6
 6 database.
 7
 8

9
 10 **Figure 7.12** Historic land sector GHG flux estimates and illustrative AFOLU mitigation pathways to
 11 2050, based on data presented in Sections 7.2, 7.4 and 7.5. Historic trends consider both (A)
 12 anthropogenic (AFOLU) GHG fluxes (GtCO₂-eq yr⁻¹) according to FAOSTAT (FAO 2021a; 2021b) and
 13 (B) the estimated natural land CO₂ sink according to (Friedlingstein et al. 2020). Note that for the
 14 anthropogenic net land CO₂ flux component, several approaches and methods are described within the
 15 literature (Section 7.2.2) with a wide range in estimates. For clarity, only one dataset (FAOSTAT) is
 16 illustrated here. It is not intended to indicate preference for one particular method over others. Historic
 17 flux trends are illustrated to 2019, the latest year for which data is available. Projected economic
 18 mitigation potential (at costs of up to USD100 tCO₂-eq⁻¹) includes estimates from IAMs and sectoral
 19 studies (Table 7.3). The sectoral estimates are disaggregated into agriculture + forests & other
 20 ecosystems, + demand-side measures (only accounting for diverted agricultural production to avoid
 21 double counting), and + BECCS (illustrating that there may be additional potential, with the caveat that
 22 there is likely overlap with other measures). Projected mitigation assumes adoption of measures to
 23 achieve increasing, linear mitigation, reaching average annual potential in 2050, although this does not
 24 reflect deployment rates for most measures. For illustrative purposes, a pathway to projected emissions in
 25 2050 according to a scenario of current policy (C7 - Above 3.0°C - Model: GCAM 5.3) is additionally
 26 included for reference.
 27

1 **7.4.2. Forests and other ecosystems**

2 **7.4.2.1. Reduce deforestation and degradation**

3 **Activities, co-benefits, risks and implementation opportunities and barriers.** Reducing deforestation
4 and forest degradation conserves existing carbon pools in forest vegetation and soil by avoiding tree
5 cover loss and disturbance. Protecting forests involves controlling the drivers of deforestation (such as
6 commercial and subsistence agriculture, mining, urban expansion) and forest degradation (such as
7 overharvesting including fuelwood collection, poor harvesting practices, overgrazing, pest outbreaks,
8 and extreme wildfires), as well as by establishing well designed, managed and funded protected areas
9 (Barber et al. 2020), improving law enforcement, forest governance and land tenure, supporting
10 community forest management and introducing forest certification (Smith et al. 2019b). Reducing
11 deforestation provides numerous and substantial co-benefits, preserving biodiversity and ecosystem
12 services (e.g. air and water filtration, water cycling, nutrient cycling) more effectively and at lower costs
13 than afforestation/reforestation (Jia et al. 2019). Potential adverse side effects of these conservation
14 measures include reducing the potential for agriculture land expansion, restricting the rights and access
15 of local people to forest resources, or increasing the dependence of local people to insecure external
16 funding. Barriers to implementation include unclear land tenure, weak environmental governance,
17 insufficient funds, and increasing pressures associated to agriculture conversion, resource exploitation
18 and infrastructure development (Sections 7.3 and 7.6).

19 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
20 **potential, costs, and pathways.** Reducing deforestation and forest degradation represents one of the
21 most effective options for climate change mitigation, with technical potential estimated at 0.4–5.8
22 GtCO₂ yr⁻¹ by 2050 (*high confidence*) (SRCCL, Chapters 2 and 4, and Table 6.14). The higher technical
23 estimate represents a complete halting of land use conversion in forests and peatland forests (i.e.,
24 assuming recent rates of carbon loss are saved each year) and includes vegetation and soil carbon pools.
25 Ranges of economic potentials for forestry ranged in AR5 from 0.01–1.45 GtCO₂ yr⁻¹ for USD20 tCO₂⁻¹
26 to 0.2–13.8 GtCO₂ yr⁻¹ for USD100 tCO₂⁻¹ by 2030 with reduced deforestation dominating the forestry
27 mitigation potential LAM and MAF, but very little potential in OECD-1990 and EIT (IPCC AR5).

28 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Since the
29 SRCCL, several studies have provided updated and convergent estimates of economic mitigation
30 potentials by region (Busch et al. 2019; Griscom et al. 2020; Austin et al. 2020; Roe et al. 2021).
31 Tropical forests and /savannas in Latin America provide the largest share of mitigation potential (3.9
32 GtCO₂ yr⁻¹ technical, 2.5 GtCO₂ yr⁻¹ at USD100 tCO₂⁻¹) followed by Southeast Asia (2.2 GtCO₂ yr⁻¹
33 technical, 1.5 GtCO₂ yr⁻¹ at USD100 tCO₂⁻¹) and Africa (2.2 GtCO₂ yr⁻¹ technical, 1.2 GtCO₂ yr⁻¹ at
34 USD100 tCO₂⁻¹) (Roe et al. 2021). Tropical forests continue to account for the highest rates of
35 deforestation and associated GHG emissions. While deforestation shows signs of decreasing in several
36 countries, in others, it continues at a high rate or is increasing (Turubanova et al. 2018). Between 2010-
37 2020, the rate of net forest loss was 4.7 Mha yr⁻¹ with Africa and South America presenting the largest
38 shares (3.9 Mha and 2.6 Mha, respectively) (FAO 2020a).

39 A major uncertainty in all studies on avoided deforestation potential is their reliance on future reference
40 levels that vary across studies and approaches. If food demand increases in the future, for example, the
41 area of land deforested will likely increase, suggesting more technical potential for avoiding
42 deforestation. Transboundary leakage due to market adjustments could also increase costs or reduce
43 effectiveness of avoiding deforestation (e.g., Ingalls et al. 2018; Gingrich et al. 2019). Regarding forest
44 regrowth, there are uncertainties about the time for the secondary forest carbon saturation (Zhu et al.
45 2018; Houghton and Nassikas 2017). Permanence of avoided deforestation may also be a concern due
46 to the impacts of climate change and disturbance of other biogeochemical cycles on the world's forests
47 that can result in future potential changes in terrestrial ecosystem productivity, climate-driven

1 vegetation migration, wildfires, forest regrowth and carbon dynamics (Ballantyne et al. 2012; Kim et
2 al. 2017b; Lovejoy and Nobre 2018; Aragão et al. 2018).

3 **Critical assessment and conclusion.** Based on studies since AR5, the technical mitigation potential for
4 reducing deforestation and degradation is significant, providing 4.5 (2.3 - 7) GtCO₂ yr⁻¹ globally by
5 2050, of which 3.4 (2.3 – 6.4) GtCO₂ yr⁻¹ is available at below USD100 tCO₂⁻¹ (*medium confidence*)
6 (Figure 7.11). Over the last decade, hundreds of subnational initiatives that aim to reduce deforestation
7 related emissions have been implemented across the tropics (Section 7.6). Reduced deforestation is a
8 significant piece of the NDCs in the Paris Agreement (Seddon et al. 2020) and keeping the temperature
9 below 1.5°C (Crusius 2020). Conservation of forests provides multiple co-benefits linked to ecosystem
10 services, biodiversity and sustainable development (Section 7.6.). Still, ensuring good governance,
11 accountability (e.g. enhanced monitoring and verification capacity; Bos 2020), and the rule of law are
12 crucial for implementing forest-based mitigation options. In many countries with the highest
13 deforestation rates, insecure land rights often are significant barriers for forest-based mitigation options
14 (Gren and Zeleke 2016; Essl et al. 2018).

15 **7.4.2.2. Afforestation, reforestation and forest ecosystem restoration**

16 **Activities, co-benefits, risks and implementation opportunities and barriers.** Afforestation and
17 reforestation (A/R) are activities that convert land to forest, where reforestation is on land that has
18 previously contained forests, while afforestation is on land that historically has not been forested (Box
19 7.2). Forest restoration refers to a form of reforestation that gives more priority to ecological integrity
20 as well, even though it can still be a managed forest. Depending on the location, scale, and choice and
21 management of tree species, A/R activities have a wide variety of co-benefits and trade-offs. Well-
22 planned, sustainable reforestation and forest restoration can enhance climate resilience and biodiversity,
23 and provide a variety of ecosystem services including water regulation, microclimatic regulation, soil
24 erosion protection, as well as renewable resources, income and livelihoods (Ellison et al. 2017; Locatelli
25 et al. 2015; Verkerk et al. 2020; Stanturf et al. 2015). Afforestation, when well planned, can help address
26 land degradation and desertification by reducing runoff and erosion and lead to cloud formation
27 however, when not well planned, there are localised trade-offs such as reduced water yield or
28 biodiversity (Teuling et al. 2017; Ellison et al. 2017) . The use of non-native species and monocultures
29 may have adverse impacts on ecosystem structure and function, and water availability, particularly in
30 dry regions (Ellison et al. 2017). A/R activities may change the surface albedo and evapotranspiration
31 regimes, producing net cooling in the tropical and subtropical latitudes for local and global climate and
32 net warming at high latitudes (Section 7.4.2). Very large-scale implementation of A/R may negatively
33 affect food security since an increase in global forest area can increase food prices through land
34 competition (Kreidenweis et al. 2016).

35 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
36 **potential, costs, and pathways.** AR5 did not provide a new specification of A/R potential, but referred
37 to AR4 mostly for forestry measures (Nabuurs et al. 2007). AR5 did view the feasible A/R potential
38 from a diets change scenario that released land for reforestation and bioenergy crops. AR 5 provided
39 top-down estimates of costs and potentials for forestry mitigation options - including reduced
40 deforestation, forest management, afforestation, and agroforestry, estimated to contribute between 1.27
41 and 4.23 GtCO₂ yr⁻¹ of economically viable abatement in 2030 at carbon prices up to USD100/t CO₂-
42 eq (Smith et al. 2014).

43 The SRCCL remained with a reported wide range of mitigation potential for A/R of 0.5–10.1 GtCO₂
44 yr⁻¹ by 2050 (*medium confidence*) (SRCCL Chapters 2 and 6; Roe et al. 2019; Fuss et al. 2018; Griscom
45 et al. 2017; Hawken 2017; Kreidenweis et al. 2016). The higher estimate represents a technical potential
46 of reforesting all areas where forests are the native cover type (reforestation), constrained by food

1 security and biodiversity considerations, considering above and below-ground carbon pools and
2 implementation on a rather theoretical maximum of 678 Mha of land (Roe et al. 2019; Griscom et al.
3 2017). The lower estimates represent the minimum range from an Earth System Model and a sustainable
4 global CDR potential (Fuss et al. 2018). Climate change will affect the mitigation potential of
5 reforestation due to impacts in forest growth and composition, as well as changes in disturbances
6 including fire. However, none of the mitigation estimates included in the SRCCL account for climate
7 impacts.

8 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Since SRCCL,
9 additional studies have been published on A/R mitigation potential by Bastin et al. (2019), Lewis et al.
10 (2019), (Doelman et al. 2019), (Favero et al. 2020) and (Austin et al. 2020). These studies are within
11 the range reported in the SRCCL stretching the potentials at the higher range. The rising public interest
12 in nature-based solutions, along with high profile initiatives being launched (UN Decade on Restoration
13 announced in 2019, the Bonn challenge on 150 million ha of restored forest in 2020 and e.g. the trillion-
14 tree campaign launched by the World Economic Forum in 2020), has prompted intense discussions on
15 the scale, effectiveness, and pitfalls of A/R and tree planting for climate mitigation (Anderegg et al.
16 2020; Bond et al. 2019; Heilmayr et al. 2020; Holl and Brancalion 2020; Luysaert et al. 2018). The
17 sometimes sole attention on afforestation and reforestation suggesting it may solve the climate problem
18 to large extent in combination with the very high estimates of potentials have led to polarisation in the
19 debate, again resulting in a push back to nature restoration only (Lewis et al. 2019). Our assessment
20 based on most recent literature produced regional economic mitigation potential at USD100 tCO₂⁻¹
21 estimate of 100-400 MtCO₂ yr⁻¹ in Africa, 210-266 MtCO₂ yr⁻¹ in Asia and developing Pacific, 291
22 MtCO₂-eq yr⁻¹ in Developed countries (87% in North America), 30 MtCO₂-eq yr⁻¹ in Eastern Europe
23 and West-Central Asia, and 345-898 MtCO₂-eq yr⁻¹ in Latin America and Caribbean (Roe et al. 2021),
24 which totals to about 1200 MtCO₂ yr⁻¹, leaning to the lower range of the potentials in earlier IPCC
25 reports. A recent global assessment of the aggregate costs for afforestation and reforestation suggests
26 that at USD100 tCO₂⁻¹, 1.6 GtCO₂ yr⁻¹ could be sequestered globally for an annual cost of USD130
27 billion (Austin et al. 2020). Sectoral studies that are able to deal with local circumstances and limits
28 estimate A/R potentials at 20 MtCO₂ yr⁻¹ in Russia (Eastern Europe and West-Central Asia)
29 (Romanovskaya et al. 2020) and 64 MtCO₂ yr⁻¹ in Europe (Nabuurs et al. 2017). (Domke et al. 2020)
30 estimated for the USA an additional 20% sequestration rate from tree planting to achieve full stocking
31 capacity of all understocked productive forestland, in total reaching 187 MtCO₂ yr⁻¹ sequestration. A
32 new study on costs in the USA estimates 72-91 MtCO₂ yr⁻¹ could be sequestered between now and 2050
33 for USD100/t CO₂ (Wade et al. 2019). The tropical and subtropical latitudes are the most effective for
34 forest restoration in terms of carbon sequestration because of the rapid growth and lower albedo of the
35 land surface compared with high latitudes (Lewis et al. 2019).. Costs may be higher if albedo is
36 considered in North America, Russia, and Africa (Favero et al. 2017). In addition, a wide variety of
37 sequestration rates have been collected and published in e.g. IPCC Good Practice Guidance for the
38 AFOLU sector (IPCC 2006).

39 **Critical assessment and conclusion.** There is *medium confidence* that the global technical mitigation
40 potential of afforestation and reforestation activities by 2050 is 3.9 (0.5–10.1) GtCO₂ yr⁻¹, and the
41 economic mitigation potential (< USD100 tCO₂⁻¹) is 1.6 (0.5 – 3.0) GtCO₂ yr⁻¹ (requiring about 200
42 Mha). Per hectare a long (about 100 year) sustained effect of 5-10 t(CO₂) ha⁻¹ yr⁻¹ is realistic with ranges
43 between 1-20 t(CO₂) ha⁻¹ yr⁻¹. Not all sectoral studies rely on economic models that account for leakage
44 (Murray et al. 2004; Sohngen and Brown 2004), suggesting that technical potential may be
45 overestimated.

46 7.4.2.3. Improved forest management

47 **Activities, co-benefits, risks and implementation opportunities and barriers.**

1 Improved sustainable forest management of already managed forests can lead to higher forest carbon
2 stocks, better quality of produced wood, continuously produce wood while maintaining and enhancing
3 the forest carbon stock, and can also partially prevent and counteract the impacts of disturbances (Kurz
4 et al. 2008; Marlon et al. 2012; Abatzoglou and Williams 2016; Tian et al. 2018; Seidl et al. 2017;
5 Nabuurs et al. 2017; Ekholm 2020). Furthermore it can provide benefits for climate change adaptation,
6 biodiversity conservation, microclimatic regulation, soil erosion protection and water and flood
7 regulation with reduced lateral C fluxes (Ashton et al. 2012; Verkerk et al. 2020; Martínez-Mena et al.
8 2019). Often, in existing (managed) forests with existing C stocks, large changes per hectare cannot be
9 expected, although many forest owners may respond to carbon price incentives (Favero et al. 2020;
10 Ekholm 2020). The full mitigation effects can be assessed in conjunction with the overall forest and
11 wood use system i.e., carbon stock changes in standing trees, soil, harvested wood products (HWPs)
12 and its bioenergy component with the avoided emissions through substitution. Forest management
13 strategies aimed at increasing the biomass stock may have adverse side effects, such as decreasing the
14 stand-level structural complexity, large emphasis on pure fast growing stands, risks for biodiversity and
15 resilience to natural disasters.

16 Generally measures can consist of one or combination of longer rotations, less intensive harvests,
17 continuous-cover forestry, mixed stands, more adapted species, selected provenances, high quality
18 wood assortments, etc. Further, there is a trade-off between management in various parts of the forest
19 product value chain, resulting in a wide range of results on the role of managed forests in mitigation
20 (Agostini et al. 2013; Braun et al. 2016; Gustavsson et al. 2017; Erb et al. 2017; Soimakallio et al. 2016;
21 Hurmekoski et al. 2020; Favero et al. 2020). Some studies conclude that reduction in forest carbon
22 stocks due to harvest exceeds for decades the joint sequestration of carbon in harvested wood product
23 stocks and emissions avoided through wood use (Soimakallio et al. 2016; Seppälä et al. 2019), whereas
24 others emphasise country level examples where investments in forest management have led to higher
25 growing stocks while producing more wood (Cowie et al. 2021; Schulze et al. 2020; Ouden et al. 2020).

26 ***Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation***
27 ***potential, costs, and pathways.*** In the SRCCL, forest management activities have the potential to
28 mitigate 0.4–2.1 GtCO₂-eq yr⁻¹ by 2050 (*medium confidence*) (SRCCL: Griscom et al. 2017; Roe et al.
29 2019). The higher estimate stems from assumptions of applications on roughly 1.9 billion ha of already
30 managed forest which can be seen as very optimistic. It combines both natural forest management as
31 well as improved plantations, on average with a small net additional effect per hectare, not including
32 substitution effects in the energy sector nor the buildings sector.

33 ***Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).*** The area of
34 forest under management plans has increased in all regions since 2000 by 233 Mha (FAO-FRA 2020).
35 The roughly 1 billion ha of secondary and degraded forests would be ideal to invest in and develop a
36 sustainable sector that pays attention to biodiversity, wood provision and climate mitigation at the same
37 time. This all depends on the effort made, the development of expertise, know-how in the field, nurseries
38 with adapted provenances, etc as was also found for Russian climate smart forestry options (Leskinen
39 et al. 2020). Regionally, recently updated economic mitigation potential at USD100 tCO₂⁻¹ have 179-
40 186 MtCO₂-eq yr⁻¹ in Africa, 193-313 MtCO₂-eq yr⁻¹ in Asia and developing Pacific, 215-220 MtCO₂-
41 eq yr⁻¹ in Developed countries, 82-152 MtCO₂-eq yr⁻¹ in Eastern Europe and West-Central Asia, and
42 62-204 MtCO₂-eq yr⁻¹ in Latin America and Caribbean (Roe et al. 2021).

43 Regional studies can take into account the local situation better: Russia Romanovskaya et al. (2020)
44 estimate the potential of forest fires management at 220–420 MtCO₂ yr⁻¹, gentle logging technology at
45 15–59, reduction of wood losses at 61–76 MtCO₂ yr⁻¹. In North America, (Austin et al. 2020) estimate
46 that in the next 30 years, forest management could contribute 154 MtCO₂ yr⁻¹ in the USA and Canada
47 with 81 MtCO₂ yr⁻¹ available at less than USD100 tCO₂⁻¹. In one production region (British Columbia)

1 a cost-effective portfolio of scenarios was simulated that directed more of the harvested wood to longer-
2 lived wood products, stopped burning of harvest residues and instead produced bioenergy to displace
3 fossil fuel burning, and reduced harvest levels in regions with low disturbance rates. Net GHG emissions
4 were reduced by an average of $-9 \text{ MtCO}_2\text{-eq yr}^{-1}$ (Smyth et al. 2020). In Europe, climate smart forestry
5 could mitigate an additional $0.19 \text{ GtCO}_2 \text{ yr}^{-1}$ by 2050 (Nabuurs et al. 2017), in line with the regional
6 estimates in (Roe et al. 2021).

7 In the tropics, estimates of the pantropical climate mitigation potential of natural forest management (a
8 light intensity management in secondary forests), across three tropical regions (Latin America, Africa,
9 Asia), is around $0.66 \text{ GtCO}_2\text{-eq yr}^{-1}$ with Asia responding for the largest share followed by Africa and
10 Latin America (Roe et al. 2021). Selective logging occurs in at least 20% of the world's tropical forests
11 and causes at least half of the emissions from tropical forest degradation (Asner et al. 2005; Blaser and
12 K uchli 2011; Pearson et al. 2017). Reduced-impact logging for climate (RIL-C; promotion of reduced
13 wood waste, narrower haul roads, and lower impact skidding equipment) has the potential to reduce
14 logging emissions by 44% (Ellis et al. 2019), while also providing timber production.

15 **Critical assessment and conclusion.** There is *medium confidence* that the global technical mitigation
16 potential for improved forest management by 2050 is $1.7 (1\text{--}2.1) \text{ GtCO}_2 \text{ yr}^{-1}$, and the economic
17 mitigation potential ($< \text{USD}100 \text{ tCO}_2^{-1}$) is $1.1 (0.6\text{--}1.9) \text{ GtCO}_2 \text{ yr}^{-1}$. Efforts to change forest
18 management do not only require e.g. a carbon price incentive, but especially require knowledge,
19 institutions, skilled labour, good access etc. These requirements outline that although the potential is of
20 medium size, we estimate a feasible potential towards the lower end. The net effect is also difficult to
21 assess, as management changes impact not only the forest biomass, but also the wood chain and
22 substitution effects. Further, leakage can arise from efforts to change management for carbon
23 sequestration. Efforts e.g. to set aside large areas of forest may be partly counteracted by higher
24 harvesting pressures elsewhere (Kallio and Solberg 2018). studies such as (Austin et al. 2020) implicitly
25 account for leakage and thus suggest higher costs than other studies. We therefore judge the mitigation
26 potential at medium potential with medium agreement.

27

28 **[START BOX 7.2 HERE]**

29

Box 7.2 Climate Smart Forestry in Europe

Summary

31 European forests have been regarded as prospering and increasing for the last 5 decades. However,
32 these views also changed recently. Climate change is putting a large pressure on mono species and high
33 stocked areas of Norway spruce in Central Europe (Hl asny et al. 2021; Senf and Seidl 2021) with
34 estimates of mortality reaching 200 million m^3 , biodiversity under pressure, the Mediterranean area
35 showing a weak sector and harvesting pressure in the Baltics and north reaching maxima achievable. A
36 European strategy for unlocking the EU's forests and forest sector potential was needed at the time of
37 developing the LULUCF regulation and was based on the concept of "Climate Smart Forestry" (CSF)
38 (Nabuurs et al. 2017; Verkerk et al. 2020).

Background

40 The idea behind CSF is that it considers the whole value chain from forest to wood products and energy,
41 illustrating that a wide range of measures can be applied to provide positive incentives for more firmly
42 integrating climate objectives into the forest and forest sector framework. CSF is more than just storing
43 carbon in forest ecosystems; it builds upon three main objectives; (i) reducing and/or removing GHG
44 emissions; (ii) adapting and building diverse forests for forest resilience to climate change; and (iii)

1 sustainably increasing forest productivity and incomes. These three CSF objectives can be achieved by
2 tailoring policy measures and actions to regional circumstances in Member States forest sectors.

3 **Case description**

4 The 2015 annual mitigation effect of EU-28 forests via contributions to the forest sink, material
5 substitution and energy substitution is estimated at 569 MtCO₂ yr⁻¹, or 13% of total current EU
6 emissions. With the right set of incentives in place at EU and Member States levels, it was found that
7 the EU-28 has the potential to achieve an additional combined mitigation impact through the
8 implementation of CSF of 441 MtCO₂ yr⁻¹ by 2050. Also, with the Green Deal and its Biodiversity and
9 Forest Strategy more emphasis will be placed on forests, forest management and the provision of
10 renewables. It is the diversity of measures (from strict reserves to more intensively managed systems
11 while adapting the resource) that will determine the success. Only with co-benefits in e.g. nature
12 conservation, soil protection, and provision of renewables, wood for buildings and income, the
13 mitigation and adaptation measures will be successful.

14 **Interactions, limitations and lessons**

15 Climate Smart Forestry is now taking shape across Europe with various research and implementation
16 projects (Climate Smart Forest and Nature Management, 2021). Pilots and projects are being
17 implemented by a variety of forest owners, some with more attention on biodiversity and adaptation,
18 some with more attention on production functions. They establish examples and in longer term the
19 outreach to the 16 million private owners in Europe. However, the right triggers and incentives are often
20 still lacking. E.g. adapting the spruce forest areas in Central Europe to climate change requires
21 knowledge about different species, biodiversity and different management options and eventually use
22 in industry. It requires alternative species to be available from the nurseries, as well improved
23 monitoring to assess the success and steer activities.

24 **[END BOX 7.2 HERE]**

25

26 **7.4.2.4. Fire management (forest and grassland/savanna fires)**

27 **Activities, co-benefits, risks and implementation opportunities and barriers.** Fire management
28 objectives include safeguarding life, property, and resources through the prevention, detection, control,
29 restriction, and management of fire for diverse purposes in natural ecosystems (SRCCL Chapter 6).
30 Controlled burning is an effective economic method of reducing fire danger and stimulating natural
31 regeneration. Co-benefits of fire management include reduced air pollution compared to much larger,
32 uncontrolled fires, prevention of soil erosion and land degradation, biodiversity conservation in
33 rangelands, and improvement of forage quality (Hurteau et al. 2019; Hurteau and Brooks 2011; Falk
34 2017). Fire management is still challenging because it is not only fire suppression at times of fire, but
35 especially proper natural resource management in between fire events. Furthermore, it is challenging
36 because of legal and policy issues, equity and rights concerns, governance, capacity, and research needs
37 (Russell-Smith et al. 2017; Goldammer 2016 ; Wiedinmyer and Hurteau 2010). It will increasingly be
38 needed under future enhanced climate change.

39 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
40 **potential, costs, and pathways.** In the SRCCL, fire management is among the nine options that can
41 deliver medium-to-large benefits across multiple land challenges (climate change mitigation,
42 adaptation, desertification, land degradation, and food security) (*high confidence*). Total emissions from
43 fires have been on the order of 8.1 GtCO₂-eq yr⁻¹ in terms of gross biomass loss for the period 1997–
44 2016 (SRCCL, Chapter 2 and Cross-Chapter Box 3 in Chapter 2). Reduction in fire CO₂ emissions was

1 calculated to enhance land carbon sink by 0.48 GtCO₂-eq yr⁻¹ for the 1960–2009 period (Arora and
2 Melton 2018) (SRCCL, Table 6.16).

3 ***Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).***

4 ***Savannas.*** Savannas constitute one of the most fire-prone vegetation types on Earth and are a significant
5 source of GHG emissions. Savanna fires contributed 62% (4.92 PgCO₂-eq yr⁻¹) of gross global mean
6 fire emissions between 1997 and 2016. Regrowth from vegetation postfire sequesters the CO₂ released
7 into the atmosphere, but not the CH₄ and N₂O emissions which contributed an approximate net of 2.1
8 PgCO₂-eq yr⁻¹ (Lipsett-Moore et al. 2018). Therefore, implementing prescribed burning with low
9 intensity fires, principally in the early dry season, to effectively manage the risk of wildfires occurring
10 in the late dry season is associated with reducing emissions (Whitehead et al. 2014). Considering this
11 fire management practice, estimates of global opportunities for emissions reductions were estimate at
12 69.1 MtCO₂-eq yr⁻¹ in Africa (29 countries, with 20 least developed African countries accounting for
13 74% of the mitigation potential), 13.3 MtCO₂-eq yr⁻¹ in South America (six countries), and 6.9 MtCO₂-
14 eq yr⁻¹ in Australia and Papua New Guinea (Lipsett-Moore et al. 2018). In Australia, savanna burning
15 emissions abatement methodologies have been available since 2012, and abatement has exceeded 4
16 MtCO₂-eq mainly through the management of low intensity early dry season fire (Lynch et al. 2018).
17 Until August 2021, 78 were registered (Australian Government, Clean Energy Regulator, 2021).

18 ***Forests.*** Fire is also a prevalent forest disturbance (Scott et al. 2014; Falk et al. 2011; Andela et al.
19 2019). About 98 Mha of forest were affected by fire in 2015, affecting about 4% of the tropical (dry)
20 forests, 2% of the subtropical forests, and 1% of temperate and boreal forests (FAO 2020a). Between
21 2001–2018, remote sensing data showed that tree-covered areas correspond to about 29% of the total
22 area burned by wildfires, most in Africa. Prescribed fires are also applied routinely in forests worldwide
23 for fuel reduction and ecological reasons (Kalies and Yocom Kent 2016). Fire resilience is increasingly
24 managed in southwestern USA forest landscapes, which have experienced droughts and widespread,
25 high-severity wildfires (Keeley et al. 2019). In these forests, fire exclusion management, coupled with
26 a warming climate, has led to increasingly severe wildfires (Hurteau et al. 2014). However, the impacts
27 of prescribed fires in forests in reducing carbon emissions are still inconclusive. Some positive impacts
28 of prescribed fires are associated with other fuel reduction techniques (Loudermilk et al. 2017; Flanagan
29 et al. 2019; Stephens et al. 2020), leading to maintaining C stocks and reducing C emissions in the
30 future where extreme fire weather events are more frequent (Krofcheck et al. 2018, 2019; Hurteau et
31 al. 2019). (Bowman et al. 2020b,a; Goodwin et al. 2020; Hurteau et al. 2019). Land management
32 approaches will certainly need to consider the new climatic conditions (e.g., the proportion of days in
33 fire seasons with the potential for unmanageable fires more than doubling in some regions in northern
34 and eastern boreal forest) (Wotton et al. 2017).

35 ***Critical assessment and conclusion.*** There is *low confidence* that the global technical mitigation
36 potential for grassland and savanna fire management by 2050 is 0.1 (0.09–0.1) GtCO₂ yr⁻¹, and the
37 economic mitigation potential (< USD100 tCO₂⁻¹) is 0.05 (0.03–0.07) GtCO₂ yr⁻¹. Savanna fires produce
38 significant emissions globally, but prescribed fires in the early dry season could mitigate emissions in
39 different regions, particularly Africa. Evidence is less clear for fire management of forests, with the
40 contribution of GHG mitigation depending on many factors that affect the carbon balance (e.g.,
41 Simmonds et al. 2021). Although prescribed burning is promoted to reduce uncontrolled wildfires in
42 forests, the benefits for the management of carbon stocks are unclear, with different studies reporting
43 varying results especially concerning its long term effectiveness. (Bowman et al. 2020b; Wotton et al.
44 2017). Under increasing climate change however, an increased attention on fire management will be
45 necessary.

1 **7.4.2.5. Reduce degradation and conversion of grasslands and savannas**

2 **Activities, co-benefits, risks and implementation opportunities and barriers.** Grasslands cover
3 approximately 40.5 % of the terrestrial area (i.e., 52.5 million km²) divided as 13.8% woody savanna
4 and savanna; 12.7% open and closed shrub; 8.3 % non-woody grassland; and 5.7% is tundra (White et
5 al. 2000). Sub-Saharan Africa and Asia have the most extensive total area, 14.5 and 8.9 million km²,
6 respectively. A review by Conant et al. (2017) reported based on data on grassland area (FAO 2013)
7 and grassland soil carbon stocks (Sombroek et al. 1993) a global estimate of about 343 Pg C (in the top
8 1 m), nearly 50% more than is stored in forests worldwide (FAO 2007). Reducing the conversion of
9 grasslands and savannas to croplands prevents soil carbon losses by oxidation, and to a smaller extent,
10 biomass carbon loss due to vegetation clearing (SRCCL, Chapter 6). Restoration of grasslands through
11 enhanced soil carbon sequestration, including a) management of vegetation, b) animal management,
12 and c) fire management, was also included in the SRCCL and is covered in Section 7.4.3.1. Similar to
13 other measures that reduce conversion, conserving carbon stocks in grasslands and savannas can be
14 achieved by controlling conversion drivers (e.g., commercial and subsistence agriculture, see Section
15 7.3) and improving policies and management. In addition to mitigation, conserving grasslands provide
16 various socio-economic, biodiversity, water cycle and other environmental benefits (Claassen et al.
17 2010; Ryals et al. 2015; Bengtsson et al. 2019). Annual operating costs, and opportunity costs of income
18 foregone by undertaking the activities needed for avoiding conversion of grasslands making costs one
19 of the key barriers for implementation (Lipper et al. 2010).

20 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
21 **potential, costs, and pathways.** The SRCCL reported a mitigation potential for reduced conversion of
22 grasslands and savannas of 0.03–0.12 GtCO₂-eq yr⁻¹ (SRCCL: Griscom et al. 2017) considering the
23 higher loss of soil organic carbon in croplands (Sanderman et al. 2017). Assuming an average starting
24 soil organic carbon stock of temperate grasslands (Poelplau et al. 2011), and the mean annual global
25 cropland conversion rates (1961–2003) (Krause et al. 2017), the equivalent loss of soil organic carbon
26 over 20 years would be 14 GtCO₂-eq, i.e. 0.7 GtCO₂ yr⁻¹ (SRCCL, Chapter 6). IPCC AR5 and AR4 did
27 not explicitly consider the mitigation potential of avoided conversion of grasslands-savannas but the
28 management of grazing land is accounted for considering plant, animal, and fire management with a
29 mean mitigation potential of 0.11-0.80 tCO₂-eq ha⁻¹ yr⁻¹ depending on the climate region. This resulted
30 in 0.25 GtCO₂-eq yr⁻¹ at USD20 tCO₂⁻¹ to 1.25 GtCO₂-eq yr⁻¹ at USD100 tCO₂⁻¹ by 2030.

31 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Unlike most of
32 the measures covered in Section 7.4, there are currently no global, spatially explicit mitigation potential
33 estimates for reduced grassland conversion to generate technical and economic potentials by region.
34 Literature developments since AR5 and SRCCL are studies that provide mitigation estimates in one or
35 a few countries or regions. Modelling experiments comparing Californian forests and grasslands found
36 that grasslands resulted in a more resilient C sink than forests to future climate change (Dass et al.
37 2018). However, previous studies indicated that precipitation is a key controller of the carbon storage
38 in these grasslands, with the grassland became a carbon sink in 2005, when the region received
39 relatively high spring precipitation (Ma et al. 2007). In North America, grassland conversion was the
40 source for 77% of all new croplands from 2008-2012 (Lark et al. 2015). Avoided conversion of North
41 American grasslands to croplands presents an economic mitigation potential of 0.024 GtCO₂-eq yr⁻¹ and
42 technical potential of 0.107 GtCO₂-eq yr⁻¹ (Fargione et al. 2018). This potential is related mainly to root
43 biomass and soils (81% of emissions from soils). Estimates of GHG emissions from any future
44 deforestation in Australian savannas also point to the potential mitigation of around 0.024 GtCO₂-eq
45 yr⁻¹ (Bristow et al. 2016). The expansion of the Soy Moratorium (SoyM) from the Brazilian Amazon
46 to the Cerrado (Brazilian savannas) would prevent the direct conversion of 3.6 Mha of native vegetation
47 to soybeans by 2050 and avoid the emission of 0.02 GtCO₂-eq yr⁻¹ (Soterroni et al. 2019).

1 **Critical assessment and conclusion.** There is *low confidence* that the global technical mitigation
2 potential for reduced grassland and savanna conversion by 2050 is 0.2 (0.1–0.4) GtCO₂ yr⁻¹, and the
3 economic mitigation potential (< USD100 tCO₂⁻¹) is 0.04 GtCO₂ yr⁻¹. Most of the carbon sequestration
4 potential is in belowground biomass and soil organic matter. However, estimates of potential are still
5 based on few studies and vary according the levels of soil carbon, and ecosystem productivity (e.g. in
6 response to rainfall distribution). Conservation of grasslands presents significant benefits for
7 desertification control, especially in arid areas (SRCCL, Chapter 3). Policies supporting avoided
8 conversion can help protect at-risk grasslands, reduce GHG emissions, and produce positive outcomes
9 for biodiversity and landowners (Ahlering et al. 2016). In comparison to tropical rainforest regions that
10 have been the primary target for mitigation policies associated to natural ecosystems (e.g. REDD+),
11 Conversion grasslands and savannas has received less national and international attention, despite
12 growing evidence of concentrated cropland expansion into these areas with impacts of carbon losses.

13 **7.4.2.6. Reduce degradation and conversion of peatlands**

14 **Activities, co-benefits, risks and implementation barriers.** Peatlands are carbon-rich wetland
15 ecosystems with organic soil horizons in which soil organic matter concentration exceeds 30% (dry
16 weight) and soil carbon concentrations can exceed 50% (Page and Baird 2016, Boone Kauffman et al.
17 2017). Reducing the conversion of peatlands avoids emissions of above- and below-ground biomass
18 and soil carbon due to vegetation clearing, fires, and peat decomposition from drainage. Similar to
19 deforestation, peatland carbon stocks can be conserved by controlling the drivers of conversion and
20 degradation (e.g. commercial and subsistence agriculture, mining, urban expansion) and improving
21 governance and management. Reducing conversion is urgent because peatland carbon stocks
22 accumulate slowly and persist over millennia; loss of existing stocks cannot be easily reversed over the
23 decadal timescales needed to meet the Paris Agreement (Goldstein et al. 2020). The main co-benefits
24 of reducing conversion of peatlands include conservation of a unique biodiversity including many
25 critically endangered species, provision of water quality and regulation, and improved public health
26 through decreased fire-caused pollutants (Griscom et al. 2017). Although reducing peatland conversion
27 will reduce land availability for alternative uses including agriculture or other land-based mitigation,
28 drained peatlands constitute a small share of agricultural land globally while contributing significant
29 emissions (Joosten 2009). Mitigation through reduced conversion of peatlands therefore has a high
30 potential of avoided emissions per hectare (Roe et al. 2019).

31 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
32 **potential, costs, and pathways.** In the SRCCL (Chapters 2 and 6), it was estimated that avoided peat
33 impacts could deliver 0.45–1.22 GtCO₂-eq yr⁻¹ technical potential by 2030-2050 (*medium confidence*)
34 (Griscom et al. 2017; Hawken 2017; Hooijer et al. 2010). The mitigation potential estimates cover
35 tropical peatlands and include CO₂, N₂O and CH₄ emissions. The mitigation potential is derived from
36 quantification of losses of carbon stocks due to land conversion, shifts in GHG fluxes, alterations in net
37 ecosystem productivity, input factors such as fertilisation needs, and biophysical climate impacts (e.g.,
38 shifts in albedo, water cycles, etc). Tropical peatlands account for only ~10% of peatland area and about
39 20% of peatland carbon stock but about 80% of peatland carbon emissions, primarily from peatland
40 conversion in Indonesia (about 60%) and Malaysia (about 10%) (Page et al. 2011; Leifeld and
41 Menichetti 2018; Hooijer et al. 2010). While the total mitigation potential of peatland conservation is
42 considered moderate, the per hectare mitigation potential is the highest among land-based mitigation
43 measures (Roe et al. 2019).

44 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Recent studies
45 continue to report high carbon stocks in peatlands and emphasize the vulnerability of peatland carbon
46 after conversion. The carbon stocks of tropical peatlands are among the highest of any forest, 1,211-
47 4,257 tCO₂-eq ha⁻¹ in the Peruvian Amazon (Bhomia et al. 2019) and 1,956-14,757 tCO₂-eq ha⁻¹ in

1 Indonesia (Novita et al. 2021). Ninety percent of tropical peatland carbon stocks are vulnerable to
2 emission during conversion and may not be recoverable through restoration; in contrast, boreal and
3 temperate peatlands hold similar carbon stocks (1,439-5,619 tCO₂-eq ha⁻¹) but only 30% of northern
4 carbon stocks are vulnerable to emission during conversion and irrecoverable through restoration
5 (Goldstein et al. 2020). A recent study shows global mitigation potential of about 0.2 GtCO₂-eq yr⁻¹ at
6 costs up to USD100 tCO₂⁻¹ (Roe et al. 2021). Another study estimated that 72% of mitigation is achieved
7 through avoided soil carbon impacts, with the remainder through avoided impacts to vegetation (Bossio
8 et al. 2020). Recent model projections show that both peatland protection and peatland restoration
9 (Section 7.4.2.7) are needed to achieve a 2°C mitigation pathway and that peatland protection and
10 restoration policies will have minimal impacts on regional food security (Leifeld et al. 2019,
11 Humpenöder et al. 2020). Global studies have not accounted for extensive peatlands recently reported
12 in the Congo Basin, estimated to cover 145,500 km² and contain 30.6 Pg C, as much as 29% of total
13 tropical peat carbon stock (Dargie et al. 2017). These Congo peatlands are relatively intact; continued
14 preservation is needed to prevent major emissions (Dargie et al. 2019). In northern peatlands that are
15 underlain by permafrost (roughly 50% of the total peatlands north of 23° latitude, (Hugelius et al. 2020),
16 climate change (i.e. warming) is the major driver of peatland degradation (e.g. through permafrost thaw)
17 (Schoor et al. 2015, Goldstein et al. 2020). However, in non-permafrost boreal and temperate peatlands,
18 reduction of peatland conversion is also a cost-effective mitigation strategy. Peatlands are sensitive to
19 climate change and there is *low confidence* about the future peatland sink globally (SRCCL, Chapter
20 2). Permafrost thaw may shift northern peatlands from a net carbon sink to net source (Hugelius et al.
21 2020). Uncertainties in peatland extent and the magnitude of existing carbon stocks, in both northern
22 (Loisel et al. 2014) and tropical (Dargie et al. 2017) latitudes limit understanding of current and future
23 peatland carbon dynamics (Minasny et al. 2019).

24 **Critical assessment and conclusion.** Based on studies to date, there is *medium confidence* that peatland
25 conservation has a technical potential of 0.86 (0.43–2.02) GtCO₂-eq yr⁻¹ of which 0.48 (0.2–0.68)
26 GtCO₂-eq yr⁻¹ is available at USD100 tCO₂⁻¹ (Figure 7.11). High per hectare mitigation potential and
27 high rate of co-benefits particularly in tropical countries, support the effectiveness of this mitigation
28 strategy (Roe et al. 2019). Feasibility of reducing peatland conversion may depend on countries’
29 governance, financial capacity and political will.

30 **7.4.2.7. Peatland restoration**

31 **Activities, co-benefits, risks and implementation barriers.** Peatland restoration involves restoring
32 degraded and damaged peatlands, for example through rewetting and revegetation, which both increases
33 carbon accumulation in vegetation and soils and avoids ongoing CO₂ emissions. Peatlands only account
34 for about 3% of the terrestrial surface, predominantly occurring in boreal ecosystems (78%), with a
35 smaller proportion in tropical regions (13%), but may store about 600 Gt Carbon or 21% of the global
36 total soil organic Carbon stock of about 3000 Gt (Leifeld and Menichetti 2018; Page et al. 2011).
37 Peatland restoration delivers co-benefits for biodiversity, as well as regulating water flow and
38 preventing downstream flooding, while still allowing for extensive management such as paludiculture
39 (Tan et al. 2021). Rewetting of peatlands also reduces the risk of fire, but may also mobilize salts and
40 contaminants in soils (van Diggelen et al. 2020) and in severely degraded peatlands, restoration of
41 peatland hydrology and vegetation may not be feasible (Andersen et al. 2017). At a local level,
42 restoration of peatlands drained for agriculture could displace food production and damage local food
43 supply, although impacts to regional and global food security would be minimal (Humpenöder et al.
44 2020). Collaborative and transparent planning processes are needed to reduce conflict between
45 competing land uses (Tanneberger et al. 2020b). Adequate resources for implementing restoration
46 policies are key to engage local communities and maintain livelihoods (Ward et al. 2021; Resosudarmo
47 et al. 2019).

1 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
2 **potential, costs, and pathways.** Large areas (0.51 Mkm²) of global peatlands are degraded of which
3 0.2 Mkm² are tropical peatlands (Griscom et al. 2017; Leifeld and Menichetti 2018). According to the
4 SRCCL, peatland restoration could deliver technical mitigation potentials of 0.15 - 0.81 GtCO₂-eq yr⁻¹
5 by 2030-2050 (*low confidence*) (Chapter 2 and 6 of the SRCCL; (Couwenberg et al. 2010; Griscom et
6 al. 2017), though there could be an increase in methane emissions after restoration (Jauhiainen et al.
7 2008). The mitigation potential estimates cover global peatlands and include CO₂, N₂O and CH₄
8 emissions. Peatlands are highly sensitive to climate change (*high confidence*), however there are
9 currently no studies that estimate future climate effects on mitigation potential from peatland
10 restoration.

11 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** The most recent
12 literature and reviews indicate with *high confidence* that restoration would decrease CO₂ emissions and
13 with *medium confidence* that restoration would decrease net GHG emissions from degraded peatlands
14 (Wilson et al. 2016; Ojanen and Minkkinen 2020; van Diggelen et al. 2020). Although rewetting of
15 drained peatlands increases CH₄ emissions, this effect is often outweighed by decreases in CO₂ and N₂O
16 emissions but depends very much on local circumstances (Günther et al. 2020). Restoration and
17 rewetting of almost all drained peatlands is needed by 2050 to meet 1.5-2°C pathways which is unlikely
18 to happen (Leifeld et al. 2019); immediate rewetting and restoration minimises the warming from
19 cumulative CO₂ emissions (Nugent et al. 2019).

20 According to recent data, the technical mitigation potential for global peatland restoration is estimated
21 at 0.5-1.3 GtCO₂-eq yr⁻¹ (Leifeld and Menichetti 2018; Griscom et al. 2020; Bossio et al. 2020; Roe et
22 al. 2021; Figure 7.11), with 80% of the mitigation potential derived from improvements to soil carbon
23 (Bossio et al. 2020). The regional mitigation potentials of all peatlands outlined in Roe et al. (2021)
24 reflect the country-level estimates from (Humpenöder et al. 2020).

25 Climate mitigation effects of peatland rewetting depend on the climate zone and land use. Recent
26 analysis shows the strongest mitigation gains from rewetting drained temperate and boreal peatlands
27 used for agriculture and drained tropical peatlands (Ojanen and Minkkinen 2020). However, estimates
28 of emission factors from rewetting drained tropical peatlands remain uncertain (Wilson et al. 2016;
29 Murdiyarto et al. 2019). Topsoil removal, in combination with rewetting, may improve restoration
30 success and limit CH₄ emissions during restoration of highly degraded temperate peatlands (Zak et al.
31 2018). In temperate and boreal regions, co-benefits mentioned above are major motivations for peatland
32 restoration (Chimner et al. 2017; Tanneberger et al. 2020a).

33 **Critical assessment and conclusion.** Based on studies to date, there is *medium confidence* that peatland
34 restoration has a technical potential of 0.79 (0.49–1.3) GtCO₂-eq yr⁻¹ (median) of which 0.4 (0.2–0.6)
35 GtCO₂-eq yr⁻¹ is available up to USD100 tCO₂⁻¹. The large land area of degraded peatlands suggests
36 that significant emissions reductions could occur through large-scale restoration especially in tropical
37 peatlands. There is *medium confidence* in the large carbon stocks of tropical peat forests (1,956-14,757
38 tCO₂-eq ha⁻¹) and large rates of carbon loss associated with land cover change (640-1,650 tCO₂-eq ha⁻¹)
39 (Novita et al. 2021; Goldstein et al. 2020). However, large-scale implementation of tropical peatland
40 restoration will likely be limited by costs and other demands for these tropical lands.

41 **7.4.2.8. Reduce conversion of coastal wetlands**

42 **Activities, co-benefits, risks and implementation barriers.** Reducing conversion of coastal wetlands,
43 including mangroves, marshes and seagrass ecosystems, avoids emissions from above and below
44 ground biomass and soil carbon through avoided degradation and/or loss. Coastal wetlands occur
45 mainly in estuaries and deltas, areas that are often densely settled, with livelihoods closely linked to
46 coastal ecosystems and resources (Moser et al. 2012). The carbon stocks of these highly productive

1 ecosystems are sometimes referred to as “blue carbon”. Loss of existing stocks cannot be easily reversed
2 over decadal timescales (Goldstein et al. 2020). The main drivers of conversion include intensive
3 aquaculture, agriculture, salt ponds, urbanisation and infrastructure development, the extensive use of
4 fertilisers, and extraction of water resources (Lovelock et al. 2018). Reduced conversion of coastal
5 wetlands has many co-benefits, including biodiversity conservation, fisheries production, soil
6 stabilisation, water flow and water quality regulation, flooding and storm surge prevention, and
7 increased resilience to cyclones (UNEP 2020; Windham-Myers et al. 2018a). Risks associated with the
8 mitigation potential of coastal wetland conservation include uncertain permanence under future climate
9 scenarios, including the effects of coastal squeeze, where coastal wetland area may be lost if upland
10 area is not available for migration as sea levels rise (IPCC WGII Ch. 3.4.2.5; (Lovelock and Reef 2020).
11 Preservation of coastal wetlands also conflicts with other land use in the coastal zone, including
12 aquaculture, agriculture, and human development; economic incentives are needed to prioritise wetland
13 preservation over more profitable short-term land use. Integration of policies and efforts aimed at
14 coastal climate mitigation, adaptation, biodiversity conservation, and fisheries, for example through
15 Integrated Coastal Zone Management and Marine Spatial Planning, will bundle climate mitigation with
16 co-benefits and optimise outcomes (Herr et al. 2017).

17 ***Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL); mitigation***
18 ***potential, costs, and pathways.*** Coastal wetlands contain high, yet variable, organic carbon stocks,
19 leading to a range of estimates of the global mitigation potential of reduced conversion. The SRCCL
20 (Chapter 2) and SROCCC (Chapter 5), report a technical mitigation potential of 0.15–5.35 GtCO₂-eq
21 yr⁻¹ by 2050 (Lovelock et al. 2017; Pendleton et al. 2012; Howard et al. 2017; Griscom et al. 2017). The
22 mitigation potential is derived from quantification of losses of carbon stocks in vegetation and soil due
23 to land conversion, shifts in GHG fluxes associated with land use, and alterations in net ecosystem
24 productivity. The wide range in estimates mostly relate to the scope (all coastal ecosystems vs.
25 mangroves only) and different assumptions on decomposition rates. Loss rates of coastal wetlands have
26 been estimated at 0.2-3% yr⁻¹, depending on the vegetation type and location (Atwood et al. 2017;
27 Howard et al. 2017).

28 ***Developments since AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL).*** Global technical
29 mitigation potential for conservation of coastal wetlands from recent literature have focused on
30 protection of mangroves; estimates range from 0.06–2.25 GtCO₂-eq yr⁻¹ (Griscom et al. 2020; Bossio
31 et al. 2020) with 80% of the mitigation potential derived from improvements to soil carbon (Bossio et
32 al. 2020). Regional potentials (Roe et al. 2021) reflect mangrove protection; marsh and seagrass
33 protection were not included due to lack of country-level data on marsh and seagrass distribution and
34 conversion.

35 Global estimates show mangroves have the largest per hectare carbon stocks (see IPCC WGII AR6
36 Box 3.4 for estimates of carbon stocks, burial rates and ecosystem extent for coastal wetland
37 ecosystems). Mean ecosystem carbon stock in mangroves is 3131 tCO₂-eq ha⁻¹ among the largest carbon
38 stocks on Earth. Recent studies emphasize the variability in total ecosystem carbon stocks for each
39 wetland type, based on species and climatic and edaphic conditions (Kauffman et al. 2020; Bedulli et
40 al. 2020; Ricart et al. 2020; Wang et al. 2021; Alongi et al. 2020), and highlight the vulnerability of soil
41 carbon below 1 m depth (Arifanti et al. 2019). Sea level strongly influences coastal wetland distribution,
42 productivity, and sediment accretion; therefore, sea level rise will impact carbon accumulation and
43 persistence of existing carbon stocks (Macreadie et al. 2019, IPCC WGII AR6 Box 3.4).

44 Recent loss rates of mangroves are 0.16-0.39% y⁻¹ and are highest in Southeast Asia (Friess et al. 2019;
45 Hamilton and Casey 2016). Assuming loss of soil C to 1 m depth after deforestation, avoiding mangrove
46 conversion has the technical potential to mitigate approximately 23.5-38.7 MtCO₂-eq y⁻¹ (Ouyang and
47 Lee 2020); note, this potential is additional to reduced conversion of forests (Griscom et al. 2020,

1 7.4.2.1). Regional estimates show that about 85% of mitigation potential for avoided mangrove
2 conversion is in Southeast Asia and Developing Pacific (32 MtCO₂-eq yr⁻¹ at USD100 tCO₂⁻¹), 10% is
3 in Latin American and the Caribbean (4 MtCO₂-eq yr⁻¹), and approximately 5% in other regions
4 (Griscom et al. 2020; Roe et al. 2021).

5 Key uncertainties remain in mapping extent and conversion rates for salt marshes and seagrasses
6 (McKenzie et al. 2020). Seagrass loss rates were estimated at 1-2% yr⁻¹ (Dunic et al. 2021) with
7 stabilization in some regions (IPCC WGII Ch. 3.4.2.5; (de los Santos et al. 2019); however, loss occurs
8 non-linearly and depends on site-specific context. Tidal marsh extent and conversion rates remains
9 poorly estimated, outside of the USA, Europe, South Africa, and Australia (Mcowen et al. 2017;
10 Macreadie et al. 2019).

11 **Critical assessment and conclusion.** There is *medium confidence* that coastal wetland protection has a
12 technical potential of 0.8 (0.06–5.4) GtCO₂-eq yr⁻¹ of which 0.17 (0.06–0.27) GtCO₂-eq yr⁻¹ is available
13 up to USD100 tCO₂⁻¹. There is a *high certainty* (robust evidence, high agreement) that coastal
14 ecosystems have among the largest carbon stocks of any ecosystem. As these ecosystems provide many
15 important services, reduced conversion of coastal wetlands is a valuable mitigation strategy with
16 numerous co-benefits. However, the vulnerability of coastal wetlands to climatic and other
17 anthropogenic stressors may limit the permanence of climate mitigation.

18 **7.4.2.9. Coastal wetland restoration**

19 **Activities, co-benefits, risks and implementation barriers.** Coastal wetland restoration involves
20 restoring degraded or damaged coastal wetlands including mangroves, salt marshes, and seagrass
21 ecosystems, leading to sequestration of ‘blue carbon’ in wetland vegetation and soil (SRCCL Ch 6,
22 SROCCC Ch 5). Successful approaches to wetland restoration include: (1) passive restoration, the
23 removal of anthropogenic activities that are causing degradation or preventing recovery; and (2) active
24 restoration, purposeful manipulations to the environment in order to achieve recovery to a naturally
25 functioning system (Elliott et al. 2016; IPCC WGII Ch 3). Restoration of coastal wetlands delivers
26 many valuable co-benefits, including enhanced water quality, biodiversity, aesthetic values, fisheries
27 production (food security), and protection from rising sea levels and storm impacts (Barbier et al. 2011;
28 Hochard et al. 2019; Sun and Carson 2020; Duarte et al. 2020). Of the 0.3 Mkm² coastal wetlands
29 globally, 0.11 Mkm² of mangroves are considered feasible for restoration (Griscom et al. 2017). Risks
30 associated with coastal wetland restoration include uncertain permanence under future climate scenarios
31 (IPCC WGII AR6 Box 3.4), partial offsets of mitigation through enhanced methane and nitrous oxide
32 release and carbonate formation, and competition with other land uses, including aquaculture and
33 human settlement and development in the coastal zone (SROCCC, Chapter 5). To date, many coastal
34 wetland restoration efforts do not succeed due to failure to address the drivers of degradation (van
35 Katwijk et al. 2016). However, improved frameworks for implementing and assessing coastal wetland
36 restoration are emerging that emphasize the recovery of ecosystem functions (Cadier et al. 2020; Zhao
37 et al. 2016). Restoration projects that involve local communities at all stages and consider both
38 biophysical and socio-political context are more likely to succeed (Brown et al. 2014; Wylie et al. 2016).

39 **Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL); mitigation**
40 **potential, costs, and pathways.** The SRCCL reported that mangrove restoration has the technical
41 potential to mitigate 0.07 GtCO₂ yr⁻¹ through rewetting (Crooks et al. 2011) and take up 0.02–0.84
42 GtCO₂ yr⁻¹ from vegetation biomass and soil enhancement through 2030 (*medium confidence*) (Griscom
43 et al. 2017). The SROCCC concluded that cost-effective coastal blue carbon restoration had a potential
44 of ~0.15-0.18 GtCO₂-eq yr⁻¹, a low global potential compared to other ocean-based solutions but with
45 extensive co-benefits and limited adverse side effects (Gattuso et al. 2018).

1 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Recent studies
2 emphasise the timeframe needed to achieve the full mitigation potential (Duarte et al. 2020; Taillardat
3 et al. 2020). The first project-derived estimate of the net GHG benefit from seagrass restoration found
4 1.54 tCO₂-eq (0.42 MgC) ha⁻¹ yr⁻¹ 10 years after restoration began (Oreska et al. 2020); comparable to
5 the default emission factor in the Wetlands Supplement (IPCC 2014). Recent studies of rehabilitated
6 mangroves also indicate that annual carbon sequestration rates in biomass and soils can return to natural
7 levels within decades of restoration (Cameron et al. 2019; Sidik et al. 2019). A meta-analysis shows
8 increasing carbon sequestration rates over the first 15 years of mangrove restoration with rates
9 stabilising at 25.7 ± 7.7 tCO₂-eq (7.0 ± 2.1 MgC) ha⁻¹ yr⁻¹ through forty years, although success depends
10 on climate, sediment type, and restoration methods (Sasmito et al. 2019). Overall, 30% of mangrove
11 soil carbon stocks and 50-70% of marsh and seagrass carbon stocks are unlikely to recover within 30
12 years of restoration, underscoring the importance of preventing conversion of coastal wetlands (7.4.2.8)
13 (Goldstein et al. 2020).

14 According to recent data, the technical mitigation potential for global coastal wetland restoration is
15 0.04-0.84 GtCO₂-eq yr⁻¹ (Griscom et al. 2020; Bossio et al. 2020; Roe et al. 2021) with 60% of the
16 mitigation potential derived from improvements to soil carbon (Bossio et al. 2020). Regional potentials
17 based on country-level estimates from Griscom et al. (2020) show the technical and economic (up to
18 USD100 tCO₂⁻¹) potential of mangrove restoration; seagrass and marsh restoration was not included
19 due to lack of country-level data on distribution and conversion (but see (McKenzie et al. (2020) for
20 updates on global seagrass distribution). Although global potential is relatively moderate, mitigation
21 can be quite significant for countries with extensive coastlines (e.g., Indonesia, Brazil) and for small
22 island states where coastal wetlands have been shown to comprise 24-34% of their total national carbon
23 stock (Donato et al. 2012). Furthermore, non-climatic co-benefits can strongly motivate coastal wetland
24 restoration worldwide (UNEP 2021a). Major successes in both active and passive restoration of
25 seagrasses have been documented in North America and Europe (Lefcheck et al. 2018; Orth et al. 2020;
26 de los Santos et al. 2019); passive restoration may also be feasible for mangroves (Cameron et al. 2019).

27 There is high site-specific variation in carbon sequestration rates and uncertainties regarding the
28 response to future climate change (Jennerjahn et al. 2017; Nowicki et al. 2017; IPCC WGII AR6 Box
29 3.4). Changes in distributions (Kelleway et al. 2017; Wilson and Lotze 2019), methane release (Al-Haj
30 and Fulweiler 2020), carbonate formation (Saderne et al. 2019), and ecosystem responses to interactive
31 climate stressors are not well-understood (Short et al. 2016; Fitzgerald and Hughes 2019; Lovelock and
32 Reef 2020).

33 **Critical assessment and conclusion.** There is *medium confidence* that coastal wetland restoration has a
34 technical potential of 0.3 (0.04–0.84) GtCO₂-eq yr⁻¹ of which 0.1 (0.05–0.2) GtCO₂-eq yr⁻¹ is available
35 up to USD100 tCO₂⁻¹. There is *high confidence* that coastal wetlands, especially mangroves, contain
36 large carbon stocks relative to other ecosystems and *medium confidence* that restoration will reinstate
37 pre-disturbance carbon sequestration rates. There is *low confidence* on the response of coastal wetlands
38 to climate change; however, there is *high confidence* that coastal wetland restoration will provide a suite
39 of valuable co-benefits.

40 **7.4.3. Agriculture**

41 **7.4.3.1. Soil carbon management in croplands and grasslands**

42 **Activities, co-benefits, risks and implementation opportunities and barriers.** Increasing soil organic
43 matter in croplands are agricultural management practices that include (1) crop management: for
44 example, high input carbon practices such as improved crop varieties, crop rotation, use of cover crops,
45 perennial cropping systems (including agroforestry see Section 7.4.3.3), integrated production systems,

1 crop diversification, agricultural biotechnology, (2) nutrient management including fertilization with
2 organic amendments / green manures (Section 7.4.3.6), (3) reduced tillage intensity and residue
3 retention, (4) improved water management: including drainage of waterlogged mineral soils and
4 irrigation of crops in arid / semi-arid conditions, (5) improved rice management (Section 7.4.3.5) and
5 (6) biochar application (Section 7.4.3.2) (Smith et al. 2019d). For increased soil organic matter in
6 grasslands, practices include (1) *management of vegetation*: including improved grass varieties/sward
7 composition, deep rooting grasses, increased productivity, and nutrient management, (2) *livestock*
8 *management*: including appropriate stocking densities fit to carrying capacity, fodder banks, and fodder
9 diversification, and (3) *fire management*: improved use of fire for sustainable grassland management,
10 including fire prevention and improved prescribed burning (Smith et al. 2014, 2019d). All these
11 measures are recognized as Sustainable Soil Management Practices by FAO (Baritz et al. 2018). Whilst
12 there are co-benefits for livelihoods, biodiversity, water provision and food security Smith et al. 2019b
13 , and impacts on leakage, indirect land-use change and foregone sequestration do not apply (since
14 production is not displaced), the climate benefits of soil carbon sequestration in croplands can be
15 negated if achieved through additional fertiliser inputs (potentially causing increased N₂O emissions;
16 (Guenet et al. 2021), and both saturation and permanence are relevant concerns. When considering
17 implementation barriers, soil carbon management in croplands and grasslands is a low-cost option at a
18 high level of technology readiness (it is already widely deployed globally) with low socio-cultural and
19 institutional barriers, but with difficulty in monitoring and verification proving a barrier to
20 implementation (Smith et al. 2020a).

21 ***Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL); mitigation***
22 ***potential, costs, and pathways.*** Building on AR5, the SRCCL reported the global mitigation potential
23 for soil carbon management in croplands to be 1.4–2.3 GtCO₂-eq yr⁻¹ (Smith et al. 2014), though the
24 full literature range was 0.3–6.8 GtCO₂-eq yr⁻¹ (Frank et al. 2017; Sommer and Bossio 2014; Conant et
25 al. 2017; Dickie et al. 2014b; Fuss et al. 2018; Griscom et al. 2017; Hawken 2017; Henderson et al.
26 2015; Herrero et al. 2016; Paustian et al. 2016; Powlson et al. 2014; Sanderman et al. 2017; Zomer et
27 al. 2016; Roe et al. 2019). The global mitigation potential for soil organic carbon management in
28 grasslands was assessed to be 1.4–1.8 GtCO₂-eq yr⁻¹, with the full literature range being 0.1–2.6 GtCO₂-
29 eq yr⁻¹ (Conant et al. 2017; Herrero et al. 2016;2013; Roe et al. 2019). Lower values in the range
30 represented economic potentials, whilst higher values represented technical potentials – and uncertainty
31 was expressed by reporting the whole range of estimates. The SR1.5 outlined associated costs reported
32 in literature to range from USD -45 to 100 tCO₂⁻¹, describing enhanced soil carbon sequestration as a
33 cost-effective measure (IPCC 2018). Despite significant mitigation potential, there is limited inclusion
34 of soil carbon sequestration as a response option within IAM mitigation pathways (Rogelj et al. 2018a).

35 ***Developments since AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL).*** No recent
36 literature has been published which conflict with the mitigation potentials reported in the SRCCL.
37 Relevant papers include Lal et al. (2018) which estimated soil carbon sequestration potential to be 0.7–
38 4.1 GtCO₂-eq yr⁻¹ for croplands and 1.1–2.9 GtCO₂-eq yr⁻¹ for grasslands. Bossio et al. (2020) assessed
39 the contribution of soil carbon sequestration to natural climate solutions and found the potential to be
40 5.5 GtCO₂ yr⁻¹ across all ecosystems, with only small portions of this (0.41 GtCO₂-eq yr⁻¹ for cover
41 cropping in croplands; 0.23, 0.15, 0.15 GtCO₂-eq yr⁻¹ for avoided grassland conversion, optimal grazing
42 intensity and legumes in pastures, respectively) arising from croplands and grasslands. Regionally, soil
43 carbon management in croplands is feasible anywhere, but effectiveness can be limited in very dry
44 regions (Sanderman et al. 2017). For soil carbon management in grasslands the feasibility is greatest in
45 areas where grasslands have been degraded (e.g. by overgrazing) and soil organic carbon is depleted.
46 For well managed grasslands, soil carbon stocks are already high and the potential for additional carbon
47 storage is low (Roe et al. (2021) estimate greatest economic (up to USD100 tCO₂⁻¹) potential between

1 2020 and 2050 for croplands to be in Asia and the developing Pacific (339.7 MtCO₂ yr⁻¹) and for
2 grasslands, in Developed Countries (253.6 MtCO₂ yr⁻¹).

3 **Critical assessment and conclusion.** In conclusion, there is *medium confidence* that enhanced soil
4 carbon management in croplands has a global technical mitigation potential of 1.9 (0.4-6.8) GtCO₂ yr⁻¹,
5 and in grasslands of 1.0 (0.2-2.6) GtCO₂ yr⁻¹, of which, 0.6 (0.4-0.9) and 0.9 (0.3-1.6) GtCO₂ yr⁻¹ is
6 estimated to be available at up to USD100 tCO₂⁻¹ respectively. Regionally, soil carbon management in
7 croplands and grasslands is feasible anywhere, but effectiveness can be limited in very dry regions, and
8 for grasslands it is greatest in areas where degradation has occurred (e.g. by overgrazing) and soil
9 organic carbon is depleted. Barriers to implementation include regional capacity for monitoring and
10 verification (especially in developing countries), and more widely through concerns over saturation and
11 permanence.

12 7.4.3.2. Biochar

13 **Activities, co-benefits, risks and implementation opportunities and barriers.** Biochar is produced by
14 heating organic matter in oxygen-limited environments (pyrolysis and gasification) (Lehmann and
15 Joseph 2012). Feedstocks include forestry and sawmill residues, straw, manure and biosolids. When
16 applied to soils, biochar is estimated to persist from decades to thousands of years, depending on
17 feedstock and production conditions (Singh et al. 2015; Wang et al. 2016). Biochar systems producing
18 biochar for soil application plus bioenergy, generally give greater mitigation than bioenergy alone and
19 other uses of biochar, and are recognised as a CDR strategy. Biochar persistence is increased through
20 interaction with clay minerals and soil organic matter (Fang et al. 2015). Additional CDR benefits arise
21 through “negative priming” whereby biochar stabilises soil carbon and rhizodeposits (Archanjo et al.
22 2017; Hagemann et al. 2017; Weng et al. 2015; Han Weng et al. 2017; Weng et al. 2018; Wang et al.
23 2016). Besides CDR, additional mitigation can arise from displacing fossil fuels with pyrolysis gases,
24 lower soil N₂O emissions (Cayuela et al. 2014, 2015; Song et al. 2016; He et al. 2017; Verhoeven et al.
25 2017; Borchard et al. 2019), reduced nitrogen fertiliser requirements due to reduced nitrogen leaching
26 and volatilisation from soils (Liu et al. 2019; Borchard et al. 2019), and reduced GHG emissions from
27 compost when biochar is added (Agyarko-Mintah et al. 2017; Wu et al. 2017). Biochar application to
28 paddy rice has resulted in substantial reductions (20-40% on average) in N₂O (Awad et al. 2018; Liu et
29 al. 2018; Song et al. 2016) (Section 7.4.3.5) and smaller reduction in CH₄ emissions (Kammann et al.
30 2017; Kim et al. 2017a; Song et al. 2016; He et al. 2017; Awad et al. 2018). Potential co-benefits include
31 yield increases particularly in sandy and acidic soils with low cation exchange capacity (Woolf et al.
32 2016; Jeffery et al. 2017); increased soil water-holding capacity (Omondi et al. 2016), nitrogen use
33 efficiency (Liu et al. 2019; Borchard et al. 2019), biological nitrogen fixation (Van Zwieten et al. 2015);
34 adsorption of organic pollutants and heavy metals (e.g. Silvani et al. 2019); odour reduction from
35 manure handling (e.g. Hwang et al. 2018) and managing forest fuel loads (Puettmann et al. 2020). Due
36 to its dark colour, biochar could decrease soil albedo (Meyer et al. 2012), though this is insignificant
37 under recommended rates and application methods. Biochar could reduce enteric CH₄ emissions when
38 fed to ruminants (Section 7.4.3.4). Barriers to upscaling include insufficient investment, limited large-
39 scale production facilities, high production costs at small scale, lack of agreed approach to monitoring,
40 reporting and verification, and limited knowledge, standardisation and quality control, restricting user
41 confidence (Gwenzi et al. 2015).

42 **Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL); mitigation**
43 **potential, costs, and pathways.** Biochar is discussed as a mitigation option in AR5 and CDR strategy
44 in the SR1.5. Consideration of potential was limited as biochar is not included in IAMs. The SRCCL
45 estimated mitigation potential of 0.03-6.6 GtCO₂-eq yr⁻¹ by 2050 based on studies with widely varying
46 assumptions, definitions of potential, and scope of mitigation processes included (SRCCL, Chapters 2

1 and 4: (Roberts et al. 2010; Pratt and Moran 2010; Hristov; Lee and Day 2013; Dickie et al. 2014a;
2 Hawken 2017; Fuss et al. 2018; Powell and Lenton 2012; Woolf et al. 2010).

3 **Developments since AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL).** Developments
4 include mechanistic understanding of ‘negative priming’ and biochar-soil-microbes-plant interactions
5 (DeCiucies et al. 2018; Fang et al. 2019). Indirect climate benefits are associated with persistent yield
6 response to biochar (Kätterer et al. 2019; Ye et al. 2020), improved crop water use efficiency (Du et al.
7 2018; Gao et al. 2020) and reduced GHG and ammonia emissions from compost and manure (Sanchez-
8 Monedero et al. 2018; Bora et al. 2020a,b; Zhao et al. 2020). A quantification method based on biochar
9 properties is included in the IPCC guidelines for NGHGs (IPCC 2019b). Studies report a range of
10 biochar responses, from positive to occasionally adverse impacts, including on GHG emissions, and
11 identify risks (Tisserant and Cherubini 2019). This illustrates the expected variability (Lehmann and
12 Rillig 2014) of responses, which depend on the biochar type and climatic and edaphic characteristics of
13 the site (Zygourakis 2017). Biochar properties vary with feedstock, production conditions and post-
14 production treatments, so mitigation and agronomic benefits are maximised when biochars are chosen
15 to suit the application context (Mašek et al. 2018). A recent assessment finds greatest economic potential
16 (up to USD100 tCO₂⁻¹) between 2020 and 2050 to be in Asia and the developing Pacific (793 MtCO₂
17 yr⁻¹) followed by Developed Countries (447 MtCO₂ yr⁻¹) (Roe et al. 2021). Mitigation through biochar
18 will be greatest where biochar is applied to responsive soils (acidic, low fertility), where soil N₂O
19 emissions are high (intensive horticulture, irrigated crops), and where the syngas co-product displaces
20 fossil fuels. Due to the early stage of commercialisation, mitigation estimates are based pilot-scale
21 facilities, leading to uncertainty. However, the long-term persistence of biochar carbon in soils has been
22 widely studied (e.g. Singh et al. 2012; Fang et al. 2019; Zimmerman and Ouyang 2019). The greatest
23 uncertainty is the availability of sustainably-sourced biomass for biochar production.

24 **Critical assessment and conclusion.** Biochar has significant mitigation potential through CDR and
25 emissions reduction, and can also improve soil properties, enhancing productivity and resilience to
26 climate change (*medium agreement, robust evidence*). There is *medium evidence* that biochar has a
27 technical potential of 2.6 (0.2–6.6) GtCO₂-eq yr⁻¹, of which 1.1 (0.3–1.8) GtCO₂-eq yr⁻¹ is available up
28 to USD100 tCO₂⁻¹. However mitigation and agronomic co-benefits depend strongly on biochar
29 properties and the soil to which biochar is applied (*strong agreement, robust evidence*). While biochar
30 could provide moderate to large mitigation potential, it is not yet included in IAMs, which has restricted
31 comparison and integration with other CDR strategies.

32 7.4.3.3. Agroforestry

33 **Activities, co-benefits, risks and implementation opportunities and barriers.** Agroforestry is a set of
34 diverse land management systems that integrate trees and shrubs with crops and/or livestock in space
35 and/or time. Agroforestry accumulates carbon in woody vegetation and soil (Ramachandran Nair et al.
36 2010) and offers multiple co-benefits such as increased land productivity, diversified livelihoods,
37 reduced soil erosion, improved water quality, and more hospitable regional climates (Ellison et al. 2017;
38 Kuyah et al. 2019; Mbow et al. 2020; Zhu et al. 2020). Incorporation of trees and shrubs in agricultural
39 systems, however, can affect food production, biodiversity, local hydrology and contribute to social
40 inequality (Amadu et al. 2020; Fleischman et al. 2020; Holl and Brancalion 2020). To minimise risks
41 and maximise co-benefits, agroforestry should be implemented as part of support systems that deliver
42 tools, and information to increase farmers’ agency. This may include reforming policies, strengthening
43 extension systems and creating market opportunities that enable adoption (Jamnadass et al. 2020,
44 Sendzimir et al. 2011, Smith et al. 2019b). Consideration of carbon sequestration in the context of food
45 and fuel production, as well as environmental co-benefits at the farm, local, and regional scales can
46 further help support decisions to plant, regenerate and maintain agroforestry systems (Miller et al. 2020;
47 Kumar and Nair 2011). In spite of the advantages, biophysical and socioeconomic factors can limit the

1 adoption (Pattanayak et al. 2003). Contextual factors may include, but are not limited to; water
2 availability, soil fertility, seed and germplasm access, land policies and tenure systems affecting farmer
3 agency, access to credit, and to information regarding the optimum species for a given location.

4 **Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL); mitigation**
5 **potential, costs, and pathways.** The SRCCL estimated the global technical mitigation potential of
6 agroforestry, with medium confidence, to be between 0.08 and 5.6 GtCO₂-eq yr⁻¹ by 2050 (Griscom et
7 al. 2017; Dickie et al. 2014a; Zomer et al. 2016; Hawken 2017). Estimates are derived from syntheses
8 of potential area available for various agroforestry systems e.g., windbreaks, farmer managed natural
9 regeneration, and alley cropping and average annual rates of carbon accumulation. The cost-effective
10 economic potential, also with medium confidence, is more limited at 0.3-2.4 GtCO₂-eq yr⁻¹ (Zomer et
11 al. 2016; Griscom et al. 2017; Roe et al. 2019). Despite this potential, agroforestry is currently not
12 considered in integrated assessment models used for mitigation pathways (Section 7.5).

13 **Developments since AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL).** Updated
14 estimates of agroforestry's technical mitigation potential and synthesised estimates of carbon
15 sequestration across agroforestry systems have since been published. The most recent global analysis
16 estimates technical potential of 9.4 GtCO₂-eq yr⁻¹ (Chapman et al. 2020) of agroforestry on 1.87 and
17 1.89 billion ha of crop and pasture lands below median carbon content, respectively. This estimate is at
18 least 68% greater than the largest estimate reported in the SRCCL (Hawken 2017) and represents a new
19 conservative upper bound as Chapman et al. (2020) only accounted for aboveground carbon.
20 Considering both above- and belowground carbon of windbreaks, alley cropping and silvopastoral
21 systems at a more limited areal extent (Griscom et al. 2020), the economic potential of agroforestry was
22 estimated to be only about 0.8 GtCO₂-eq yr⁻¹. Variation in estimates primarily result from assumptions
23 on the agroforestry systems including, extent of implementation and estimated carbon sequestration
24 potential when converting to agroforestry.

25 Regional estimates of mitigation potential are scant with agroforestry options differing significantly by
26 geography (Feliciano et al. 2018). For example, multi-strata shaded coffee and cacao are successful in
27 the humid tropics (Somarriba et al. 2013; Blaser et al. 2018), silvopastoral systems are prevalent in
28 Latin American (Peters et al. 2013; Landholm et al. 2019) while agrosilvopastoral systems, shelterbelts,
29 hedgerows, and windbreaks are common in Europe (Joffre et al. 1988; Rigueiro-Rodriguez 2009). At
30 the field scale, agroforestry accumulates between 0.59 and 6.24 t ha⁻¹ yr⁻¹ of carbon aboveground.
31 Belowground carbon often constitutes 25% or more of the potential carbon gains in agroforestry
32 systems (De Stefano and Jacobson 2018; Cardinael et al. 2018). Roe et al. (2021) estimate greatest
33 regional economic (up to USD100 tCO₂⁻¹) mitigation potential for the period 2020-2050 to be in Asia
34 and the developing Pacific (368.4 MtCO₂-eq yr⁻¹) and Developed Countries (264.7 MtCO₂-eq yr⁻¹).

35 Recent research has also highlighted co-benefits and more precisely identified implementation barriers.
36 In addition to aforementioned co-benefits, evidence now shows that agroforestry can improve soil
37 health, regarding infiltration and structural stability (Muchane et al. 2020); reduces ambient
38 temperatures and crop heat stress (Arenas-Corraliza et al. 2018; Sida et al. 2018); increases groundwater
39 recharge in drylands when managed at moderate density (Ilstedt et al. 2016; Bargués-Tobella et al.
40 2020); positively influences human health (Rosenstock et al. 2019); and can improve dietary diversity
41 (McMullin et al. 2019). Along with previously mentioned barriers, low social capital, assets, and labour
42 availability have been identified as pertinent to adoption. Practically all barriers are interdependent and
43 subject to the context of implementation.

44 **Critical assessment and conclusion.** There is medium confidence that agroforestry has a technical
45 potential of 4.1 (0.3-9.4) GtCO₂-eq yr⁻¹ for the period 2020-2050, of which 0.8 (0.4-1.1) GtCO₂-eq yr⁻¹
46 is available at USD100 tCO₂⁻¹. Despite uncertainty around global estimates due to regional preferences

1 for management systems, suitable land availability, and growing conditions, there is high confidence in
2 agroforestry's mitigation potential at the field scale. With countless options for farmers and land
3 managers to implement agroforestry, there is medium confidence in the feasibility of achieving
4 estimated regional mitigation potential. Appropriately matching agroforestry options, to local
5 biophysical and social contexts is important in maximising mitigation and co-benefits, while avoiding
6 risks (Sinclair and Coe 2019).

8 [START BOX 7.3 HERE]

9 **Box 7.3 Case study: agroforestry in Brazil – CANOPIES**

10 **Summary**

11 Brazilian farmers are integrating trees into their croplands in various ways, ranging from simple to
12 highly complex agroforestry systems. While complex systems are more effective in the mitigation of
13 climate change, trade-offs with scalability need to be resolved for agroforestry systems to deliver on
14 their potential. The Brazilian-Dutch CANOPIES project (Janssen 2020) is exploring transition
15 pathways to agroforestry systems optimised for local ecological and socio-economic conditions

16 **Background**

17 The climate change mitigation potential of agroforestry systems is widely recognised (FAO 2017b;
18 Zomer et al. 2016) and Brazilian farmers and researchers are pioneering diverse ways of integrating
19 trees into croplands, from planting rows of eucalyptus trees in pastures up to highly complex agroforests
20 consisting of >30 crop and tree species. The degree of complexity influences the multiple functions that
21 farmers and societies can attain from agroforestry: the more complex it is, the more it resembles a
22 natural forest with associated benefits for its C storage capacity and its habitat quality for biodiversity
23 (Santos et al. 2019). However, trade-offs exist between the complexity and scalability of agroforestry
24 as complex systems rely on intensive manual labour to achieve high productivity (Tscharntke et al.
25 2011). To date, mechanisation of structurally diverse agroforests is scarce and hence, efficiencies of
26 scale are difficult to achieve.

27 **Case description**

28 These synergies and trade-offs between complexity, multifunctionality and scalability are studied in the
29 CANOPIES (*Co-existence of Agriculture and Nature: Optimisation and Planning of Integrated*
30 *Ecosystem Services*) project, a collaboration between Wageningen University (NL), the University of
31 São Paulo and EMBRAPA (both Brazil). Soil and management data are collected on farms of varying
32 complexity to evaluate C sequestration and other ecosystem services, economic performance and labour
33 demands.

34 **Interactions and limitations**

35 The trade-off between complexity and labour demand is less pronounced in EMBRAPA's integrated
36 crop-livestock-forestry (ICLF) systems, where grains and pasture are planted between widely spaced
37 tree rows. Here, barriers for implementation relate mostly to livestock and grain farmers' lack of
38 knowledge on forestry management and financing mechanisms⁵ (Gil et al. 2015). Additionally, linking
39 these financing mechanisms to C sequestration remains a Monitoring, Reporting and Verification
40 challenge (Smith et al. 2020b).

41 **Lessons**

1 Successful examples of how more complex agroforestry can be upscaled do exist in Brazil. For example,
2 on farm trials and consistent investments over several years have enabled Rizoma Agro to develop a
3 citrus production system that integrates commercial and native trees in a large-scale multi-layered
4 agroforestry system. The success of their transition resulted in part from their corporate structure that
5 allowed them to tap into the certified Green Bonds market (CBI 2020). However, different transition
6 strategies need to be developed for family farmers and their distinct socio-economic conditions.

7 [END BOX 7.3 HERE]

9 7.4.3.4. Enteric fermentation

10 **Activities, co-benefits, risks and implementation opportunities and barriers.** Mitigating CH₄ emissions
11 from enteric fermentation can be direct (i.e. targeting ruminal methanogenesis and emissions per animal
12 or unit of feed consumed) or indirect, by increasing production efficiency (i.e. reducing emission
13 intensity per unit of product). Measures can be classified as those relating to (1) feeding, (2)
14 supplements, additives and vaccines, and (3) livestock breeding and wider husbandry (Jia et al. 2019).
15 Co-benefits include enhanced climate change adaptation and increased food security associated with
16 improved livestock breeding (Smith et al. 2014). Risks include mitigation persistence, ecological
17 impacts associated with improving feed quality and supply, or potential toxicity and animal welfare
18 issues concerning feed additives. Implementation barriers include feeding/administration constraints,
19 the stage of development of measures, legal restrictions on emerging technologies and negative impacts,
20 such as the previously described risks (Smith et al. 2014; Jia et al. 2019; Smith et al. 2019b).

21 **Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL); mitigation**
22 **potential, costs, and pathways.** AR5 indicated medium (5-15%) technical mitigation potential from
23 both feeding and breeding related measures (Smith et al. 2014). More recently, the SRCCL estimated
24 with *medium confidence*, a global potential of 0.12-1.18 GtCO₂-eq yr⁻¹ between 2020 and 2050, with
25 the range reflecting technical, economic and sustainability constraints (SRCCL, Chapter 2: Hristov et
26 al. 2013; Dickie et al. 2014a; Herrero et al. 2016; Griscom et al. 2017). The underlying literature used
27 a mixture of IPCC GWP₁₀₀ values for CH₄, preventing conversion of CO₂-eq to CH₄. Improved livestock
28 feeding and breeding were included in IAM emission pathway scenarios within the SRCCL and SR1.5,
29 although it was suggested that the full mitigation potential of enteric CH₄ measures is not captured in
30 current models (Rogelj et al. 2018b; IPCC 2018).

31 **Developments since AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL).** Recent reviews
32 generally identify the same measures as those outlined in the SRCCL, with the addition of early life
33 manipulation of the ruminal biome (Grossi et al. 2019; Eckard and Clark 2020; Thompson and
34 Rowntree 2020; Beauchemin et al. 2020; Ku-Vera et al. 2020; Honan et al. 2021). There is *robust*
35 *evidence* and *high agreement* that chemically synthesised inhibitors are promising emerging near-term
36 measures (Patra 2016; Jayanegara et al. 2018; Van Wesemael et al. 2019; Beauchemin et al. 2020) with
37 high (e.g. 16-70% depending on study) mitigation potential reported (e.g. Hristov et al. 2015; McGinn
38 et al. 2019; Melgar et al. 2020) and commercial availability expected within two years in some countries
39 (Reisinger et al. 2021). However, their mitigation persistence (McGinn et al. 2019), cost (Carroll and
40 Daigneault 2019; Alvarez-Hess et al. 2019) and public acceptance (Jayasundara et al. 2016) or
41 regulatory approval is currently unclear while administration in pasture-based systems is likely to be
42 challenging (Patra et al. 2017; Leahy et al. 2019). Research into other inhibitors/feeds containing
43 inhibitory compounds, such as macroalgae or seaweed (Chagas et al. 2019; Kinley et al. 2020; Roque et
44 al. 2019), shows promise, although concerns have been raised regarding palatability, toxicity,
45 environmental impacts and the development of industrial-scale supply chains (Abbott et al. 2020; Vijn
46 et al. 2020). In the absence of CH₄ vaccines, which are still under development (Reisinger et al. 2021)

1 pasture-based and non-intensive systems remain reliant on increasing production efficiency
2 (Beauchemin et al. 2020). Breeding of low emitting animals may play an important role and is a subject
3 under on-going research (Pickering et al. 2015; Jonker et al. 2018; López-Paredes et al. 2020).

4 Approaches differ regionally, with more focus on direct, technical options in developed countries, and
5 improved efficiency in developing countries (Caro Torres et al. 2016; Mottet et al. 2017b; MacLeod et
6 al. 2018; Frank et al. 2018). A recent assessment finds greatest economic (up to USD100 tCO₂-eq⁻¹)
7 potential (using the IPCC AR4 GWP₁₀₀ value for CH₄) for 2020-2050 in Asia and the developing Pacific
8 (32.9 MtCO₂-eq yr⁻¹) followed by Developed Countries (25.5 MtCO₂-eq yr⁻¹) (Roe et al. 2021). Despite
9 numerous country and sub-sector specific studies, most of which include cost analysis (Hasegawa and
10 Matsuoka 2012; Hoa et al. 2014; Jilani et al. 2015; Eory et al. 2015; Pradhan et al. 2017; Pellerin et al.
11 2017; Ericksen and Crane 2018; Habib and Khan 2018; Kashangaki and Ericksen 2018; Salmon et al.
12 2018; Brandt et al. 2019b; Dioha and Kumar 2020; Kiggundu et al. 2019; Kavanagh et al. 2019; Mosnier
13 et al. 2019; Pradhan et al. 2019; Sapkota et al. 2019; Carroll and Daigneault 2019; Leahy et al. 2019),
14 sectoral assessment of regional technical and notably economic (Beach et al. 2015; USEPA 2019)
15 potential is restricted by lack comprehensive and comparable data. Therefore, verification of regional
16 estimates indicated by global assessments is challenging. Feed quality improvement, which may have
17 considerable potential in developing countries (Mottet et al. 2017a; Caro et al. 2016), may have negative
18 wider impacts. For example, potential land use change and greater emissions associated with production
19 of concentrates (Brandt et al. 2019b).

20 **Critical review and conclusion.** Based on studies to date, using a range of IPCC GWP₁₀₀ values for
21 CH₄, there is *medium confidence* that activities to reduce enteric CH₄ emissions have a global technical
22 potential of 0.8 (0.2–1.2) GtCO₂-eq yr⁻¹, of which 0.2 (0.1–0.3) GtCO₂-eq yr⁻¹ is available up to USD100
23 tCO₂-eq⁻¹ (Figure 7.11). The CO₂-eq value may also slightly differ if the GWP₁₀₀ IPCC AR6 CH₄ value
24 was uniformly applied within calculations. Lack of comparable country and sub-sector studies to assess
25 the context applicability of measures, associated costs and realistic adoption likelihood, prevents
26 verification of estimates.

27 **7.4.3.5. Improve rice management**

28 **Activities, co-benefits, risks and implementation opportunities and barriers.** Emissions from rice
29 cultivation mainly concern CH₄ associated with anaerobic conditions, although N₂O emission also occur
30 via nitrification and denitrification processes. Measures to reduce CH₄ and N₂O emissions include (1)
31 improved water management (e.g. single drainage and multiple drainage practices), (2) improved
32 residue management, (3) improved fertiliser application (e.g. using slow release fertiliser and nutrient
33 specific application), and (4) soil amendments (including biochar and organic amendments) (Pandey et
34 al. 2014; Yagi et al. 2020; Sriphirom et al. 2020; Kim et al. 2017b). These measures not only have
35 mitigation potential but can improve water use efficiency, reduce overall water use, enhance drought
36 adaptation and overall system resilience, improve yield, reduce production costs from seed, pesticide,
37 pumping and labour, increase farm income, and promote sustainable development (Sriphirom et al.
38 2019; Tran et al. 2018; Yamaguchi et al. 2017; Quynh and Sander 2015). However, in terms of
39 mitigation of CH₄ and N₂O, antagonistic effects can occur, whereby water management can enhance
40 N₂O emissions due to creation of alternate wet and dry conditions (Sriphirom et al. 2019), with trade-
41 offs between CH₄ and N₂O during the drying period potentially off-setting some mitigation benefits.
42 Barriers to adoption may include site-specific limitations regarding soil type, percolation and seepage
43 rates or fluctuations in precipitation, water canal or irrigation infrastructure, paddy surface level and
44 rice field size, and social factors including farmer perceptions, pump ownership, and challenges in
45 synchronising water management between neighbours and pumping stations (Yamaguchi et al. 2019;
46 Yamaguchi et al. 2017; Quynh and Sander 2015).

1 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
2 **potential, costs, and pathways.** AR5 outlined emissions from rice cultivation of 0.49-0.723 GtCO₂-eq
3 yr⁻¹ in 2010 with an average annual growth of 0.4% yr⁻¹. The SRCCL estimated a global mitigation
4 potential from improved rice cultivation of 0.08-0.87 GtCO₂-eq yr⁻¹ between 2020 and 2050, with the
5 range representing the difference between technical and economic constraints, types of activities
6 included (e.g. improved water management and straw residue management) and GHGs considered
7 (SRCCL, Chapter 2: Dickie et al. 2014a; Paustian et al. 2016; Beach et al. 2015; Griscom et al. 2017;
8 Hawken 2017).

9 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Since AR5 and
10 the SRCCL, studies on mitigation have principally focused on water and nutrient management practices
11 with the aim of improving overall sustainability as well as measurements of site-specific emissions to
12 help improve the resolution of regional estimates. Intensity of emissions show considerable spatial and
13 temporal variation, dependent on site specific factors including degradation of soil organic matter,
14 management of water levels in the field, the types and amount of fertilisers applied, rice variety and
15 local cultivation practices. Variation in CH₄ emissions have been found to range from 0.5-41.8 mg/m²/hr
16 in Southeast Asia (Sander et al. 2014; Chidthaisong et al. 2018; Setyanto et al. 2018; Sibayan et al.
17 2018; Wang et al. 2018; Maneepitak et al. 2019), 0.5-37.0 mg/m²/hr in Southern and Eastern Asia
18 (Zhang et al. 2010; Wang et al. 2012; Oo et al. 2018; Takakai et al. 2020; Wang et al. 2018), and 0.5-
19 10.4 mg/m²/hr in North America (Wang et al. 2018). Current studies on emissions of N₂O also showed
20 high variation in the range of 0.13-654 ug/m²/hr (Akiyama et al. 2005; Islam et al. 2018; Kritee et al.
21 2018; Zschornack et al. 2018; Oo et al. 2018).

22 Recent studies on water management have highlighted the potential to mitigate GHG emissions, while
23 also enhancing water use efficiency (Tran et al. 2018). A meta-analysis on multiple drainage systems
24 found that Alternative Wetting and Drying (AWD) with irrigation management, can reduce CH₄
25 emissions by 20-30% and water use by 25.7 %, though this resulted in a slight yield reduction (5.4%)
26 (Carrizo et al. 2017). Other studies have described improved yields associated with AWD (Tran et al.
27 2018). Water management for both single and multiple drainage can (most likely) reduce methane
28 emissions by ~35 % but increase N₂O emissions by about 20% (Yagi et al. 2020). However, N₂O
29 emissions occur only under dry conditions, therefore total reduction in terms of net GWP is
30 approximately 30%. Emissions of N₂O are higher during dry seasons (Yagi et al. 2020) and depend on
31 site specific factors as well as the quantity of fertiliser and organic matter inputs into the paddy rice
32 system. Variability of N₂O emissions from single and multiple drainage can range from 0.06-33 kg/ha
33 (Hussain et al. 2015; Kritee et al. 2018). AWD in Vietnam was found to reduce both CH₄ and N₂O
34 emissions by 29-30 and 26-27% respectively with the combination of net GWP about 30% as compared
35 to continuous flooding (Tran et al. 2018). Overall, greatest average economic mitigation potential (up
36 to USD100 tCO₂-eq⁻¹) between 2020 and 2050 is estimated to be in Asia and the developing Pacific
37 (147.2 MtCO₂-eq yr⁻¹) followed by Latin America and the Caribbean (8.9 MtCO₂-eq yr⁻¹) using the
38 IPCC AR4 GWP₁₀₀ value for CH₄ (Roe et al. 2021).

39 **Critical assessment and conclusion.** There is *medium confidence* that improved rice management has
40 a technical potential of 0.3 (0.1-0.8) GtCO₂-eq yr⁻¹ between 2020 and 2050, of which 0.2 (0.05-0.3)
41 GtCO₂-eq yr⁻¹ is available up to USD100 tCO₂-eq⁻¹ (Figure 7.11). Improving rice cultivation practices
42 will not only reduce GHG emissions, but also improve production sustainability in terms of resource
43 utilisation including water consumption and fertiliser application. However, emission reductions show
44 high variability and are dependent on site specific conditions and cultivation practices.

1 **7.4.3.6. Crop nutrient management**

2 **Activities, co-benefits, risks and implementation opportunities and barriers.** Improved crop nutrient
3 management can reduce N₂O emissions from cropland soils. Practices include optimising fertiliser
4 application delivery, rates and timing, utilising different fertiliser types (i.e. organic manures, composts
5 and synthetic forms), and using slow or controlled-released fertilisers or nitrification inhibitors (Smith
6 et al. 2014; Griscom et al. 2017; Smith et al. 2019b). In addition to individual practices, integrated
7 nutrient management that combines crop rotations including intercropping, nitrogen biological fixation,
8 reduced tillage, use of cover crops, manure and bio-fertilizer application, soil testing and comprehensive
9 nitrogen management plans, is suggested as central for optimising fertiliser use, enhancing nutrient
10 uptake and potentially reducing N₂O emissions (Bationo et al. 2012; Lal et al. 2018; Bolinder et al.
11 2020; Jensen et al., 2020; Namatsheve et al., 2020). Such practices may generate additional mitigation
12 by indirectly reducing synthetic fertilizer manufacturing requirements and associated emissions, though
13 such mitigation is accounted for in the Industry Sector and not considered in this chapter. Tailored
14 nutrient management approaches, such as 4R nutrient stewardship, are implemented in contrasting
15 farming systems and contexts and supported by best management practices to balance and match
16 nutrient supply with crop requirements, provide greater stability in fertilizer performance and to
17 minimize N₂O emissions and nutrient losses from fields and farms (Fixen 2020; Maaz et al. 2021). Co-
18 benefits of improved nutrient management can include enhanced soil quality (notably when manure,
19 crop residues or compost is utilised), carbon sequestration in soils and biomass, soil water holding
20 capacity, adaptation capacity, crop yields, farm incomes, water quality (from reduced nitrate leaching
21 and eutrophication), air quality (from reduced ammonia emissions) and in certain cases, it may facilitate
22 land sparing (Sapkota et al. 2014; Johnston and Bruulsema 2014; Zhang et al. 2017; Smith et al. 2019b;
23 Mbow et al. 2019).

24 A potential risk under certain circumstances, is yield reduction, while implementation of practices
25 should consider current soil nutrient status. There are significant regional imbalances, with some
26 regions experiencing nutrient surpluses from over fertilization and others, nutrient shortages and
27 chronic deficiencies (FAO 2021e). Additionally, depending on context, practices may be inaccessible,
28 expensive or require expertise to implement (Hedley 2015; Benson and Moguees 2018) while impacts
29 of climate change may influence nutrient use efficiency (Amouzou et al. 2019) and therefore, mitigation
30 potential.

31 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
32 **potential, costs, and pathways.** The SRCCL broadly identified the same practices as outlined in AR5
33 and estimated that improved cropland nutrient management could mitigate between 0.03 and 0.71
34 GtCO₂-eq yr⁻¹ between 2020 and 2050 (SRCCL Chapter 2: Dickie et al. 2014a; Beach et al. 2015;
35 Paustian et al. 2016; Griscom et al. 2017; Hawken 2017).

36 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Research since
37 the SRCCL highlights the mitigation potential and co-benefits of adopting improved nutrient
38 management strategies, notably precision fertiliser application methods and nutrient expert systems,
39 and applicability in both large-scale mechanised and small-scale systems (Aryal et al. 2020; USEPA
40 2019; Hijbeek et al. 2019; Griscom et al. 2020; Tian et al. 2020; Sapkota et al. 2021). Improved crop
41 nutrient management is feasible in all regions, but effectiveness is context dependent. Sub-Saharan
42 Africa has one of the lowest global fertiliser consumption rates, with increased fertiliser use suggested
43 as necessary to meet projected future food requirements (Mueller et al. 2012; Adam et al. 2020; ten
44 Berge et al. 2019; Falconnier et al. 2020). Fertiliser use in Developed Countries is already high (Figure
45 7.10) with increased nutrient use efficiency among the most promising mitigation measures (Roe et al.
46 2019; Hijbeek et al. 2019). Considering that Asia and developing Pacific, and Developed Countries
47 accounted for the greatest share of global nitrogen fertiliser use, it is not surprising that these regions

1 are estimated to have greatest economic mitigation potential (up to USD100 tCO₂-eq⁻¹) between 2020
2 and 2050, at 161.8 and 37.1 MtCO₂-eq yr⁻¹ respectively (using the IPCC AR4 GWP₁₀₀ value for N₂O)
3 (Roe et al. 2021).

4 **Critical assessment and conclusion.** There is *medium confidence* that crop nutrient management has a
5 technical potential of 0.3 (0.06–0.7) GtCO₂-eq yr⁻¹ of which 0.2 (0.05–0.6) GtCO₂-eq yr⁻¹ is available
6 up to USD100 tCO₂-eq⁻¹. This value is based on GWP100 using a mixture of IPCC values for N₂O and
7 may slightly differ if calculated using AR6 values. The development of national roadmaps for
8 sustainable fertilizer (nutrient) management can help in scaling-up related practices and in realising this
9 potential. Crop nutrient management measures can contribute not only to mitigation, but food and
10 nutrition security and wider environmental sustainability goals.

11

12 [START BOX 7.4 HERE]

13

Box 7.4 Case study: the climate-smart village approach

14 Summary

15 The climate-smart villages (CSV) approach aims to generate local knowledge, with the involvement of
16 farmers, researchers, practitioners, and governments, on climate change adaptation and mitigation while
17 improving productivity, food security, and farmers' livelihoods (Aggarwal et al. 2018). This knowledge
18 feeds a global network that includes 36 climate-smart villages in South and Southeast Asia, West and
19 East Africa, and Latin America.

20 Background

21 It is expected that agricultural production systems across the world will change in response to climate
22 change, posing significant challenges to the livelihoods and food security of millions of people (IPCC
23 2014). Maintaining agricultural growth while minimising climate shocks is crucial to building a resilient
24 food production system and meeting sustainable development goals in vulnerable countries.

25 Case description

26 The CSV approach seeks an integrated vision so that sustainable rural development is the final goal for
27 rural communities. At the same time, it fosters the understanding of climate change with the
28 implementation of adaptation and mitigation actions, as much as possible. Rural communities and local
29 stakeholders are the leaders of this process, where scientists facilitate their knowledge to be useful for
30 the communities and learn at the same time about challenges but also the capacity those communities
31 have built through time. The portfolio includes weather-smart activities, water-smart practices,
32 seed/breed smart, carbon/nutrient-smart practices, and institutional/market smart activities.

33 Interactions and limitations

34 The integration of technologies and services that are suitable for the local conditions resulted in many
35 gains for food security and adaptation and for mitigation where appropriate. It was also shown that, in
36 all regions, there is considerable yield advantage when a portfolio of technologies is used, rather than
37 the isolated use of technologies (Govaerts et al. 2005; Zougmore et al. 2014). Moreover, farmers are
38 using research results to promote their products as climate-smart leading to increases in their income
39 (Acosta-Alba et al. 2019). However, climatic risk sites and socioeconomic conditions together with a
40 lack of resource availability are key issues constraining agriculture across all five regions.

41 Lessons

- 1 **1.** Understanding the priorities, context, challenges, capacity, and characteristics of the territory and
2 the communities regarding climate, as well as the environmental and socioeconomic dimensions,
3 is the first step. Then, understanding climate vulnerability in their agricultural systems based on
4 scientific data but also listening to their experience will set the pathway to identify climate-smart
5 agriculture (CSA) options (practices and technologies) to reduce such vulnerability.
- 6 **2.** Building capacity is also a critical element of the CSV approach, rural families learn about the
7 practices and technologies in a neighbour's house, and as part of the process, families commit to
8 sharing their knowledge with other families, to start a scaling-out process within the communities.
9 Understanding the relationship between climate and their crop is key, as well as the use of weather
10 forecasts to plan their agricultural activities.
- 11 **3.** The assessment of the implementation of the CSA options should be done together with community
12 leaders to understand changes in livelihoods and climate vulnerability. Also, knowledge
13 appropriation by community leaders has led to farmer-to-farmer knowledge exchange within and
14 outside the community (Ortega Fernandez and Martínez-Barón 2018).

15 **[END BOX 7.4 HERE]**

16

17 **7.4.3.7. Manure management**

18 **Activities, co-benefits, risks and implementation opportunities and barriers.** Manure management
19 measures aim to mitigate CH₄ and N₂O emissions from manure storage and deposition. Mitigation of
20 N₂O considers both direct and indirect (i.e. conversion of ammonia and nitrate to N₂O) sources.
21 According to the SRCCL, measures may include (1) anaerobic digestion, (2) applying nitrification or
22 urease inhibitors to stored manure or urine patches, (3) composting, (4) improved storage and
23 application practices, (5) grazing practices and (6) alteration of livestock diets to reduce nitrogen
24 excretion (Mbow et al. 2019; Jia et al. 2019). Implementation of manure management with other
25 livestock and soil management measures can enhance system resilience, sustainability, food security
26 and help prevent land degradation (Smith et al. 2014; Mbow et al. 2019; Smith et al. 2019d), while
27 potentially benefiting the localised environment, for example, regarding water quality (Di and Cameron
28 2016). Risks include increased N₂O emission from the application of manure to poorly drained or wet
29 soils, trade-offs between N₂O and ammonia emissions and potential eco-toxicity associated with some
30 measures.

31 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
32 **potential, costs, and pathways.** AR5 reported manure measures to have high (> 10%) mitigation
33 potential. The SRCCL estimated a technical global mitigation potential between 2020 and 2050 of 0.01-
34 0.26 GtCO₂-eq yr⁻¹, with the range depending on economic and sustainable capacity (SRCCL, Chapter
35 2: (Dickie et al. 2014a; Herrero et al. 2016). Conversion of estimates to native units is restricted as a
36 mixture of GWP₁₀₀ values was used in underlying studies. Measures considered were typically more
37 suited to confined production systems (Jia et al. 2019; Mbow et al. 2019), while improved manure
38 management is included within IAM emission pathways (Rogelj et al. 2018b).

39 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Research
40 published since SRCCL broadly focuses on measures relevant to intensive or confined systems (e.g.
41 (Hunt et al. 2019; Sokolov et al. 2020; Im et al. 2020; Adghim et al. 2020; Mostafa et al. 2020; Kavanagh
42 et al. 2019), highlighting co-benefits and risks. For example, measures may enhance nutrient recovery,
43 fertiliser value (Sefeepari et al. 2019; Ba et al. 2020; Yao et al. 2020) and secondary processes such as
44 biogas production (Shin et al. 2019). However, the potential antagonistic relationship between GHG
45 and ammonia mitigation and need for appropriate management is emphasised (Aguirre-Villegas et al.

1 2019; Kupper et al. 2020; Grossi et al. 2019; Ba et al. 2020). In some circumstances, fugitive emissions
2 may reduce the potential mitigation benefits of biogas production (Scheutz and Fredenslund 2019;
3 Bakkaloglu et al. 2021), while high implementation cost is identified as an adoption barrier, notably of
4 anaerobic digestion (Liu and Liu 2018; Niles and Wiltshire 2019; Ndambi et al. 2019; Ackrill and Abdo
5 2020; Adghim et al. 2020). Nitrification inhibitors have been found to be effective at reducing N₂O
6 emissions from pasture deposited urine (López-Aizpún et al. 2020), although the use of nitrification
7 inhibitors is restricted in some jurisdictions due to concerns regarding residues in food products (Di and
8 Cameron 2016; Eckard and Clark 2020) while *limited evidence* suggests eco-toxicity risk under certain
9 circumstances (Kösler et al. 2019). Some forage crops may naturally contain inhibitory substances
10 (Simon et al. 2019, 2020; de Klein et al. 2020), though this warrants further research (Podolyan et al.
11 2020; Gardiner et al. 2020).

12 Country specific studies provide insight into regionally applicable measures, with emphasis on small-
13 scale anaerobic digestion (e.g. dome digesters), solid manure coverage and daily manure spreading in
14 Asia and the developing Pacific, and Africa (Hasegawa et al. 2016; Hasegawa and Matsuoka 2012; Hoa
15 et al. 2014; Jilani et al. 2015; Pradhan et al. 2017; Ericksen and Crane 2018; Pradhan et al. 2019;
16 Kiggundu et al. 2019; Dioha and Kumar 2020). Tank/lagoon covers, large-scale anaerobic digestion,
17 improved application timing, nitrogen inhibitor application to urine patches, soil-liquid separation,
18 reduced livestock nitrogen intake, trailing shoe, band or injection slurry spreading and acidification are
19 emphasised in developed countries (Kaparaju and Rintala 2011; Pape et al. 2016; Liu and Liu 2018;
20 Lanigan et al. 2018; Eory et al. 2015; Jayasundara et al. 2016; Pellerin et al. 2017; Carroll and
21 Daigneault 2019; Eckard and Clark 2020). Using IPCC AR4 GWP₁₀₀ values for CH₄ and N₂O, a recent
22 assessment finds 69% (63.4 MtCO₂-eq yr⁻¹) of economic potential (up to USD100 tCO₂-eq⁻¹) between
23 2020-2050, to be in Developed Countries (Roe et al. 2021).

24 **Critical assessment and conclusion.** There is *medium confidence* that manure management measures
25 have a global technical potential of 0.3 (0.1-0.5) GtCO₂-eq yr⁻¹, (using a range of IPCC GWP₁₀₀ values
26 for CH₄ and N₂O), of which 0.1 (0.09-0.1) GtCO₂-eq yr⁻¹ is available at up to USD100 tCO₂-eq⁻¹ (Figure
27 7.11). As with other non-CO₂ GHG mitigation estimates, values may slightly differ depending upon
28 which IPCC GWP₁₀₀ values were used. There is *robust evidence and high agreement* that there are
29 measures that can be applied in all regions, but greatest mitigation potential is estimated in developed
30 countries in more intensive and confined production systems.

31

32 [START BOX 7.5 HERE]

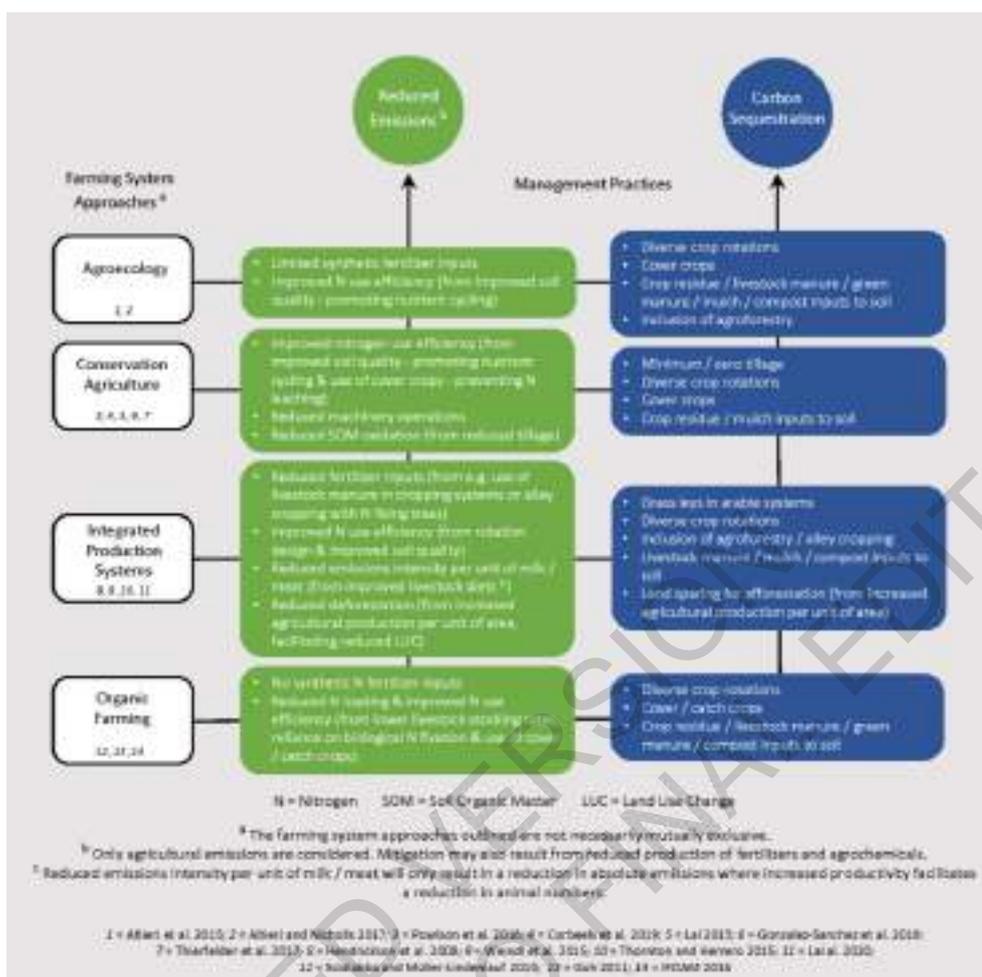

33

Box 7.5 Farming system approaches and mitigation

Introduction

35 There is *robust evidence* and *high agreement* that agriculture needs to change to facilitate environment
36 conservation while maintaining and where appropriate, increase overall production. The SRCLL
37 identified several farming system approaches, deemed alternative to conventional systems (Olsson et
38 al. 2019; Mbow et al. 2019; Smith et al. 2019a). These may incorporate several of the mitigation
39 measures described in 7.4.3, while potentially also delivering environmental co-benefits. This Box
40 assesses evidence specifically on the mitigation capacity of some such system approaches. The
41 approaches are not mutually exclusive, may share similar principles or practices and can be
42 complimentary. In all cases, mitigation may result from either (1) emission reductions or (2) enhanced
43 carbon sequestration, via combinations of management practices as outlined in Figure 1 within this Box.
44 The approaches will have pros and cons concerning multiple factors, including mitigation, yield and
45 co-benefits, with trade-offs subject to the diverse contexts and ways in which they are implemented.

1

2

3

Box 7.5, Figure 1 Potential mitigation mechanisms and associated management practices

4

Is there evidence that these approaches deliver mitigation?

5

Agroecology (AE) including Regenerative Agriculture (RA)

6

There is limited discussion on the mitigation potential of AE (Gliessman 2013; Altieri and Nicholls 2017), but *robust evidence* that AE can improve system resilience and bring multiple co-benefits

7

(Aguilera et al. 2020; Tiftonell 2020; Wanger et al. 2020; Altieri et al. 2015; Mbow et al. 2019) (IPCC

8

WGII AR6 Box 5.10). *Limited evidence* concerning the mitigation capacity of AE at a system level (Saj

9

et al. 2017; Snapp et al. 2021) makes conclusions difficult, yet studies into specific practices that may

10

be incorporated, suggest AE may have mitigation potential (Section 7.4.3) (*medium confidence*).

11

However, AE, that incorporates management practices used in organic farming (see below), may result

12

in reduced yields, driving compensatory agricultural production elsewhere. Research into GHG

13

mitigation by AE as a system and impacts of wide-scale implementation is required. Despite absence

14

of a universally accepted definition (see Annex I), RA is gaining increasing attention and shares

15

principles of AE. Some descriptions include carbon sequestration as a specific aim (Elevitch et al.

16

2018). Few studies have assessed mitigation potential of RA at a system level (e.g. Colley et al. 2020).

17

Like AE, it is *likely* that RA can contribute to mitigation, the extent to which is currently unclear and

18

by its case-specific design, will vary (*medium confidence*).

19

by its case-specific design, will vary (*medium confidence*).

1 **Conservation Agriculture (CA)**

2 The SRCCL noted both positive and inconclusive results regarding CA and soil carbon, with sustained
3 sequestration dependent on productivity and residue returns (Jia et al. 2019; Mirzabaev et al. 2019;
4 Mbow et al. 2019). Recent research is in broad agreement (Ogle et al. 2019; Corbeels et al. 2020, 2019;
5 Gonzalez-Sanchez et al. 2019; Munkholm et al. 2020) with greatest mitigation potential suggested in
6 dry regions (Sun et al. 2020). Theoretically, CA may facilitate improved nitrogen use efficiency (Lal
7 2015; Powlson et al. 2016) (*limited evidence*), though CA appears to have mixed effects on soil N₂O
8 emission (Six et al. 2004; Mei et al. 2018). CA is noted for its adaptation benefits, with *wide agreement*
9 that CA can enhance system resilience to climate related stress, notably in dry regions. There is evidence
10 that CA can contribute to mitigation, but its contribution is depended on multiple factors including
11 climate and residue returns (*high confidence*).

12 **Integrated Production Systems (IPS)**

13 The integration of different enterprises in space and time (e.g. diversified cropping, crop and livestock
14 production, agroforestry), therefore facilitating interaction and transfer of resources between systems,
15 is suggested to enhance sustainability and adaptive capacity (Franzluebbers et al. 2014; Lemaire et al.
16 2014; Gil et al. 2017; Peterson et al. 2020; Walkup et al. 2020; Garrett et al. 2020; Hendrickson et al.
17 2008; Weindl et al. 2015; Olseen et al. 2019). Research indicates some mitigation potential, including
18 by facilitating sustainable intensification (Box 7.11), though benefits are likely to be highly context
19 specific (e.g. (Herrero et al. 2013; Carvalho et al. 2014; Piva et al. 2014; de Figueiredo et al. 2017;
20 Guenet et al. 2021; Rosenstock et al. 2014; Weindl et al. 2015; Thornton and Herrero 2015; Lal 2020;
21 Descheemaeker et al. 2016). The other systems outlined within this Box may form or facilitate IPS.

22 **Organic Farming (OF)**

23 OF can be considered a form of AE (Lampkin et al. 2017) though is discussed separately here as it is
24 guided by specific principles and associated regulations (Annex I). OF is perhaps noted more for
25 potential co-benefits, such as enhanced system resilience and biodiversity promotion, than mitigation.
26 Several studies have reviewed the emissions footprint of organic compared to conventional systems
27 (e.g. Mondelaers et al. 2009; Tuomisto et al. 2012; Skinner et al. 2014; Meier et al. 2015; Seufert and
28 Ramankutty 2017; Clark and Tilman 2017; Meemken and Qaim 2018; Bellassen et al. 2021).
29 Acknowledging potential assessment limitations (Meier et al. 2015; van der Werf et al. 2020), evidence
30 suggests organic production to typically generate lower emissions per unit of area, while emissions per
31 unit of product vary and depend on the product (*high agreement, medium evidence*). OF has been
32 suggested to increase soil carbon sequestration (Gattinger et al. 2012), though definitive conclusions
33 are challenging (Leifeld et al. 2013). Fewer studies consider impacts of large-scale conversion from
34 conventional to organic production globally. Though context specific (Seufert and Ramankutty 2017),
35 OF is reported to typically generate lower yields (Seufert et al. 2012; De Ponti et al. 2012; Kirchmann
36 2019; Biernat et al. 2020). Large-scale conversion, without fundamental changes in food systems and
37 diets (Muller et al. 2017; Theurl et al. 2020), may lead to increases in absolute emissions from land use
38 change, driven by greater land requirements to maintain production (e.g. Leifeld 2016; Meemken and
39 Qaim 2018). OF may have mitigation capacity in certain instances though impacts of large-scale
40 conversion require further research.

41 **[END BOX 7.5 HERE]**

42

43 **[START BOX 7.6 HERE]**

44 **Box 7.6 Case study: Mitigation Options and Costs in the Indian Agricultural Sector**

1 **Objective**

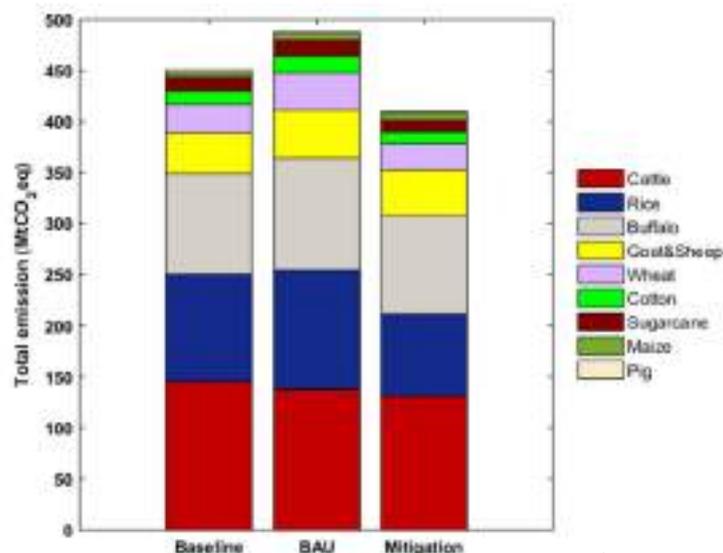

2 To assess the technical mitigation potentials of Indian agriculture and costs under a Business as Usual
3 scenario (BAU) and Mitigation scenario up to 2030 (Sapkota et al. 2019).

4 **Results**

5 The study shows that by 2030 under BAU scenario GHG emissions from the agricultural sector in India
6 would be 515 MtCO₂-eq yr⁻¹ (using GWP₁₀₀ and IPCC AR4 values) with a technical mitigation potential
7 of 85.5 MtCO₂-eq yr⁻¹ through the adoption of various mitigation practices. About 80% of the technical
8 mitigation potential could be achieved by adopting cost-saving measures. Three mitigation options, i.e.,
9 efficient use of fertiliser, zero-tillage, and rice-water management, could deliver more than 50% of the
10 total technical abatement potential. Under the BAU scenario the projected GHG emissions from major
11 crop and livestock species is estimated at 489 MtCO₂-eq in 2030, whereas under mitigation scenario
12 GHG emissions are estimated at 410 MtCO₂-eq implying a technical mitigation option of about 78.67
13 MtCO₂-eq yr⁻¹ (Box 7.6, Figure 1). Major sources of projected emissions under the BAU scenario, in
14 order of importance, were cattle, rice, buffalo, and small ruminants. Although livestock production and
15 rice cultivation account for a major share of agricultural emissions, the highest mitigation potential was
16 observed in rice (about 36 MtCO₂-eq yr⁻¹) followed by buffalo (about 14 MtCO₂-eq yr⁻¹), wheat (about
17 11 MtCO₂-eq yr⁻¹) and cattle (about 7 MtCO₂-eq yr⁻¹). Crops such as cotton and sugarcane each offered
18 mitigation potential of about 5 MtCO₂-eq yr⁻¹ while the mitigation potential from small ruminants
19 (goat/sheep) was about 2 MtCO₂-eq yr⁻¹.

20 Sapkota et al. (2019) also estimated the magnitude of GHG savings per year through adoption of various
21 mitigation measures, together with the total cost and net cost per unit of CO₂-eq abated. When the
22 additional benefits of increased yield due to adoption of the mitigation measures were considered, about
23 80% of the technical mitigation potential (67.5 out of 85.5 MtCO₂-eq) could be achieved by cost-saving
24 measures. When yield benefits were considered, green fodder supplements to ruminant diets were the
25 most cost-effective mitigation measure, followed by vermicomposting and improved diet management
26 of small ruminants. Mitigation measures such as fertigation and micro-irrigation, various methods of
27 restoring degraded land and feed additives in livestock appear to be cost-prohibitive, even when
28 considering yield benefits, if any. The study accounted for GHG emissions at the farm level and
29 excluded emissions arising due to processing, marketing or consumption post farm-gate. It also did not
30 include emissions from feed production, since livestock in India mostly rely on crop by-products and
31 concentrates. Further the potential of laser land levelling seems exaggerated which may also be
32 redundant with already accounted potential from 'improved water management in rice'. The mitigation
33 potential of agro-ecological approaches/technologies such as natural farming which is picking up in
34 India in recent years has also been overlooked.

35

Box 7.6, Figure 1 Contribution of various crops and livestock species to total agricultural emission in 2012 (baseline) and by 2030 under business as usual (BAU) and mitigation scenarios for Indian Agricultural sector. Source: Sapkota et al. (2019).

7.4.4. Bioenergy and BECCS

Activities, co-benefits, risks and implementation opportunities and barriers. Bioenergy refers to energy products (solid, liquid and gaseous fuels, electricity, heat) derived from multiple biomass sources including organic waste, harvest residues and by-flows in the agriculture and forestry sectors, and biomass from tree plantations, agroforestry systems, lignocellulosic crops, and conventional food/feed crops. It may reduce net GHG emissions by displacing the use of coal, oil and natural gas with renewable biomass in the production of heat, electricity, and fuels. When combined with carbon capture and storage (BECCS) and biochar production, bioenergy systems may provide CDR by durably storing biogenic carbon in geological, terrestrial, or ocean reservoirs, or in products, further contributing to mitigation (Section 7.4.3.2, Chapters 3, 4, 6 and 12) (Chum et al. 2011; Hammar and Levihn 2020; Emenike et al. 2020; Cabral et al. 2019; Moreira et al. 2020b; Wang et al. 2020; Johnsson et al. 2020).

This section addresses especially aspects related to land use and biomass supply for bioenergy and BECCS. The mitigation potential presented here and in Table 7.3, includes only the CDR component of BECCS. The additional mitigation achieved from displacing fossil fuels is covered elsewhere (Chapters 6, 8, 9, 10, 11 and 12).

Modern bioenergy systems (as opposed to traditional use of fuelwood and other low-quality cooking and heating fuels) currently provide approximately 30 EJ yr⁻¹ of primary energy, making up 53% of total renewable primary energy supply (IEA 2019). Bioenergy systems are commonly integrated within forest and agriculture systems that produce food, feed, lumber, paper and other biobased products. They can also be combined with other AFOLU mitigation options: deployment of energy crops, agroforestry and A/R can provide biomass while increasing land carbon stocks (Sections 7.4.2.2 and 7.4.3.3) and anaerobic digestion of manure and wastewater, to reduce methane emissions, can produce biogas and CO₂ for storage (Section 7.4.3.7). But ill-deployment of energy crops can also cause land carbon losses (Hanssen et al. 2020) and increased biomass demand for energy could hamper other mitigation measures such as reduced deforestation and degradation (Sections 7.4.2.1).

1 Bioenergy and BECCS can be associated with a range of co-benefits and adverse side-effects (Section
2 12.5; Jia et al. 2019; Calvin et al. 2021; Smith et al. 2016). It is difficult to disentangle bioenergy
3 development from the overall development in the AFOLU sector given its multiple interactions with
4 food, land, and energy systems. It is therefore not possible to precisely determine the scale of bioenergy
5 and BECCS deployment at which negative impacts outweigh benefits. Important uncertainties include
6 governance systems, future food and biomaterials demand, land use practices, energy systems
7 development, climate impacts, and time scale considered when weighing negative impacts against
8 benefits (SRCCL, Cross-Chapter Box 7; Box 7.7). (Turner et al. 2018b; Daioglou et al. 2019; Kalt et
9 al. 2020; Wu et al. 2019; Robledo-Abad et al. 2017; Hanssen et al. 2020; Calvin et al, 2021;Cowie et
10 al. 2021). The use of municipal organic waste, harvest residues, and biomass processing by-products as
11 feedstock is commonly considered to have relatively lower risk, provided that associated land use
12 practices are sustainable (Cowie et al. 2021). Deployment of dedicated biomass production systems can
13 have positive and negative implications on mitigation and other sustainability criteria, depending on
14 location and previous land use, feedstock, management practice, and deployment strategy and scale
15 (Sections 12.5 and 17.3.3.1;(Popp et al. 2017; Humpenöder et al. 2018; Rulli et al. 2016; Brondizio et
16 al. 2019; Hasegawa et al. 2020; Fujimori et al. 2019; Drews et al. 2020; Schulze et al. 2020; Stenzel et
17 al. 2020; Daioglou et al. 2017; Staples et al. 2017; Carvalho et al. 2017; Mouratiadou et al. 2020;
18 Buchspies et al. 2020; Hanssen et al. 2020).

19 ***Conclusions from AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL); mitigation***
20 ***potential, costs, and pathways.*** Many more stringent mitigation scenarios in AR5 relied heavily on
21 bioenergy and BECCS. The SR1.5 reported a range for the CDR potential of BECCS (2100) at 0.5 to 5
22 GtCO₂-eq yr⁻¹ when applying constraints reflecting sustainability concerns, at a cost of 100-200 USD
23 tCO₂⁻¹ (Fuss et al. 2018). The SRCCL reported a technical CDR potential for BECCS at 0.4-11.3 GtCO₂
24 yr⁻¹ (*medium confidence*), noting that most estimates do not include socio-economic barriers, the
25 impacts of future climate change, or non-GHG climate forcing (IPCC. 2019a). The SR1.5 and SRCCL
26 highlighted that bioenergy and BECCS can be associated with multiple co-benefits and adverse side-
27 effects that are context specific.

28 ***Developments since AR5 and IPCC Special Reports (SR1.5, SROCCC and SRCCL).*** The role of
29 bioenergy and BECCS in mitigation pathways has been reduced as IAM-based studies have
30 incorporated broader mitigation portfolios and have explored non-CO₂ emissions reduction and a wider
31 variation of underlying assumptions about socio-economic drivers and associated energy and food
32 demand, as well as deployment limits such as land availability for A/R and for cultivation of crops used
33 for bioenergy and BECCS (Grubler et al. 2018; Van Vuuren et al. 2018).

34 Increased availability of spatially explicit data and advances in the modelling of crop productivity and
35 land use, land carbon stocks, hydrology, and ecosystem properties, have enabled more comprehensive
36 analyses of factors that influence the contribution of bioenergy and BECCS in IAM-based mitigation
37 scenarios, and also associated co-benefits and adverse side-effects (Wu et al, 2019, Li et al. 2020, Turner
38 et al 2018a, Hanssen et al. 2020; Ai et al. 2021; Drews et al. 2020; Hasegawa et al. 2021). Yet, IAMs
39 are still coarse in local land use practices. (Daioglou et al. 2019; Wu et al. 2019; Moreira et al. 2020b).
40 Literature complementary to IAM studies indicate opportunities for integration of biomass production
41 systems into agricultural landscapes (e.g., agroforestry, double cropping) to produce biomass while
42 achieving co-benefits (Section 12.5). Similarly, climate-smart forestry puts forward measures (Box 7.3)
43 adapted to regional circumstances in forest sectors, enabling co-benefits in nature conservation, soil
44 protection, employment and income generation, and provision of wood for buildings, bioenergy and
45 other biobased products (Nabuurs et al. 2017).

46 Studies have also investigated the extent and possible use of marginal, abandoned, and degraded lands,
47 and approaches to help restore the productive value of these lands (Elbersen et al. 2019; Awasthi et al.

1 2017; Chiaramonti and Panoutsou, 2018; Fernando et al. 2018; Rahman et al. 2019; Fritsche et al. 2017;
2 Næss et al. 2021). In the SRCCL, the presented range for degraded or abandoned land was 32 - 1400
3 Mha (Jia et al. 2019). Recent regional assessments not included in the SRCCL found up to 69 Mha in
4 EU-28, 185 Mha in China, 9.5 Mha in Canada, and 127 Mha in the USA (Elbersen et al. 2019; Zhang
5 et al. 2020; Emery et al. 2017; Liu et al. 2017; Vera et al. 2021). The definition of
6 marginal/abandoned/degraded land, and the methods used to assess such lands remain inconsistent
7 across studies (Jiang et al. 2019), causing large variation amongst them (Jiang et al. 2021). Furthermore,
8 the availability of such lands has been contested since they may serve other functions (subsistence,
9 biodiversity protection, etc.) (Baka 2014).

10

11 **[START BOX 7.7 HERE]**

12

Box 7.7 Climate change mitigation value of bioenergy and BECCS

13 Besides emissions, and possible avoided emissions, related to the supply chain, the GHG effects of
14 using bioenergy depend on: (i) change in GHG emissions when bioenergy substitutes another energy
15 source; and (ii) how the associated land use and possible land use change influence the amount of carbon
16 that is stored in vegetation and (Calvin et al. 2021) soils over time. Studies arrive at varying mitigation
17 potentials for bioenergy and BECCS due to the large diversity of bioenergy systems, and varying
18 conditions concerning where and how they are deployed (Cowie et al. 2021; Elshout 2015; Harper et al
19 2018; Kalt et al 2019; Muri 2018; Brandão et al. 2019; Buchspies et al. 2020; Calvin et al. 2021).
20 Important factors include feedstock type, land management practice, energy conversion efficiency, type
21 of bioenergy product (and possible co-products), emissions intensity of the products being displaced,
22 and the land use/cover prior to bioenergy deployment (Zhu et al. 2017; Hanssen et al. 2020; Staples et
23 al. 2017; Daioglou et al. 2017; Carvalho et al. 2017; Mouratiadou et al. 2020). Studies arrive at
24 contrasting conclusions also when similar bioenergy systems and conditions are analysed, due to
25 different methodologies, assumptions, and parameterisation (Harper et al 2018; Kalt et al 2019; Brandão
26 et al. 2019; Albers et al. 2019; Buchspies et al. 2020; Bessou et al. 2020; Rolls and Forster 2020; Cowie
27 et al. 2021).

28 Box 7.7 Figure 1 shows emissions associated with biomass supply (residues and crops grown on
29 cropland not needed for food) in 2050, here designated emission-supply curves. The curves are
30 constructed assuming that additional biomass supply consistently comes from the available
31 land/biomass resource that has the lowest GHG emissions, i.e., the marginal GHG emissions increase
32 with increasing biomass use for bioenergy. Net negative emissions indicate cases where biomass
33 production increases land carbon stocks.

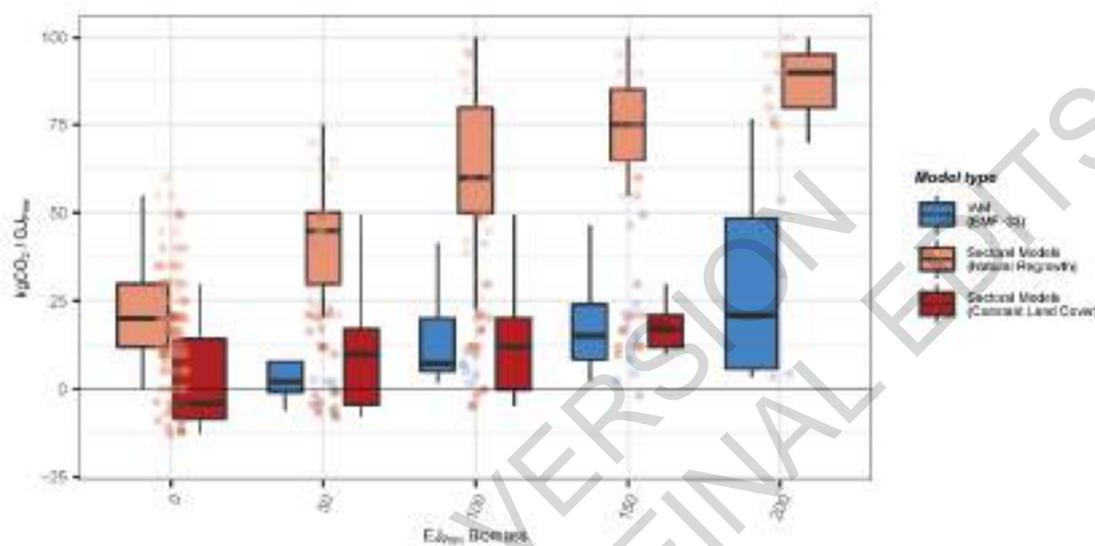

34 One curve (*EMF-33*) is determined from stylised scenarios using IAMs (Rose et al. 2020). One of the
35 two curves determined from sectoral models, *Constant Land Cover*, reflects supply chain emissions and
36 changes in land carbon storage caused by the biomass supply system itself. These two curves are
37 obtained with modelling approaches compatible with the modelling protocol used for the scenarios in
38 the AR6 database, which accounts for the land-use change and all other GHG emissions along a given
39 transformation trajectory, enabling assessments of the warming level incurred.

40 The *Natural Regrowth* curve attribute additional “counterfactual emissions” to the bioenergy system,
41 corresponding to estimated uptake of CO₂ in a counterfactual scenario where land is not used for
42 bioenergy but instead subject to natural vegetation regrowth. This curve does not show actual emissions
43 from the bioenergy system, but it provides insights in the mitigation value of the bioenergy option
44 compared to alternative land-use strategies. To illustrate, if biomass is used instead of a primary energy
45 source with emission factor 75 kg CO₂ GJ⁻¹, and the median values in the *Natural Regrowth* curve are

1 adopted, then the curve indicates that up to about 150 EJ of biomass can be produced and used for
 2 energy while achieving higher net GHG savings than the alternative to set aside the same land for natural
 3 vegetation regrowth (assuming same conversion factor).

4 The large ranges in the bars signify the importance of uncertainties and how the biomass is deployed.
 5 Variation in energy conversion efficiencies and uncertainty about magnitude, timing, and permanence
 6 of land carbon storage further complicate the comparison. Finally, not shown in Box 7.7 Figure 1, the
 7 emission-supply curves would be adjusted downwards if displacement of emission intensive energy
 8 was included or if the bioenergy is combined with CCS to provide CDR.

9

10

11 **Box 7.7, Figure 1 Emissions associated with primary biomass supply in 2050 (residues and crops grown**
 12 **on cropland not needed for food), as determined from sectoral models (Daioglou et al. 2017; Kalt et al.**
 13 **2020), and stylised scenarios from the EMF-33 project using Integrated Assessment Models (Rose et al.**
 14 **2020). All methods include LUC (direct and indirect) emissions. Emissions associated with *Natural***
 15 ***Regrowth* include counterfactual carbon fluxes (see text). The sectoral models include a more detailed**
 16 **representation of the emissions, including Life-Cycle emissions from fertiliser production. IAM models**
 17 **may include economic feedbacks such as intensification as a result of increasing prices. As an indication:**
 18 **for natural gas the emission factor is around 56, for coal around 95 kg CO₂ GJ⁻¹.**

19 [END BOX 7.7 HERE]

20

21 ***Critical assessment and conclusion.*** Recent estimates of technical biomass potentials constrained by
 22 food security and environmental considerations fall within previous ranges corresponding to *medium*
 23 *agreement*, (e.g., Turner et al. 2018b; Daioglou et al. 2019; Wu et al. 2019, Hansen et al 2020; Kalt et
 24 al. 2020) arriving at 4-57 and 46-245 EJ yr⁻¹ by 2050 for residues and dedicated biomass crops,
 25 respectively. Based on studies to date, the technical net CDR potential of BECCS (including LUC and
 26 other supply chain emissions, but excluding energy carrier substitution) by 2050 is 5.9 (0.5-11.3) GtCO₂
 27 yr⁻¹ globally, of which 1.6 (0.5-3.5) GtCO₂ yr⁻¹ is available at below USD100 tCO₂⁻¹ (*medium*
 28 *confidence*) (Figure 7.11) (Lenton 2010; Koornneef et al. 2012; McLaren 2012; Powell and Lenton
 29 2012; Fuss et al. 2018; Turner et al. 2018a; Hanssen et al. 2020; Roe et al. 2021). The equivalent
 30 economic potential as derived from IAMs is 1.8 (0.2 - 9.9) GtCO₂ yr⁻¹ (Table 7.3).

31

1 Technical land availability does not imply that dedicated biomass production for bioenergy and BECCS
2 is the most effective use of this land for mitigation. Further, implications of deployment for climate
3 change mitigation and other sustainability criteria are context dependent and influenced by many
4 factors, including rate and total scale. While governance has a critical influence on outcome, larger
5 scale and higher expansion rate generally translates into higher risk for negative outcomes for GHG
6 emissions, biodiversity, food security and a range of other sustainability criteria (Rochedo et al. 2018;
7 Daioglou et al. 2019; Junginger et al. 2019; Galik et al. 2020; Searchinger 2017; Vaughan et al. 2018;
8 de Oliveira Garcia et al. 2018; Stenzel et al. 2020).

9 However, literature has also highlighted how the agriculture and forestry sectors may respond to
10 increasing demand by devising management approaches that enable biomass production for energy in
11 conjunction with supply of food, construction timber, and other biobased products, providing climate
12 change mitigation while enabling multiple co-benefits including for nature conservation (Parodi et al.
13 2018; Springmann et al. 2018; Nabuurs et al. 2017; Rosenzweig et al. 2020; Clark et al. 2020; Favero
14 et al. 2020; Hanssen et al. 2020; Section 7.4 and Cross-Working Group Box 3 in Chapter 12).

15 Strategies to enhance the benefits of bioenergy and BECCS include (i) management practices that
16 protect carbon stocks and the productive and adaptive capacity of lands, as well as their environmental
17 and social functions (van Ittersum et al. 2013, Gerssen-Gondelach et al. 2015; Moreira et al. 2020b) (ii)
18 supply chains from primary production to final consumption that are well managed and deployed at
19 appropriate levels (Donnison et al. 2020; Fajardy et al. 2018); and (iii) development of a cross-sectoral
20 agenda for biobased production within a circular economy, and international cooperation and
21 governance of global trade in products to maximize synergies while limiting trade-offs concerning
22 environmental, economic and social outcomes (*very high confidence*). Finally, the technical feasibility
23 of BECCS depends on investments in and the roll-out of advanced bioenergy technologies currently not
24 widely available (Daioglou et al. 2020b, Baker et al 2015).

25 **7.4.5. Demand-side measures**

26 **7.4.5.1. Shift to sustainable healthy diets**

27 **Activities, co-benefits, risks and implementation opportunities and barriers.** The term ‘Sustainable
28 healthy diets’ refers to dietary patterns that ‘promote all dimensions of individuals’ health and
29 wellbeing; have low environmental pressure and impact; are accessible, affordable, safe and equitable;
30 and are culturally acceptable’ (FAO and WHO 2019). In addition to climate mitigation gains, a
31 transition towards more plant-based consumption and reduced consumption of animal-based foods,
32 particularly from ruminant animals, could reduce pressure on forests and land used for feed, support the
33 preservation of biodiversity and planetary health (Theurl et al. 2020; FAO 2018c), and contribute to
34 preventing forms of malnutrition (i.e. undernutrition, micronutrient deficiency, and obesity) in
35 developing countries (Chapter 12, Section 12.4.). Other co-benefits include lowering the risk of
36 cardiovascular disease, type 2 diabetes, and reducing mortality from diet-related non-communicable
37 diseases (Toumpanakis et al. 2018; Satija and Hu 2018; Faber et al. 2020; Magkos et al. 2020).
38 However, transition towards sustainable healthy diets could have adverse impacts on the economic
39 stability of the agricultural sector (MacDiarmid 2013; Aschemann-Witzel 2015; Van Loo et al. 2017).
40 Therefore, shifting toward sustainable and healthy diets requires effective food-system oriented reform
41 policies that integrate agriculture, health, and environment policies to comprehensively address
42 synergies and conflicts in co-lateral sectors (agriculture, trade, health, environment protection etc.) and
43 capture spill-over effects (climate change, biodiversity loss, food poverty) (Galli et al. 2020; FAO and
44 WHO 2019).

45 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
46 **potential, costs, and pathways.** According to the AR5, changes in human diets and consumption

1 patterns can reduce emissions 5.3 to 20.2 GtCO₂-eq yr⁻¹ by 2050 from diverted agricultural production
2 and avoided land-use change (Smith et al. 2014). In the SRCCL, a “contract and converge” model of
3 transition to sustainable healthy diets was suggested as an effective approach, reducing food
4 consumption in over-consuming populations and increasing consumption of some food groups in
5 populations where minimum nutritional needs are not met (Smith et al. 2019b). The total technical
6 mitigation potential of changes in human diets was estimated as 0.7 - 8 GtCO₂-eq yr⁻¹ by 2050 (SRCCL,
7 Chapter 2 and 6; (Springmann et al. 2016; Hawken 2017; Tilman and Clark 2014), ranging from a 50%
8 adoption of healthy diets (<60g of animal-based protein) and only accounting for diverted agricultural
9 production, to the global adoption of a vegetarian diet.

10 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Since the
11 SRCCL, global studies continue to find high mitigation potential from reducing animal-source foods
12 and increasing proportions of plant-rich foods in diets. Springmann et al. (2018) estimated that diet
13 changes in line with global dietary guidelines for total energy intake and consumption of red meat,
14 sugar, fruits, and vegetables, could reduce GHG emissions by 29% and other environmental impacts by
15 5–9% compared with the baseline in 2050. Poore and Nemecek (2018) revealed that shifting towards
16 diets that exclude animal-source food could reduce land use by 3.1 billion ha, decrease food-related
17 GHG emissions by 6.5 GtCO₂-eq yr⁻¹, acidification by 50%, eutrophication by 49%, and freshwater
18 withdrawals by 19% for a 2010 reference year. Frank et al. (2019) estimated non-CO₂ emissions
19 reductions of 0.4 GtCO₂-eq yr⁻¹ at a carbon price of USD100 tCO₂⁻¹ and 0.6 GtCO₂-eq yr⁻¹ at USD20
20 tCO₂⁻¹ in 2050 from shifting to lower animal-source diets (430 kcal of livestock calorie intake) in
21 developed and emerging countries. From a systematic literature review, Ivanova et al. (2020) found
22 mitigation potentials of 0.4-2.1 tCO₂-eq capita⁻¹ for a vegan diet, of 0.01-1.5 for a vegetarian diet, and
23 of 0.1-2.0 for Mediterranean or similar healthy diet.

24 Regionally, mitigation potentials for shifting towards sustainable healthy diets (50% convergence to
25 <60g of meat-based protein, only accounting for diverted production) vary across regions. A recent
26 assessment finds greatest economic (up to USD100 tCO₂⁻¹) potential for 2020-2050 in Asia and the
27 developing Pacific (609 MtCO₂-eq yr⁻¹) followed by Developed Countries (322 MtCO₂-eq yr⁻¹) based
28 on IPCC AR4 GWP₁₀₀ values for CH₄ and N₂O) (Roe et al. 2021). In the EU, (Latka et al. 2021) found
29 that moving to healthy diets through price incentives could bring about annual reductions of non-CO₂
30 emissions from agriculture of 12-111 MtCO₂-eq yr⁻¹. At the country level, recent studies show that
31 following National Dietary Guidelines (NDG) would reduce food system GHG emissions by 4–42%,
32 confer large health gains (1.0–1.5 million quality-adjusted life-years) and lower health care system costs
33 (NZD 14–20 billion) in New Zealand Drew et al. (2020); reduce 28% of GHG emissions in Argentina
34 Arrieta and González (2018); about 25% in Portugal Esteve-Llorens et al. (2020) and reduce GHG
35 emissions, land use and blue water footprint by 15–60% in Spain Batlle-Bayer et al. (2020). In contrast,
36 Aleksandrowicz et al. (2019) found that meeting healthy dietary guidelines in India required increased
37 dietary energy intake overall, which slightly increased environmental footprints by about 3–5% across
38 GHG emissions, blue and green water footprints and land use.

39 **Critical assessment and conclusion.** Shifting to sustainable healthy diets has large potential to achieve
40 global GHG mitigation targets as well as public health and environmental benefits (*high confidence*).
41 Based on studies to date, there is *medium confidence* that shifting toward sustainable healthy diets has
42 a technical potential including savings in the full value chain of 3.6 (0.3-8.0) GtCO₂-eq yr⁻¹ of which
43 2.5 (1.5-3.9) GtCO₂-eq yr⁻¹ is considered plausible based on a range of GWP₁₀₀ values for CH₄ and N₂O.
44 When accounting for diverted agricultural production only, the feasible potential is 1.7 (1 – 2.7) GtCO₂-
45 eq yr⁻¹. A shift to more sustainable and healthy diets is generally feasible in many regions (*medium*
46 *confidence*). However, potential varies across regions as diets are location- and community- specific,
47 and thus may be influenced by local production practices, technical and financial barriers and associated

1 livelihoods, everyday life and behavioural and cultural norms around food consumption (Meybeck and
2 Gitz 2017; Creutzig et al. 2018; FAO 2018b). Therefore, a transition towards low-GHG emission diets
3 and achieving their mitigation potential requires a combination of appropriate policies, financial and
4 non-financial incentives and awareness-raising campaigns to induce changes in consumer behaviour
5 with potential synergies between climate objectives, health and equity (Rust et al. 2020).

6 **7.4.5.2. Reduce food loss and waste**

7 **Activities, co-benefits, risks and implementation opportunities and barriers.** Food loss and waste
8 (FLW) refer to the edible parts of plants and animals produced for human consumption that are not
9 ultimately consumed (UNEP 2021b). Food loss occurs through spoilage, spilling or other unintended
10 consequences due to limitations in agricultural infrastructure, storage and packaging (Parfitt et al. 2010).
11 Food waste typically takes place at the distribution (retail and food service) and consumption stages in
12 the food supply chain and refers to food appropriate for human consumption that is discarded or left to
13 spoil (HLPE 2014). Options that could reduce FLW include: investing in harvesting and post-harvesting
14 technologies in developing countries, taxing and other incentives to reduce business and consumer-
15 level waste in developed countries, mandatory FLW reporting and reduction targets for large food
16 businesses, regulation of unfair trading practices, and active marketing of cosmetically imperfect
17 products (van Giesen and de Hooge 2019; Sinclair Taylor et al. 2019). Other studies suggested
18 providing options of longer-lasting products and behavioural changes (e.g. through information
19 provision) that cause dietary and consumption changes and motivate consumers to actively make
20 decisions that reduce FLW. Reductions of FLW along the food chain bring a range of benefits beyond
21 GHG mitigation, including reducing environmental stress (e.g. water and land competition, land
22 degradation, desertification), safeguarding food security, and reducing poverty (Galford et al. 2020;
23 Venkat et al. 2020). Additionally, FLW reduction is crucial for achieving SDG 12 which calls for
24 ensuring ‘sustainable consumption and production patterns’ through lowering per capita global food
25 waste by 50% at the retail and consumer level and reducing food losses along food supply chains by
26 2030. In line with these SDG targets, it is estimated that reducing FLW can free up several million km²
27 of land (*high confidence*). The interlinkages between reducing FLW and food system sustainability are
28 discussed in Chapter 12. Recent literature identifies a range of barriers to climate change mitigation
29 through FLW reduction, which are linked to technological, biophysical, socio-economic, financial and
30 cultural contexts at regional and local levels (Blok et al. 2020; Vogel and Meyer 2018; Gromko and
31 Abdurasalova 2019; Rogissart et al. 2019). Examples of these barriers include infrastructural and
32 capacity limitations, institutional regulations, financial resources, constraining resources (e.g. energy),
33 information gaps (e.g. with retailers), and consumers’ behaviour (Blok et al. 2020; Gromko and
34 Abdurasalova 2019).

35 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
36 **potential, costs, and pathways.** In AR5, reduced FLW was considered as a mitigation measure that
37 could substantially lower emissions, with estimated mitigation potential of 0.6–6.0 GtCO₂-eq yr⁻¹ in the
38 food supply chain (Smith et al. 2014). In the SRCCL, the technical mitigation potential of reducing food
39 and agricultural waste was estimated at 0.76–4.5 GtCO₂-eq yr⁻¹ (SRCCL, Chapter 2 and 6: Bajželj et al.
40 2014; Dickie et al. 2014b; Hawken 2017).

41 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Since the
42 SRCCL, there have been very few quantitative estimates of the mitigation potential of FLW reductions.
43 Evidence suggests that reducing FLW together with overall food intake could have substantial
44 mitigation potential, equating to an average of 0.3 tCO₂-eq capita⁻¹ (Ivanova et al. 2020). Some regional
45 sectoral studies indicate that reducing FLW in the EU can reduce emissions by 186 MtCO₂-eq yr⁻¹, the
46 equivalent of around 15% of the environmental impacts (climate, acidification, and eutrophication) of
47 the entire food value chain (Scherhauser et al. 2018). In the UK, disruptive low-carbon innovations

1 relating to FLW reduction were found to be associated with potential emissions reductions ranging
2 between 2.6 and 3.6 MtCO₂-eq (Wilson et al. 2019). Other studies investigated the effect of tax
3 mechanisms, such as ‘pay as you throw’ for household waste, on the mitigation potential of reducing
4 FLW. Generally, these mechanisms are recognised as particularly effective in reducing the amount of
5 waste and increasing the recycling rate of households (Carattini et al. 2018; Rogissart et al. 2019).
6 Technological FWL mitigation opportunities exist throughout the food supply chain; post-harvest
7 opportunities for FLW reductions are discussed in Chapter 12. Based on IPCC AR4 GWP₁₀₀ values for
8 CH₄ and N₂O, greatest economic mitigation potential (up to USD100 tCO₂⁻¹) for the period 2020-2050
9 from FLW reduction is estimated to be in Asia and developing Pacific (192.3 GtCO₂-eq yr⁻¹) followed
10 by Developed Countries (101.6 GtCO₂-eq yr⁻¹) (Roe et al. 2021). These estimates reflect diverted
11 agricultural production and do not capture potential from avoided land-use changes.

12 **Critical assessment and conclusion.** There is *medium confidence* that reduced FLW has large global
13 technical mitigation potential of 2.1 (0.1–5.8) GtCO₂-eq yr⁻¹ including savings in the full value chain
14 and using GWP₁₀₀ and a range of IPCC values for CH₄ and N₂O. Potentials at 3.7 (2.2–5.1) GtCO₂-eq
15 yr⁻¹ are considered plausible. When accounting for diverted agricultural production only, the feasible
16 potential is 0.5 (0.0–0.9) GtCO₂-eq yr⁻¹. See the section above for the joint land use effects of food
17 related demand-side measures which increases three-fold when accounting for the land-use effects as
18 well. But this would overlap with other measures and is therefore not additive. Regionally, FLW
19 reduction is feasible anywhere but its potential needs to be understood in a wider and changing socio-
20 cultural context that determines nutrition (*high confidence*).

21 **7.4.5.3. Improved and enhanced use of wood products**

22 **Activities, co-benefits, risks and implementation opportunities and barriers.** The use of wood products
23 refers to the fate of harvested wood for material uses and includes two distinctly different components
24 affecting the carbon cycle, including carbon storage in wood products and material substitution. When
25 harvested wood is used for the manufacture of wood products, carbon remains stored in these products
26 depending on their end use and lifetime. Carbon storage in wood products can be increased through
27 enhancing the inflow of products in use, or effectively reducing the outflow of the products after use.
28 This can be achieved through additional harvest under sustainable management (Pilli et al. 2015;
29 Johnston and Radeloff 2019), changing the allocation of harvested wood to long-lived wood products
30 or by increasing products’ lifetime and increasing recycling (Brunet-Navarro et al. 2017; Jasinevičius
31 et al. 2017; Xu et al. 2018; Xie et al. 2021). Material substitution involves the use of wood for building,
32 textiles, or other applications instead of other materials (e.g. concrete, steel which consume more energy
33 to produce) to avoid or reduce emissions associated with the production, use and disposal of those
34 products it replaces.

35 The benefits and risks of improved and enhanced improved use of wood products are closely linked to
36 forest management. First of all, the enhanced use of wood products could potentially activate or lead to
37 improved sustainable forest management that can mitigate and adapt (Verkerk et al. 2020). Secondly,
38 carbon storage in wood products and the potential for substitution effects can be increased by additional
39 harvest, but with the risk of decreasing carbon storage in forest biomass when not done sustainably
40 (Smith et al. 2019b). Conversely, reduced harvest may lead to gains in carbon storage in forest
41 ecosystems locally, but these gains may be offset through international trade of forest products causing
42 increased harvesting pressure or even degradation elsewhere (Pendrill et al. 2019b; Kastner et al. 2011;
43 Kallio and Solberg 2018). There are also environmental impacts associated with the processing,
44 manufacturing, use and disposal of wood products (Adhikari and Ozarska 2018; Baumgartner 2019).
45 See Section 9.6.4 of this report for additional discussion on benefits and risks.

1 **Conclusions from AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL); mitigation**
2 **potential, costs, and pathways.** There is strong evidence at the product level that wood products from
3 sustainably managed forests are associated with less greenhouse emissions in their production, use and
4 disposal over their life-time compared to products made from emission-intensive and non-renewable
5 materials. However, there is still limited understanding of the substitution effects at the level of markets,
6 countries (Leskinen et al. 2018). AR5 did not report on the mitigation potential of wood products. The
7 SRCCL (Chapters 2 and 6) finds that some studies indicate significant mitigation potentials for material
8 substitution, but concludes that the global, technical mitigation potential for material substitution for
9 construction applications ranges from 0.25-1 GtCO₂-eq yr⁻¹ (*medium confidence*) (McLaren 2012;
10 Miner 2010; Roe et al. 2019).

11 **Developments since AR5 and IPCC Special Reports (SRI.5, SROCCC and SRCCL).** Since the
12 SRCCL, several studies have examined the mitigation potential of the enhanced and improved use of
13 wood products. A global forest sector modelling study (Johnston and Radeloff 2019) estimated that
14 carbon storage in wood products represented a net carbon stock increase of 0.34 GtCO₂-eq yr⁻¹ globally
15 in 2015 and which could provide an average mitigation potential (by increasing the HWP pool) of 0.33–
16 0.41 GtCO₂-eq yr⁻¹ for the period 2020–2050, based on the future socio-economic development (SSP
17 scenarios) and its effect on the production and consumption of wood products. Traded feedstock
18 provided another 0.071 GtCO₂ yr⁻¹ of carbon storage in 2015 and 0.12 GtCO₂ yr⁻¹ by 2065. These
19 potentials exclude the effect of material substitution. Another recent study estimated the global
20 mitigation potential of mid-rise urban buildings designed with engineered wood products at 0.04-3.7
21 GtCO₂ yr⁻¹ (Churkina et al. 2020). Another study (Oliver et al. 2014) estimated that using wood to
22 substitute for concrete and steel as building materials could provide a technical mitigation potential of
23 0.78-1.73 GtCO₂ yr⁻¹ achieved through carbon storage in wood products and through material and
24 energy substitution.

25 The limited availability or absence of estimates of the future mitigation potential of improved use of
26 wood products for many world regions represents an important knowledge gap, especially with regards
27 to material substitution effects. At the product level, wood products are often associated with lower
28 fossil-based emissions from production, use and disposal, compared to products made from emission-
29 intensive and non-renewable materials (Sathre and O'Connor 2010; Geng et al. 2017; Leskinen et al.
30 2018).

31 **Critical assessment and conclusion.** Based on studies to date, there is *strong evidence and medium*
32 *agreement* that the improved use of wood products has a technical potential of 1.0 (0.04–3.7) GtCO₂-
33 eq yr⁻¹ and economic potential of 0.4 (0.3–0.5) GtCO₂-eq yr⁻¹. There is *strong evidence and high*
34 *agreement* at the product level that material substitution provides on average benefits for climate change
35 mitigation as wood products are associated with less fossil-based GHG emissions over their lifetime
36 compared to products made from emission-intensive and non-renewable materials. However, the
37 evidence at the level of markets or countries is uncertain and fairly limited for many parts of the world.
38 There is *medium confidence* that material substitution and carbon storage in wood products contribute
39 to climate change mitigation when also the carbon balances of forest ecosystems are considered of
40 sustainably managed large areas of forests in medium term. The total future mitigation potential will
41 depend on the forest system considered, the type of wood products that are produced and substituted
42 and the assumed production technologies and conversion efficiencies of these products.

43

1

2 **7.5. AFOLU Integrated Models and Scenarios**

3 This section assesses the literature and data available on potential future GHG dynamics in the AFOLU
4 sector, the cost-effectiveness of different mitigation measures, and consequences of climate change
5 mitigation pathways on land-use dynamics as well as relevant sustainable development indicators at the
6 regional and global level based on global integrated models.

7 Land-based mitigation options interact and create various trade-offs, and thus need to be assessed
8 together as well as with mitigation options in other sectors, and in combination with other sustainability
9 goals (Popp et al. 2014; Obersteiner et al. 2016; Roe et al. 2019; Van Vuuren et al. 2019; Prudhomme
10 et al. 2020; Strefler et al. 2021). The assessments of individual mitigation measures or sectoral estimates
11 used to estimate mitigation potential in Section 7.4, when aggregated together, do not account for
12 interactions and trade-offs. Integrative land-use models (ILMs) combine different land-based mitigation
13 options and are partially included in Integrated Assessment Models (IAMs) which combine insights
14 from various disciplines in a single framework and cover the largest sources of anthropogenic GHG
15 emissions from different sectors. Over time, ILMs and IAMs have extended their system coverage
16 (Johnson et al. 2019). However, the explicit modelling and analysis of integrated land-use systems is
17 relatively new compared to other sectoral assessments such as the energy system (Jia et al. 2019).
18 Consequently, ILMs as well as IAMs differ in their portfolio and representation of land-based
19 mitigation options, the representation of sustainability goals other than climate action as well as the
20 interplay with mitigation in other sectors (van Soest et al. 2019; Johnson et al. 2019). These structural
21 differences have implications for the regional and global deployment of different mitigation options as
22 well as their sustainability impacts.

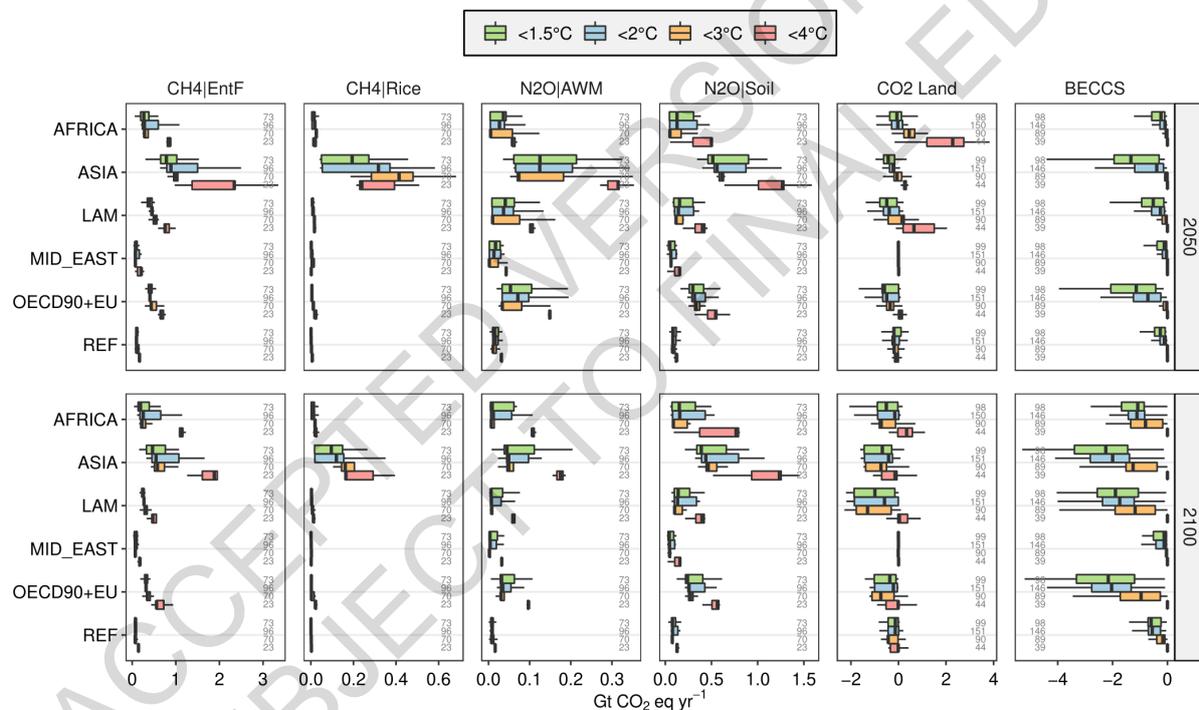

23 As a consequence of the relative novelty of land-based mitigation assessment in ILMs and IAMs, the
24 portfolio of land-based mitigation options does not cover the full option space as outlined in Section
25 7.4. The inclusion and detail of a specific mitigation measure differs across models. Land based
26 mitigation options are only partially included in ILM and IAM analyses, which mostly rely on
27 afforestation/reforestation and bioenergy with CCS (BECCS). Most ILM and IAM scenarios are based
28 on the Shared Socio-economic Pathways (SSPs) (Riahi et al. 2017), which is a set of contrasting future
29 scenarios widely used in the research community such as in the CMIP6 exercise, the SRCCL and the
30 IPBES global assessment. However, the coverage of land-based mitigation options in these scenarios
31 is mostly limited to dietary changes, higher efficiency in food processing (especially in livestock
32 production systems), reduction of food waste, increasing agricultural productivity, methane reductions
33 in rice paddies, livestock and grazing management for reduced methane emissions from enteric
34 fermentation, manure management, improvement of N-efficiency, international trade, first generation
35 of biofuels, avoided deforestation, afforestation, bioenergy and BECCS (Van Meijl et al. 2018; Popp et
36 al. 2017; Frank et al. 2019). Hence, there are mitigation options not being broadly included in integrated
37 pathway modelling as soil carbon, forest management, agroforestry or wetland management
38 (Humpenöder et al. 2020) which have the potential to alter the contribution of land-based mitigation in
39 terms of timing, potential and sustainability consequences (Frank et al. 2017).

40 **7.5.1. Regional GHG emissions and land dynamics**

41 In most of the assessed mitigation pathways, the AFOLU sector is of great importance for climate
42 change mitigation as it (i) turns from a source into a sink of atmospheric CO₂ due to large-scale
43 afforestation and reforestation, (ii) provides high amounts of biomass for bioenergy with or without
44 CCS and (iii), even under improved agricultural management, still causes residual non-CO₂ emissions
45 from agricultural production and (iv) interplays with sustainability dimensions other than climate action

1 (Popp et al. 2017; Rogelj et al. 2017; Van Vuuren et al. 2018; Frank et al. 2018; van Soest et al. 2019;
 2 Hasegawa et al. 2018). Regional AFOLU GHG emissions in scenarios with <4°C warming in 2100
 3 (scenario category C7), as shown in Figure 7.13, are shaped by considerable CH₄ and N₂O emissions
 4 throughout 2050 and 2100, mainly from ASIA and AFRICA. CH₄ emissions from enteric fermentation
 5 are largely caused by ASIA, followed by AFRICA, while CH₄ emissions from paddy rice production
 6 are almost exclusively caused by ASIA. N₂O emissions from animal waste management and soils are
 7 more equally distributed across region.

8 In most regions, CH₄ and N₂O emission are both lower in mitigation pathways that limit warming to
 9 <1.5°C, <2°C and <3°C (C1-C6) compared to scenarios with <4°C (Popp et al. 2017; Rogelj et al.
 10 2018a). In particular, the reduction of CH₄ emissions from enteric fermentation in ASIA and AFRICA
 11 is profound. Land-related CO₂ emissions, which include emissions from deforestation as well as
 12 removals from afforestation, are slightly negative (i.e. AFOLU systems turn into a sink) in <1.5°C, <
 13 2°C and <3°C mitigation pathways compared to <4°C scenarios. Carbon sequestration via BECCS is
 14 most prominent in ASIA, LAM, AFRICA and OECD90+EU, which are also the regions with the highest
 15 bioenergy area.

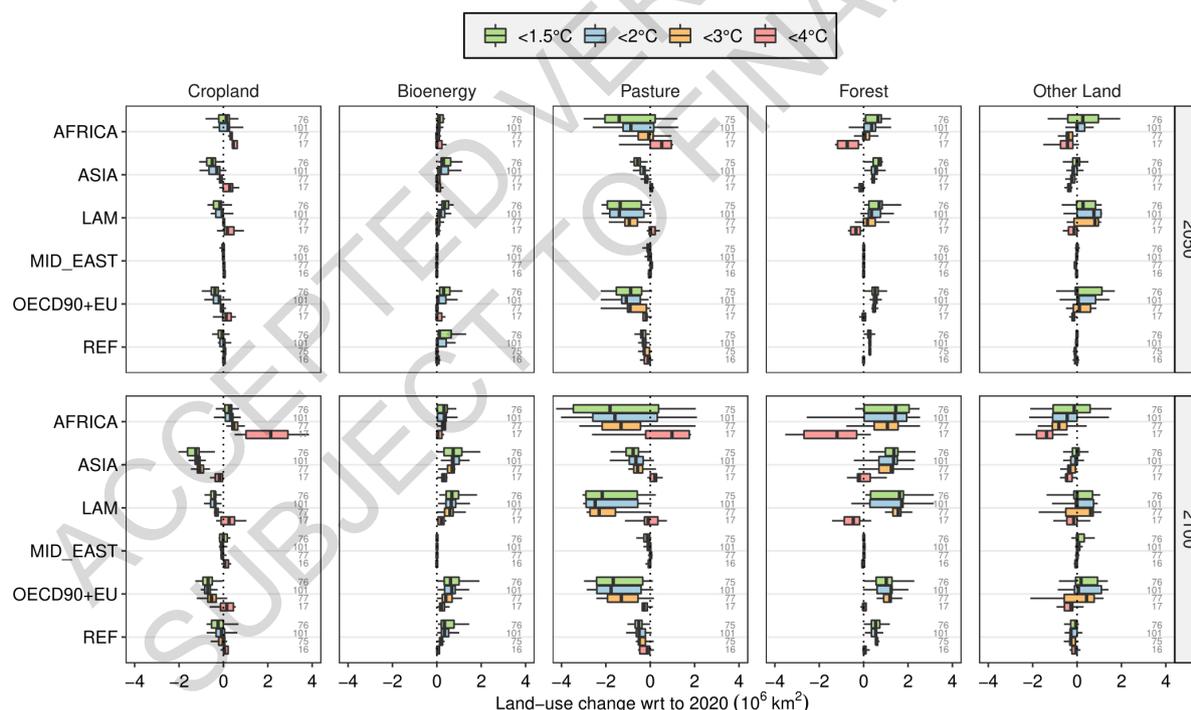

17
 18
 19 **Figure 7.13 Land-based regional GHG emissions and removals in 2050 (top) and 2100 (bottom) for**
 20 **scenarios from the AR6 Database with <1.5°C (C1, C2), <2°C (C3, C4), <3°C (C5, C6) and <4°C**
 21 **(C7) global warming in 2100 (scenario type is indicated by colour). The categories shown include**
 22 **CH₄ emissions from enteric fermentation (EntF) and rice production (Rice), N₂O emissions from**
 23 **animal waste management (AWM) and fertilisation (Soil). The category CO₂ Land includes CO₂**
 24 **emissions from land-use change as well as removals due to afforestation/reforestation. BECCS**
 25 **reflects the CO₂ emissions captured from bioenergy use and stored in geological deposits. The**
 26 **annual GHG emission data from various models and scenarios is converted to CO₂ equivalents**
 27 **using GWP factors of 27 for CH₄ and 273 for N₂O. The data is summarised in boxplots (Tukey**
 28 **style), which show the median (vertical line), the interquartile range (IQR box) and the range of**
 29 **values within 1.5 x IQR at either end of the box (horizontal lines) across all models and scenarios.**

1 **The number of data points available for each emission category, scenario type, region and year is**
 2 **shown at the edge of each panel. Regional definitions: AFRICA = Sub-Saharan Africa, ASIA =**
 3 **Asia, LAM = Latin America and Caribbean, MID_EAST = Middle East, OECD90+EU = OECD 90**
 4 **and EU, REF = Reforming Economies of Eastern Europe and the Former Soviet Union.**

6 Figure 7.14 indicates that regional land use dynamics in scenarios with <4°C warming in 2100 are
 7 characterised by rather static agricultural land (i.e. cropland and pasture) in ASIA, LAM, OECD90+EU
 8 and REF, and increasing agricultural land in AFRICA. Bioenergy area is relatively small in all regions.
 9 Agricultural land in AFRICA expands at the cost of forests and other natural land.

10 The overall land dynamics in <1.5°C, < 2°C and <3°C mitigation pathways are shaped by land-
 11 demanding mitigation options such as bioenergy and afforestation, in addition to the demand for other
 12 agricultural and forest commodities. Bioenergy production and afforestation take place largely in the
 13 (partly) tropical regions ASIA, LAM and AFRICA, but also in OECD90+EU. Land for dedicated
 14 second generation bioenergy crops and afforestation displace agricultural land for food production
 15 (cropland and pasture) and other natural land. For instance, in the <1.5°C mitigation pathway in ASIA,
 16 bioenergy and forest area together increase by about 2.1 million km² between 2020 and 2100, mostly at
 17 the cost of cropland and pasture (median values). Such large-scale transformations of land use have
 18 repercussions on biogeochemical cycles (e.g. fertiliser and water) but also on the economy (e.g. food
 19 prices) and potential socio-political conditions.

21
 22
 23 **Figure 7.14 Regional change of major land cover types by 2050 (top) and 2100 (bottom) relative to**
 24 **2020 for scenarios from the AR6 Database with <1.5°C (C1, C2), < 2°C (C3, C4), <3°C (C5, C6)**
 25 **and <4°C (C7) global warming in 2100 (scenario type is indicated by colour). The data is**
 26 **summarised in boxplots (Tukey style), which show the median (vertical line), the interquartile**
 27 **range (IQR box) and the range of values within 1.5 x IQR at either end of the box (horizontal lines)**
 28 **across all models and scenarios. The number of data points available for each land cover type,**

1 **scenario type, region and year is shown at the right edge of each panel. Regional definitions:**
2 **AFRICA = Sub-Saharan Africa, ASIA = Asia, LAM = Latin America and Caribbean, MID_EAST**
3 **= Middle East, OECD90+EU = OECD 90 and EU, REF = Reforming Economies of Eastern Europe**
4 **and the Former Soviet Union.**

6 **7.5.2. Marginal abatement costs according to integrated assessments**

7 In this section, Integrated Assessment Model (IAM) results from the AR6 database are used to derive
8 marginal abatement costs which indicate the economic mitigation potential for the different gases (N₂O,
9 CH₄, CO₂) related to the AFOLU sector, at the global level and at the level of five world regions. This
10 review provides a complementary view on the economic mitigation potentials estimated in Section 7.4
11 by implicitly taking into account the interlinkages between the land-based mitigation options
12 themselves as well as the interlinkages with mitigation options in the other sectors such as BECCS. The
13 review systematically evaluates a range of possible economic potential estimates across gases, time,
14 and carbon prices.

15 For different models and scenarios from the AR6 database, the amount of mitigated emissions is
16 presented together with the respective carbon price (Figure 7.15). To determine mitigation potentials,
17 scenarios are compared to a benchmark scenario which usually assumes business-as-usual trends and
18 no explicit additional mitigation efforts. Scenarios have been excluded, if they do not have an associated
19 benchmark scenario or fail the vetting according to the AR6 scenario database, or if they do not report
20 carbon prices and CO₂ emissions from AFOLU. Scenarios with contradicting assumptions (for example,
21 fixing some of the emissions to baseline levels) are excluded. Furthermore, only scenarios with
22 consistent³ regional and global level results are considered. Mitigation potentials are computed by
23 subtracting scenario specific emissions and sequestration amounts from their respective benchmark
24 scenario values. This difference accounts for the mitigation that can be credited to the carbon price
25 which is applied in a scenario. A few benchmark scenarios, however, apply already low carbon prices.
26 For consistency reasons, a carbon price that is applied in a benchmark scenario is subtracted from the
27 respective scenario specific carbon price. This may generate a bias because low carbon prices tend to
28 have a stronger marginal impact on mitigation than high carbon prices. Scenarios with carbon prices
29 which become negative due to the correction are not considered. The analysis considers all scenarios
30 from the AR6 database which pass the criteria and should be considered as an ensemble of opportunity
31 (Huppmann et al. 2018).

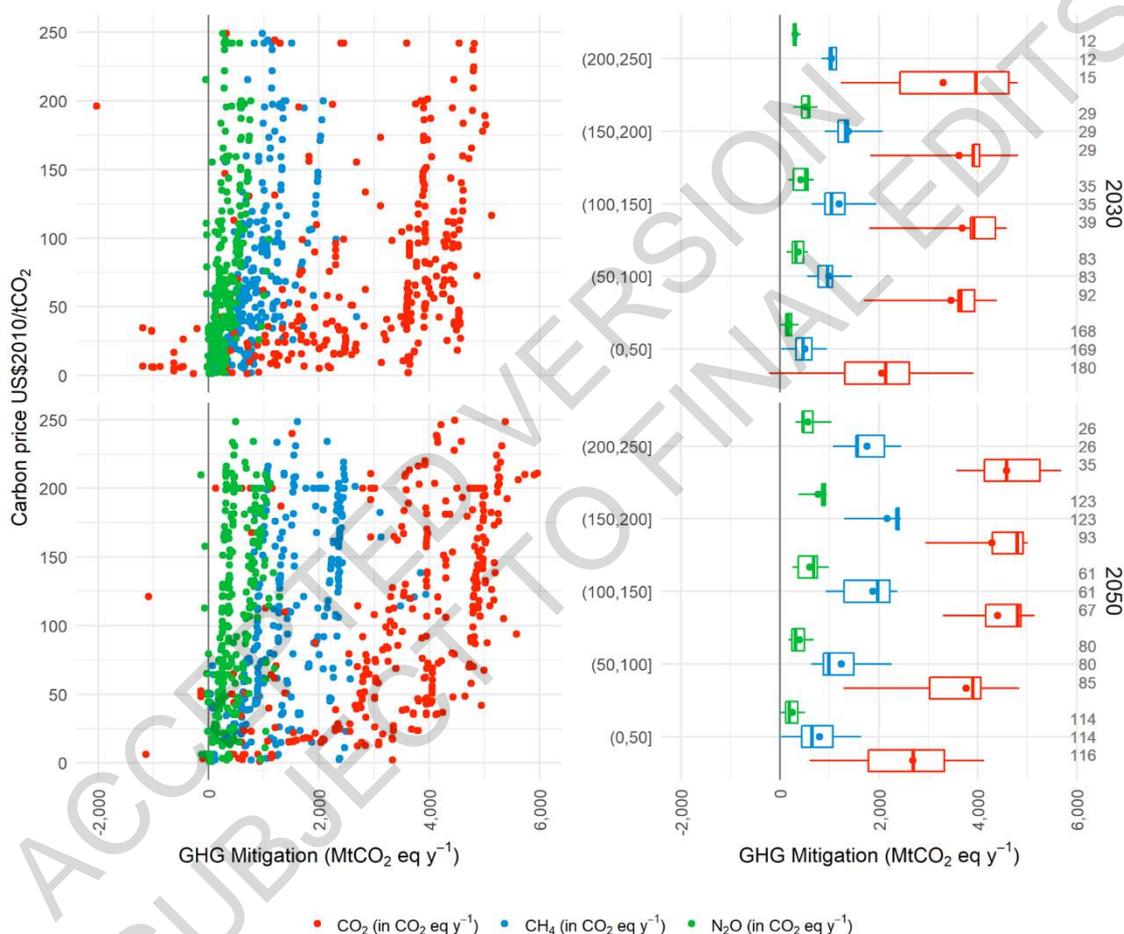

32 This approach is close to integrated assessment marginal abatement cost curves (MACCs) as described
33 in the literature (Frank et al. 2018, 2019; Harmsen et al. 2019; Fujimori et al. 2016) in the sense that it
34 incorporates besides the technical mitigation options also structural options, as well as behavioural
35 changes and market feedbacks. Furthermore, indirect emission changes and interactions with other
36 sectors can be highly relevant (Daioglou et al. 2019; Kalt et al. 2020) and are also accounted for in the
37 presented potentials. Hereby, some sequestration efforts can occur in other sectors, while leading to less
38 mitigation in the AFOLU sector. For instance, as an integral part of many scenarios, BECCS
39 deployment will lead to overall emissions reductions, and even provision of CDR as a result of the
40 interplay between three direct components i) LULUCF emissions/sinks, ii) reduction of fossil fuel
41 use/emissions, iii) carbon capture and sequestration. Since the latter two effects can compensate for the
42 LULUCF effect, BECCS deployment in ambitious stabilisation scenarios may lead to reduced

FOOTNOTE: ³ Scenarios are considered consistent between global and regional results (based on R5 regions), if the sum of regional emissions (or sequestration efforts) does not deviate more than 10% from the reported global total. To take into account that small absolute values have a higher sensitivity, a deviation of 90% is allowed for absolute values below 100.

1 sink/increased emissions in LULUCF (Kalt et al. 2020). The same holds for trade-offs between carbon
 2 sequestration in forests versus harvested wood products both for enhancing the HWP pool and for
 3 material substitution. The strengths of the competition between biomass use and carbon sequestration
 4 will depend on the biomass feedstocks considered (Lauri et al. 2019).

5 In the individual cases, the accounting of all these effects is dependent on the respective underlying
 6 model and its coverage of inter-relations of different sectors and sub-sectors. The presented potentials
 7 cover a wide range of models, and additionally, a wide range of background assumptions on macro-
 8 economic, technical, and behavioural developments as well as policies, which the models have been
 9 fed with. Subsequently, the range of the resulting marginal abatement costs is relatively wide, showing
 10 the full range of expected contributions from land use sector mitigation and sequestration in applied
 11 mitigation pathways.

12

13

14 **Figure 7.15 Mitigation of CO₂, CH₄ and N₂O emissions (in CO₂.eq yr⁻¹ using IPCC AR6 GWP₁₀₀ values)**
 15 **from the AFOLU sector for increasing carbon price levels for 2030 and 2050. In the left side panels, single**
 16 **data points are generated by comparing emissions between a policy scenario and a related benchmark**
 17 **scenario, and mapping these differences with the respective carbon price difference. Plots only show the**
 18 **price range of up to USD(2010)250 tCO₂-eq⁻¹ and the mitigation range between -2,000 and 6,000 MtCO₂-**
 19 **eq yr⁻¹ for better visibility. At the right-hand side, based on the same data as left-hand side panels,**
 20 **Boxplots show Medians (vertical line within the boxes), Means (dots), 33%-66% intervals (Box) and 10%-**
 21 **90% intervals (horizontal lines). Numbers on the very right indicate the number of observations falling**
 22 **into the respective price range per variable. A wide range of carbon price induced mitigation options**

1 **(such as technical, structural and behavioural options in the agricultural sector, afforestation,**
2 **reforestation, natural re-growth or avoided deforestation in the LULUCF sector, excluding carbon**
3 **capture and sequestration from BECCS) are reflected in different scenarios.**

4 At the global level, the analysis of the economic mitigation potentials from N₂O and CH₄ emissions
5 from AFOLU (which mainly can be related to agricultural activities) and CO₂ emissions (which mainly
6 can be related to LULUCF emissions) reveals a relatively good agreement of models and scenarios in
7 terms of ranking between the gases. On the right-hand side panels of Figure 7.15, only small overlaps
8 between the ranges (showing the 10-90% intervals of observations) and mainly for lower price levels,
9 can be observed, despite all differences in underlying model structure and scenario assumptions.

10 N₂O emissions show the smallest economic potential of the three different gases in 2030 as well as in
11 2050. The mitigation potential increases until a price range of USD150-200 and to a median value of
12 around 0.6 GtCO₂-eq yr⁻¹ mitigation in 2030 and 0.9 GtCO₂-eq yr⁻¹ in 2050, respectively, while
13 afterwards with higher prices the expansion is very limited. Mitigation of CH₄ emissions has a higher
14 potential, also with increasing mitigation potentials until a price range of USD150-200 in both years,
15 with median mitigation of around 1.3 GtCO₂-eq yr⁻¹ in 2030 and around 2.4 GtCO₂-eq yr⁻¹ in 2050,
16 respectively. The highest mitigation potentials are observed for CO₂, but also the highest ranges of
17 observations among the three gases. In 2030, a median of 4 GtCO₂-eq yr⁻¹ mitigation potential is
18 reported for the price range of USD200–250. In 2050, for the carbon price range of between USD100
19 and USD200, a median of around 4.8 GtCO₂-eq yr⁻¹ can be observed.

20 When compared with the sectoral estimates from Harmsen et al. (2019), the integrated assessment
21 median potentials are broadly comparable for the N₂O mitigation potential; Harmsen et al. 2050
22 mitigation potential at USD125 is 0.6 GtCO₂-eq yr⁻¹ while the integrated assessment estimate for the
23 same price range is 0.7 GtCO₂-eq yr⁻¹. The difference is substantially larger for the CH₄ mitigation
24 potential; 0.9 GtCO₂-eq yr⁻¹ in Harmsen et al. while 2 GtCO₂-eq yr⁻¹ the median integrated assessment
25 estimate. While the Harmsen et al. MACCs consider only technological mitigation options, integrated
26 assessments typically include also demand side response to the carbon price and GHG efficiency
27 improvements through structural change and international trade. These additional mitigation options
28 can represent more than 60% of the total non-CO₂ mitigation potential in the agricultural sector, where
29 they are more important in the livestock sector, and thus the difference between sectoral and integrated
30 assessments is more pronounced for the CH₄ emissions (Frank et al. 2019).

31 Economic CO₂ mitigation potentials from land use change and forestry are larger compared to potentials
32 from non-CO₂ gases, and at the same time reveal high levels of variation in absolute terms. The 66th
33 percentile in 2050 goes up to 5.2 GtCO₂-eq yr⁻¹ mitigation, while the lowest observations are even
34 negative, indicating higher CO₂ emissions from land use in scenarios with carbon price compared to
35 scenarios without (counterintuitive dynamics explained below).

36 Land use is at the centre of the interdependencies with other sectors, including energy. Some models
37 see a strong competition between BECCS deployment with its respective demand for biomass, and CO₂
38 mitigation/sequestration potentials in the land sector. Biomass demand may lead to an increase in CO₂
39 emissions from land use despite the application of a carbon price when land use expansion for dedicated
40 biomass production, such as energy plantations, comes from carbon rich land use/land cover
41 alternatives, or when increased extraction of biomass from existing land uses, such as forest
42 management, leads to reduction of the carbon sink (Daioglou 2019; Luderer et al. 2018, SI) and can
43 explain the high variety of observations in some cases. Overall, the large variety of observations shows
44 a large variety of plausible results, which can go back to different model structures and assumptions,
45 showing a robust range of plausible outcomes (Kriegler et al. 2015).

1 7.5.3. Interaction between mitigation in the AFOLU sector and other SDGs in the 2 context of integrated assessments

3 Besides the level of biomass supply for bioenergy, the adoption of SDGs may also significantly impact
4 AFOLU emissions and the land use sector's ability for GHG abatement (Frank et al. 2021). Selected
5 SDGs are found to have positive synergies for AFOLU GHG abatement and to consistently decrease
6 GHG emissions for both agriculture and forestry, thereby allowing for even more rapid and deeper
7 emissions cuts. In particular, the decreased consumption of animal products and less food waste
8 (SDG12), and the protection of high biodiversity ecosystems such as primary forests (SDG15) deliver
9 high synergies with GHG abatement. On the other hand, protection of highly biodiverse ecosystems
10 from conversion (SDG15) limits the global biomass potentials for bioenergy (Frank et al. 2021), and
11 while several forestry measures enhancing woody biomass supply for bioenergy may have synergies
12 with improving ecosystems conditions, many represent a threat to biodiversity (Camia et al. 2020). See
13 also Section 7.6.5. and Chapter 17 Section 17.3.3.7, Figure 17.1, Supplementary Material Table 17.1.

14

15 7.5.4. Regional AFOLU abatement for different carbon prices

16

17 **Figure 7.16** Regional mitigation efforts for CO₂, CH₄ and N₂O emissions (in CO₂-eq yr⁻¹ using IPCC AR6
18 GWP₁₀₀ values) from the AFOLU sector for increasing carbon price levels for 2030 and 2050. Underlying
19 datapoints are generated by comparing emissions between a policy scenario and a related benchmark

1 **scenario, mapping these differences with the respective carbon price differences. Boxplots show Medians**
2 **(vertical line within the boxes), Means (dots), 33%-66% intervals (box) and 10%-90% intervals**
3 **(horizontal lines) for respective scenarios of carbon prices implemented in intervals of USD50 from a**
4 **price of USD0 to USD250. Regions: Asia (ASIA), Latin America and Caribbean (LAM), Middle East**
5 **(MIDDLE_EAST), Africa (AFRICA), Developed Countries (OECD 90 and EU) (OECD+EU) and**
6 **Reforming Economies of Eastern Europe and the Former Soviet Union (REF).**

7 At the regional level (Figure 7.16), the highest potential from non-CO₂ emissions abatement, and mostly
8 from CH₄, is reported for ASIA with the median of mitigation potential observations from CH₄
9 increasing up to a price of USD200 in the year 2050, reaching a median of 1.2 GtCO₂-eq yr⁻¹. In terms
10 of economic potential, ASIA is followed by LAM, AFRICA, and OECD+EU, where emission reduction
11 mainly is achieved in the livestock sector.

12 The highest potentials from land-related CO₂ emissions, including avoided deforestation as well as
13 afforestation, can be observed in LAM and AFRICA with strong responses of mitigation (indicated by
14 the median value) to carbon prices mainly in the lower range of displayed carbon prices. In general,
15 CO₂ mitigation potentials show a wide range of results in comparison to non-CO₂ mitigation potentials,
16 but mostly also a higher median value. The most extreme ranges are reported for the regions LAM and
17 AFRICA. A medium potential is reported for ASIA and OECD+EU, while REF has the smallest
18 potential according to model submissions. These estimates reflect techno-economic potentials and do
19 not necessarily include feasibility constraints which are discussed in Chapter 7.6.

20 **7.5.5. Illustrative mitigation pathways**

21 Different mitigation strategies can achieve the net emission reductions that would be required to follow
22 a pathway limiting global warming, with very different consequences for the land system. Figure 7.17
23 shows Illustrative Mitigation Pathways (IMPs) for achieving different climate targets highlighting
24 AFOLU mitigation strategies, resulting GHG and land use dynamics as well as the interaction with
25 other sectors. For consistency this chapter discusses IMPs as described in detail in chapters 1 and 3 of
26 this report but focusing on the land-use sector. All pathways are assessed by different IAM realizations
27 and do not only reduce GHG emissions but also use CDR options, whereas the amount and timing varies
28 across pathways, as do the relative contributions of different land-based CDR options.

29 The *scenario ModAct* (below 3.0°C warming, C6) is based on the prolongation of current trends (SSP2)
30 but contains measures to strengthen policies for the implementation of National Determined
31 Contributions (NDCs) in all sectors including AFOLU (Grassi et al. 2018). This pathway shows a strong
32 decrease of CO₂ emissions from land-use change in 2030, mainly due to reduced deforestation, as well
33 as moderately decreasing N₂O and CH₄ emissions from agricultural production due to improved
34 agricultural management and dietary shifts away from emissions-intensive livestock products.
35 However, in contrast to CO₂ emissions, which turn net-negative around 2050 due to
36 afforestation/reforestation, CH₄ and N₂O emissions persist throughout the century due to difficulties of
37 eliminating these residual emissions based on existing agricultural management methods (Stevanović
38 et al. 2017; Frank et al. 2017). Comparably small amounts of BECCS are applied by the end of the
39 century. Forest area increases at the cost of other natural vegetation.

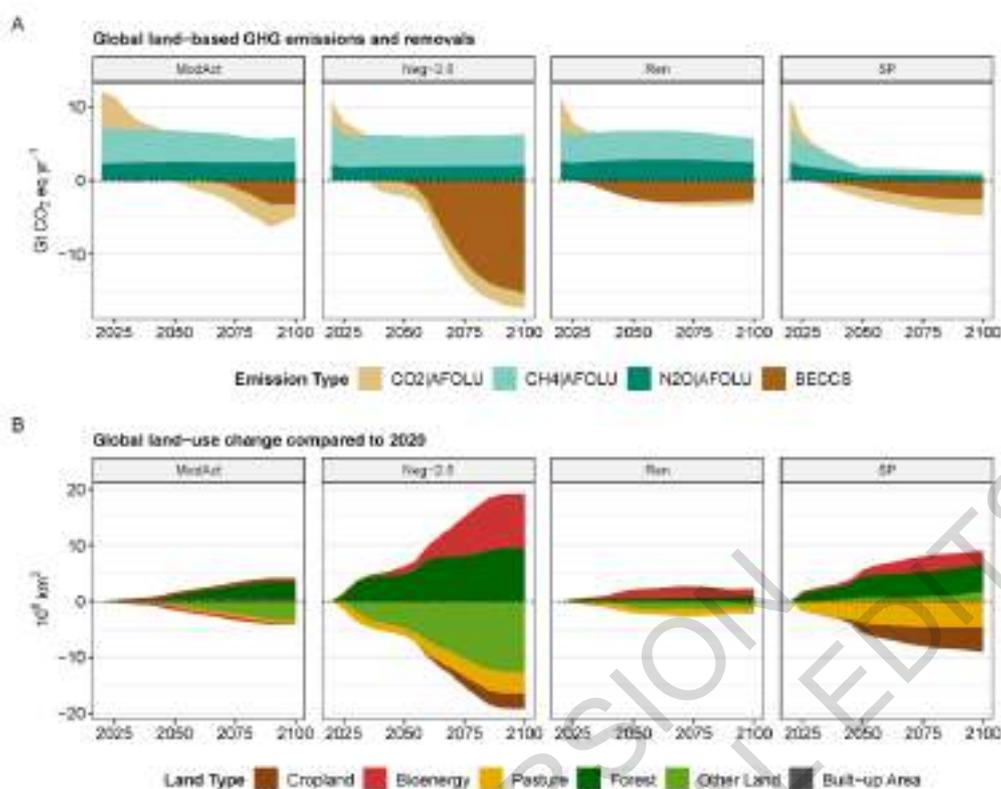

40 *IMP Neg-2.0* is similar to *ModAct* scenario in terms of socio-economic setting (SSP2) but differs
41 strongly in terms of the mitigation target (likely 2°C, C3) and its strong focus on the supply side of
42 mitigation measures with strong reliance on net-negative emissions. Consequently, all GHG emission
43 reductions as well as afforestation/reforestation and BECCS-based CDR start earlier in time at a higher
44 rate of deployment. However, in contrast to CO₂ emissions, which turn net-negative around 2030 due
45 to afforestation/reforestation, CH₄ and N₂O emissions persist throughout the century, similar to
46 *ModAct*, due to ongoing increasing demand for total calories and animal-based commodities (Bodirsky

1 et al. 2020) and difficulties of eliminating these residual emissions based on existing agricultural
2 management methods (Stevanović et al. 2017 ; (Frank et al. 2017). In addition to abating land-related
3 GHG emissions as well as increasing the terrestrial sink, this example also shows the potential
4 importance of the land sector in providing biomass for BECCS and hence CDR in the energy sector.
5 Cumulative CDR (2020-2100) amounts to 502 GtCO₂ for BECCS and 121 GtCO₂ for land-use change
6 (including afforestation and reduced deforestation). In consequence, compared to *ModAct scenario*,
7 competition for land is increasing and much more other natural land as well as agricultural land
8 (cropland and pasture land) is converted to forest or bioenergy cropland with potentially severe
9 consequences for various sustainability dimensions such as biodiversity (Hof et al. 2018) and food
10 security (Fujimori et al. 2019).

11 *IMP Ren* is similar to *IMP Neg-2.0* in terms of socio-economic setting (SSP2) but differs substantially
12 in terms of mitigation target and mitigation efforts in the energy sector. Even under the more ambitious
13 climate change mitigation target (1.5°C with no or low OS, C1), the high share of renewable energy in
14 *IMP Ren* strongly reduces the need for large-scale land-based CDR, which is reflected in smaller
15 bioenergy and afforestation areas compared to *IMP Neg-2.0*. However, CH₄ and N₂O emissions from
16 AFOLU persist throughout the century, similar to *ModAct scenario and IMP Neg-2.0*.

17 In contrast to *IMPs Neg-2.0 and Ren*, *IMP SP* (Soergel et al. 2021; 1.5°C with no or low OS, C1)
18 displays a future of generally low resource and energy consumption (including healthy diets with low
19 animal-calorie shares and low food waste) as well as significant but sustainable agricultural
20 intensification in combination with high levels of nature protection. This pathway shows a strong near-
21 term decrease of CO₂ emissions from land-use change, mainly due to reduced deforestation, and in
22 difference to all other *IMPs* described in this chapter strongly decreasing N₂O and CH₄ emissions from
23 agricultural production due to improved agricultural management but also based on dietary shifts away
24 from emissions-intensive livestock products as well as lower shares of food waste. In consequence,
25 comparably small amounts of land are needed for land demanding mitigation activities such as BECCS
26 and afforestation. In particular, the amount of agricultural land converted to bioenergy cropland is
27 smaller compared to other mitigation pathways. Forest area increases either by regrowth of secondary
28 vegetation following the abandonment of agricultural land or by afforestation / reforestation at the cost
29 of agricultural land.

30

9 **and agricultural land use (including emissions related to bioenergy production). In addition, the category**
10 **CO₂ Land includes removals due to afforestation / reforestation. BECCS reflects the CO₂ emissions**
11 **captured from bioenergy use and stored in geological deposits. CH₄ and N₂O emissions are converted to**
12 **CO₂-eq using GWP₁₀₀ factors of 27 and 273 respectively.**

14 7.6. Assessment of economic, social and policy responses

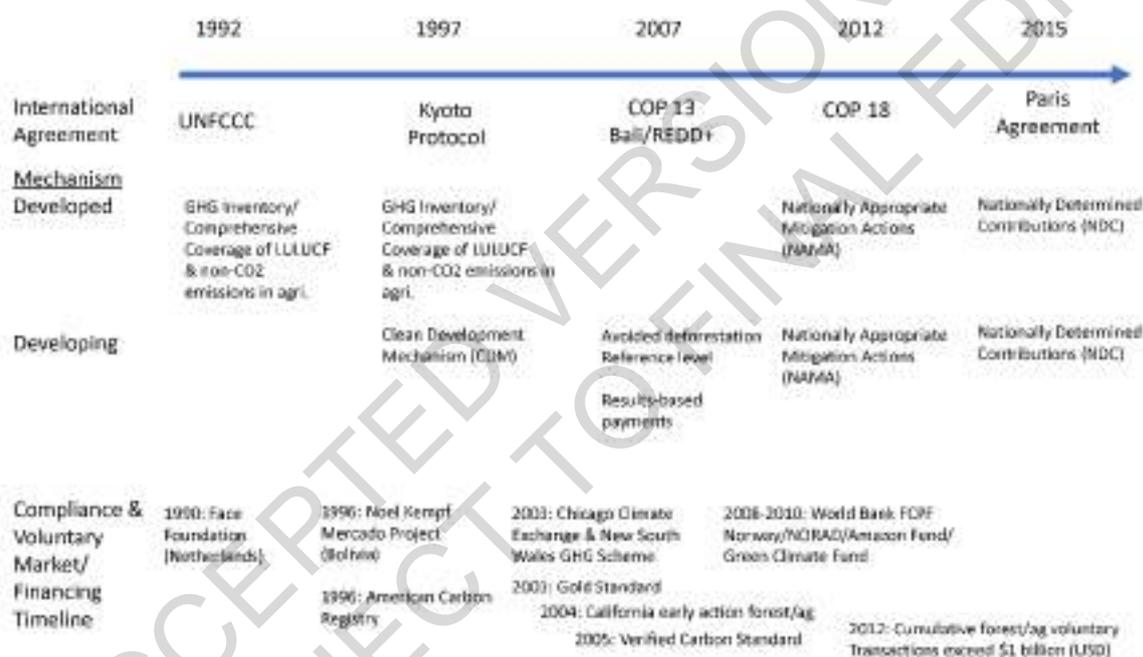

15 7.6.1. Retrospective in policy efforts and achieved mitigation within AFOLU

16 Since the establishment of the UNFCCC, international agencies, countries, sub-national units and
17 NGO's have developed policies to facilitate and encourage GHG mitigation within AFOLU (Figure
18 7.18). Early guidance and policies focused on developing GHG inventory methodology with some
19 emphasis on afforestation and reforestation projects, but the Clean Development Mechanism (CDM) in
20 the Kyoto Protocol focused attention on emission reduction projects, mostly outside of AFOLU. As
21 successive IPCC WGIII reports illustrated large potential for AFOLU mitigation, methods to quantify
22 and verify carbon emission reductions emerged within several projects in the early 2000s, through both
23 voluntary (e.g., the Chicago Climate Exchange (CCX)) and regulated (e.g., New South Wales and
24 California) markets. The CDM dedicated large attention to LULUCF, including dedicated
25 methodologies and bodies. The reasons for limited uptake of CDM afforestation/reforestation projects

1 were multiple and not limited to the regulatory constraints, but also due to the low abatement potential
2 (poor cost/performance ratio) compared to other mitigation opportunities.

3 Following COP 13 in Bali, effort shifted to advancing policies to reduce deforestation and forest
4 degradation (REDD+) in developing countries. According to Simonet et al. (2019), nearly 65 Mha have
5 been enrolled in REDD+ type programs or projects funded through a variety of sources, including UN
6 REDD, the World Bank Forest Carbon Partnership Facility, and bi-lateral agreements between countries
7 with Norway being the largest donor. While there has been considerable focus on forest and agricultural
8 project-based mitigation actions, national governments were encouraged to incorporate project-based
9 approaches with other sectoral strategies in their Nationally Appropriate Mitigation Strategies
10 (NAMAs) after 2012. NAMAs reflect the country's proposed strategy to reduce net emissions across
11 various sectors within their economy (e.g. forests or agriculture). More recently, Nationally Determined
12 Contributions (NDCs) indicate whether individual countries plan to use forestry and agricultural
13 policies or related projects amongst a set of measures in other sectors, to reduce their net emissions as
14 part of the Paris Agreement (e.g., Forsell et al. 2016; Fyson and Jeffery 2019).

15

16

17 **Figure 7.18 Milestones in policy development for AFOLU measures.**

18

19 The many protocols now available can be used to quantify the potential mitigation to date resulting
20 from various projects or programs. For instance, carbon registries issue credits using protocols that
21 typically account for additionality, permanence and leakage, thus providing evidence that the projects
22 are a net carbon benefit to the atmosphere. Protocol development engages the scientific community,
23 project developers, and the public over a multi-year period. Some protocols have been revised multiple
24 times, such as the USA State of California's forest carbon protocol, which is in its fifth revision, with
25 the latest in 2019 (see <http://www.climateactionreserve.org/how/protocols/forest/>). Credits from carbon
26 registries feed into regulatory programs, such as the cap and trade program in California, or voluntary
27 offset markets (Hamrick and Gallant 2017a). Although AFOLU measures have been deployed across a

1 range of projects and programs globally to reduce net carbon emissions, debate about the net carbon
2 benefits of some projects continues (e.g. Krug 2018).

3 A new assessment of projects over the last two decades finds emission reductions or offsets of at least
4 7.9 GtCO₂-eq (using GWP₁₀₀ and a mix of IPCC values for CH₄ and N₂O) over the last 12 years due to
5 agricultural and forestry activities (Table 7.4). More than 80% of these emission reductions or offsets
6 have been generated by forest-based activities. The total amounts to 0.66 GtCO₂ yr⁻¹ for the period
7 2010-2019, which is 1.2% of total global, and 5.5% of AFOLU emissions reported in Table 7.1, over
8 the same time period (*high confidence*).

9 The array of activities in Table 7.4 includes the Clean Development Mechanism, REDD+ activities
10 reported in technical annexes of country biennial update reports to the UNFCCC, voluntary market
11 transactions, and carbon stored as a result of carbon markets in Australia, New Zealand and California
12 in the USA. Although other countries and sub-national units have developed programs and policies,
13 these three regions are presented due to their focus on forest and agricultural carbon mitigation, their
14 use of generally accepted protocols or measures and the availability of data to quantify outcomes.

15 The largest share of emission reductions or carbon offsets in Table 7.4 has been from slowing
16 deforestation and REDD+, specifically from efforts in Brazil (86% of total), which substantially
17 reduced deforestation rates between 2004 and 2012 (Nepstad et al., 2014), as well as other countries in
18 Latin America. With the exception of Roopsind et al. (2019), estimated reductions in carbon emissions
19 from REDD+ in Table 7.4 are measured relative to a historical baseline. As noted in Brazil's Third
20 Biennial Update Report (Ministry of Foreign Affairs 2019), estimates are made in accordance with
21 established methodologies to determine the benefits of results-based REDD+ payments to Brazil.
22 REDD+ estimates from other countries also have been derived from biennial update reports.

23 Regulatory markets provide the next largest share of carbon removal to date. Data from the Australia
24 Emissions Reduction Fund is an estimate of carbon credits in agriculture and forestry purchased by the
25 Australian government. In the case of California, offset credits from forest and agricultural activities,
26 using methods approved by a third-party certification authority (Climate Action Reserve), have been
27 allowed as part of their state-wide cap and trade system. Transaction prices for forest and agricultural
28 credits in California were around USD13 tCO₂⁻¹ in 2018, and represented 7.4% of total market
29 compliance. By the end of 2018, 80 MtCO₂ had been used for compliance purposes.

30 For New Zealand, the carbon reduction in Table 7.4 represents forest removals that were surrendered
31 from post-1989 forests between 2008 and the 2020. Unlike offsets in voluntary markets or in California,
32 where permanence involves long-term contracts or insurance pools, forests in the New Zealand market
33 liable for emissions when harvested or following land use change. This means sellers account for future
34 emission risks related to harvesting when they enter forests into carbon contracts. Offset prices were
35 around USD13 tCO₂⁻¹ in 2016 but have risen to more than USD20 tCO₂⁻¹ in 2020.

36 The voluntary market data in Table 7.4 are offsets developed under the major standard-setting
37 organizations, and issued from 2008-2018 (e.g., Hamrick and Gallant 2018). Note that there is some
38 potential for double counting of voluntary offsets that may have been transacted in the California
39 compliance market, however this would only have applied to transactions of US-issued offsets, and the
40 largest share of annual transactions of voluntary AFOLU credits occurs with credits generated in Latin
41 America, followed by Africa, Asia and North America. Europe and Oceania have few voluntary carbon
42 market transactions. Within forestry and agriculture, most of the voluntary offsets were generated by
43 forestry projects. Using historical transaction data from various *Forest Trends* reports, the offsets
44 generated were valued at USD46.9 million yr⁻¹. Prices for voluntary offset transactions in the period
45 2014-2016 ranged from USD4.90 to 5.40 tCO₂⁻¹ (Hamrick and Gallant 2017a).

1 Voluntary finance has amounted to USD0.5 billion over a 10-year period for development of forest and
 2 agricultural credits. The three regulatory markets quantified amount to USD2.7 billion in funding from
 3 2010 to 2019. For the most part, this funding has focused on forest projects and programs, with
 4 agricultural projects accounting for 5-10% of the total. In total, reported funding for AFOLU projects
 5 and programs has been USD4.4 billion over the past decade, or about USD569 million yr⁻¹ (*low*
 6 *confidence*). The largest share of the total carbon includes efforts in the Amazon by Brazil. Government
 7 expenditures on regulatory programs and business expenditures on voluntary programs in Brazil (e.g.,
 8 the soy or cattle moratoriums) were not included in financing estimates due to difficulties obtaining that
 9 data. If Brazil and CDM (for which we have no cost estimates) are left out of the calculation, average
 10 cost per ton has been USD3.20 tCO₂⁻¹.

11
 12
 13
 14

Table 7.4 Estimates of achieved emission offsets or reductions in AFOLU through 2018. Data include CDM, voluntary carbon standards, compliance markets, and reduced deforestation from official UNFCCC reports. Carbon sequestration due to other government policies not included.

^g Surrendered forest carbon credits from post-1989 forests in New Zealand. Obtained from New Zealand Environmental Protection Authority. ETS Unit Movement interactive report (Excel based). <https://www.epa.govt.nz/industry-areas/emissions-trading-scheme/ets-reports/unit-movement/>. Obtained 13/08/2020.⁸ All non-CO₂ gases are converted to CO₂-eq using IPCC GWP₁₀₀ values recommended at the time the project achieved approval by the relevant organisation or agency.

The large number of policy approaches described in Table 7.4 combined with efforts by other international actors, such as the Global Environmental Facility (GEF), as well as non-state actors (e.g., eco-labelling programs and corporate social responsibility initiatives) illustrate significant policy experimentation over the last several decades. Despite widespread effort, AFOLU measures have thus far failed to achieve the large potential for climate mitigation described in earlier IPCC WG III reports (*high confidence*). The limited gains from AFOLU to date appear largely to result from lack of investment and other institutional and social barriers, rather than methodological concerns (*high confidence*).

7.6.2. Review of observed policies and policy instruments

7.6.2.1. Economic incentives

Emissions Trading/Carbon Taxes. While emissions trading programs have been developed across the globe, forest and agriculture have not been included as part of the cap in any of the existing systems. However, offsets from forestry and agriculture have been included in several of the trading programs. New Zealand has a hybrid program where carbon storage in forests can be voluntarily entered into the carbon trading program, but once entered, forests are counted both as a sink for carbon if net gains are positive, and a source when harvesting occurs. New Zealand is considering rules to include agricultural GHG emissions under a future cap (Henderson et al. 2020; see: <https://www.agmatters.nz/topics/he-waka-eke-noa/>).

The state of California has developed a formal cap and trade program that allows a limited number of forest and agricultural offset credits to be used under the cap. All offsets must meet protocols to account for additionality, permanence and leakage. Forest projects used as offsets in California currently are located in the USA, but the California Air Resources Board adopted a tropical forest carbon standard, allowing for avoided deforestation projects from outside the USA to enter the California market (CARB 2019).

Canadian provinces have developed a range of policy options that can include carbon offsets. Quebec has an emissions trading program that plans to allow forest and agricultural offsets generated within the province to be utilised. Alberta also allows offsets to be utilised by regulated sectors while British Columbia allows offsets to be utilised by the government for its carbon neutrality goals (Government of Alberta, 2021). Over 20 countries and regions have adopted explicit carbon taxes on carbon emission sources and fossil fuels, however, the charges have not been applied to non-CO₂ agricultural emissions (OECD 2021a). California may implement regulations on methane emissions from cattle, however, regulations if approved, will not go into effect until 2024. Institutional and trade-related barriers (e.g., leakage) likely will limit widespread implementation of taxes on emissions in the food sector globally. Many countries exempt purchases of fuels used in agricultural or fishery production from fuel or carbon taxes, thus lowering the effective tax rate imposed on those sectors (OECD 2021a). Furthermore, bioenergy, produced from agricultural products, agricultural waste, and wood is often exempted from

1 explicit carbon taxes. Colombia recently implemented a carbon tax on liquid fuels but allowed
2 domestically produced forestry credits to offset the tax. Colombia also is in the process of developing
3 an emissions trading scheme (OECD 2021a).

4 **REDD+/Payment for Ecosystem Services (PES).** PES programs for a variety of ecosystem services
5 have long been utilised for conservation (e.g. Wunder 2007) and may now be as large as USD42 billion
6 yr⁻¹ (Salzman et al. 2018). REDD+ emerged in the early 2000s and is a widely recognized example of
7 PES program focused on conservation of tropical forests (Table 7.4). However, our summation of
8 actually paid funds in Table 7.4 is much smaller than what is portrayed by Salzman et al. (2018).
9 REDD+ may operate at the country level, or for specific programs or forests within a country. As with
10 other PES programs, REDD+ has evolved towards a results-based program that involves payments that
11 are conditioned on meeting certain successes or milestones, such as rates of deforestation (Angelsen
12 2017).

13 A large literature has investigated whether PES programs have successfully protected habitats. Studies
14 in the USA found limited additionality for programs that encouraged conservation tillage practices, but
15 stronger additionality for programs that encouraged set-asides for grasslands or forests (Woodward et
16 al. 2016; Claassen et al. 2018;), although the set-asides led to estimated leakage of 20 up to 100% (Wu
17 2000; Pfaff and Robalino 2017; Kallio and Solberg 2018). Evidence from the EU similarly suggests
18 that payments for some agro-environmental practices may be additional, while others are not (Chabé-
19 Ferret and Subervie 2013). Other studies, in particular in Latin America where many PES programs
20 have been implemented, have found a wide range of estimates of effectiveness (e.g. Honey-Rosés et al.
21 2011; Robalino and Pfaff 2013; Mohebalian and Aguilar 2016; Jayachandran et al. 2017; Börner et al.
22 2017; Alix-Garcia et al. 2015; Robalino et al. 2015; Burivalova et al. 2019). Despite concerns, the
23 many lessons learned from PES program implementation provide critical information that will help
24 policymakers refine future PES programs to increase their effectiveness (*medium confidence*).

25 While expectations that carbon-centred REDD+ would be a simple and efficient mechanism for climate
26 mitigation have not been met (Turnhout et al. 2017; Arts et al. 2019), progress has nonetheless occurred.
27 Measuring, monitoring and verification systems have been developed and deployed, REDD readiness
28 programs have improved capacity to implement REDD+ on the ground in over 50 countries, and a
29 number of countries now have received results-based payments.

30 Empirical evidence that REDD+ funding has slowed deforestation is starting to emerge. Simonet et al.
31 (2019) showed that a REDD+ project in Brazil reduced deforestation certainly until 2018, while
32 Roopsind et al. (2019) showed that country-level REDD+ payments to Guyana encouraged reduced
33 deforestation and increased carbon storage. Although more impact evaluation (IE) analysis needs to be
34 conducted on REDD+ payments, these studies support the country-level estimates of carbon benefits
35 from REDD+ shown in Table 7.4. Nearly all of the analysis of PES and REDD+ to date has focused on
36 the presence or absence of forest cover, with little to no analysis having been conducted on forest
37 degradation, conservation, or enhancement of forest stocks.

38 **Agro-environmental Subsidy Programs/PES.** Climate policy for agriculture has developed more
39 slowly than in other sectors due to concerns with food security and livelihoods, political interests, and
40 difficulties in coordinating diffuse and diverse activities and stakeholders (e.g. nutritional health, rural
41 development, and biodiversity conservation) (Leahy et al. 2020). However, a review of the National
42 Adaptation Programme of Action (NAPAs), National Adaptation Plans (NAPs), NAMAs, and NDCs
43 in the Paris Agreement suggest an increasing focus of policy makers on agriculture and food security.
44 The vast majority of parties to the Paris Agreement recognise the significant role of agriculture in
45 supporting a secure sustainable development pathway (Richards and VanWey 2015) with the inclusion
46 of agriculture mitigation in 103 NDCs from a total of 160 NDC submissions. Livestock is the most

1 frequently cited specific agricultural sub-sector, with mitigation activities generally focusing on
2 increasing efficiency and productivity.

3 Agriculture is one of the most subsidised industries globally, especially in the European Union and the
4 USA. While subsidy payments over the last 20 years have shifted modestly to programs designed to
5 reduce the environmental impact of the agricultural sector, only 15-20% of the more than USD700
6 billion spent globally on subsidies are green payments (OECD 2021b). Under the Common Agricultural
7 Policy in the EU, up to 30% of the direct payments to farmers (Pillar 1) have been green payments
8 (Henderson et al. 2020), including some actions that could increase carbon storage or reduce emissions.
9 Similarly, at least 30% of the rural development payments (Pillar 2) are used for measures that reduce
10 environmental impact, including reduction of GHG emissions and carbon storage. There is limited
11 evidence that these policies contributed to the 20% reduction in GHG emissions from the agricultural
12 sector in the EU between 1990 and 2018 (Baudrier et al. 2015) and Eurostat 2020).

13 The USA spends USD4 billion yr⁻¹ on conservation programs, or 12% of net farm income (Department
14 Of Agriculture 2020). In real terms, this expenditure has remained constant for 15 years, supporting 12
15 Mha of permanent grass or woodland cover in the Conservation Reserve Program (CRP), which has
16 increased soil carbon sequestration by 3 tCO₂ ha⁻¹ yr⁻¹ (Paustian et al. 2019; Conant et al. 2017), as well
17 as other practices that could lower net emissions. Gross GHG emissions from the agricultural sector in
18 the US, however, have increased since 1990 (US-EPA 2020) due to reductions in the area of land in the
19 US CRP program and changes in crop rotations, both of which caused soil carbon stocks to decline
20 (US-EPA 2020). When combined with increased non-CO₂ gas emissions, the emission intensity of US
21 agriculture increased from 1.5 to 1.7 tCO₂ ha⁻¹ between 2005 and 2018 (*high confidence*).

22 China has implemented large conservation programs that have influenced carbon stocks. For example,
23 the Sloping Land Conversion Program, combined with other programs, has increased forest cover and
24 carbon stocks, reduced erosion and increased other ecosystem services in China in recent years (Ouyang
25 et al. 2016). Despite increased forest area in China, however, land use change and management
26 potentially were net contributors to carbon emissions from 1990-2010 (Lai et al. 2016). As part of
27 Brazil's national strategy, numerous practices to reduce GHG emissions from agriculture, and in
28 particular from the animal agriculture industry, have been subsidized. Estimates by Manzatto et al.
29 (2020) suggest that the program may have reduced agricultural emissions by 169 MtCO₂ between 2010
30 and 2020. Given the large technical and economic potential for agroforestry to be deployed in Africa,
31 subsidy approaches could be deployed along with other policies to enhance carbon through innovative
32 practices such as regreening (Box 7.10).

33 **7.6.2.2. Regulatory approaches**

34 **Regulations** on land use include direct controls on how land is used, zoning, or legally set limits on
35 converting land from one use to another. Since the early 2000s, Brazil has deployed various regulatory
36 measures to slow deforestation, including enforcement of regulations on land use change in the legal
37 Amazon area. Enforcement of these regulations, among other approaches is credited with encouraging
38 the large-scale reduction in deforestation and associated carbon emissions after 2004 (Nepstad et al.
39 2014). Empirical evidence has found that regulations reduced deforestation in Brazil (Arima et al. 2014)
40 but over time, reversals occurred when enforcement was not consistent (Azevedo et al. 2017) (Box 7.9).

41 Many OECD countries have strong legal frameworks that influence agricultural and forest management
42 on both public and private land. These include for example, legal requirements to protect endangered
43 species, implement conservation tillage, protect riparian areas, replant forests after harvest, maintain
44 historical species composition, forest certification, and other approaches. Increasingly, laws support
45 more widespread implementation of nature-based solutions for a range of environmental issues (e.g.
46 see European Commission 2021) The extent to which the combined influence of these regulations has

1 enhanced carbon storage in ecosystems is not quantified although they are likely to explain some of the
2 persistent carbon sink that has emerged in temperate forests of OECD countries (*high confidence*). In
3 the least developed and developing countries, regulatory approaches face challenges in part because
4 environmental issues are a lower priority than many other socioeconomic issues (e.g., poverty,
5 opportunity, essential services), and weak governance (Mayer Pelicice 2019; Walker et al. 2020); Box
6 7.2).

7 ***Set asides and protected areas*** have been a widely utilised approach for conservation, and according to
8 (FAO 2020d), 726 Mha (18%) of forests are in protected areas globally. A review of land sparing and
9 land sharing policies in developing countries indicated that most of them follow land sparing models,
10 sometimes in combination with land sharing approaches. However, there is still no clear evidence of
11 which policy provides the best results for ecosystem services provision, conservation, and livelihoods
12 (Mertz and Mertens 2017). The literature contains a wide range of results on the effectiveness of
13 protected areas to reduce deforestation (Burivalova et al. 2019), with studies suggesting that protected
14 areas provide significant protection of forests (e.g., Blackman 2015), modest protection (Andam et al.
15 2008), as well as increases in deforestation (Blackman 2015) and possible leakage of harvesting to
16 elsewhere (Kallio and Solberg 2018). An estimate of the contributions of protected areas to mitigation
17 between 2000 and 2012, showed that in the tropics, PAs reduced carbon emissions from deforestation
18 by 4.88 Pg C, or around 29%, when compared to the expected rates of deforestation (Bebber and Butt
19 2017). In that study, the tropical Americas (368.8 TgC y⁻¹) had the largest contribution, followed by
20 Asia (25.0 TgC y⁻¹) and Africa (12.7 TgC y⁻¹). The authors concluded that local factors had an
21 important influence on the effectiveness of protected areas. For example, in the Brazilian Amazon,
22 protected area effectiveness is affected by the government agency controlling the land (federal
23 indigenous lands, federal PAs, and state PAs) (Herrera et al. 2019). Because protected areas limit not
24 just land use change, but also logging or harvesting non-timber forest products, they may be relatively
25 costly approaches for forest conservation (*medium confidence*).

26 ***Community forest management (CFM)*** allows less intensive use of forest resources, while at the same
27 time providing carbon benefits by protecting forest cover. Community forest management provides
28 property rights to communities to manage resources in exchange for their efforts to protect those
29 resources. In many cases, the local communities are indigenous people who otherwise would have
30 insecure tenure due to an advancing agricultural frontier or mining activity. Other examples are forest
31 owner associations like those discussed in Box 7.8. According to the Rights and Resources Initiative
32 (2018), the area of forests under community management increased globally by 152 Mha from 2002 to
33 2017, with over 500 Mha under community management in 2017. Studies have now shown that
34 improved property rights with community forest management can reduce deforestation and increase
35 carbon storage (Bowler et al. 2012; Alix-Garcia et al. 2005; Blackman 2015; Fortmann et al. 2017;
36 Burivalova et al. 2019; Alix-Garcia 2007; Deininger and Minten 2002). Efforts to expand property
37 rights, especially community forest management, have reduced carbon emissions from deforestation in
38 tropical forests in the last two decades (*high confidence*), although the extent of carbon savings has not
39 been quantified globally.

41 [START BOX 7.8 HERE]

42 **Box 7.8 Management of native forests by the Menominee people in North America and lessons** 43 **from forest owner associations**

44 **Summary of the case – Indigenous peoples include more than 5 000 different peoples, with over 370**
45 **million people, in 70 countries on five continents (UNIPP 2012). Forests cover more than 80% of the**
46 **area occupied by indigenous peoples (330 million hectares) point to their critical for forest governance**

1 (Garnett et al. 2018; Fa et al. 2020). The Menominee people (Wisconsin, USA) practice sustainable
2 forestry on their reservation according to a land ethic integral to the tribal identity. The Tribe calls
3 themselves “The Forest Keepers,” recognizing that the connection of their future to the sustainable
4 management of the forest that allowed the forest volume standing today to be higher than when timber
5 harvesting began more than 160 years ago. Management practices are based on continuous forest
6 inventories (Mausel et al. 2017).

7 **Introduction to the case** - Forest management and timber harvesting operations began shortly after the
8 Menominee Indian Reservation was created by treaty in 1854. The Menominee reservation sits on ca.
9 95000 ha of land in Wisconsin that spans multiple forest types and is more diverse than adjacent forests.
10 The collectively maintained reservation has 87% of its land under sustained yield forestry.

11 **Case description** - The Tribe, in the 19th century, had already mastered vegetation manipulation with
12 fire, sustainable forestry, multiple-use, ecosystem, and adaptive management. The centerpiece of the
13 Tribe’s economy has been its forest product industry, Menominee Tribal Enterprises (MTE) (Pecore
14 1992). A balance between growth and removals and continuous forest inventories (CFI) are central for
15 forest management for the past 160 years, aiming not at very large volumes, but at very high quality
16 trees. During this same period, more than 2.3 billion board feet have been harvested from the same area,
17 equivalent to $0.3 \text{ m}^3 \text{ ha}^{-1} \text{ y}^{-1}$.

18 **Interactions and limitations** –In 2013, the Menominee Tribe started a collaboration with the US Forest
19 Service to implement climate adaptation measures. The Tribe actively works to reduce the risk of forest
20 damage and decided to further promote diversity by planting tree seedlings adapted to a warming
21 climate (<https://toolkit.climate.gov/case-studies/and-trees-will-last-forever>). However, new challenges
22 are related to increasing pressures on forest ecosystems such as non-native insects, pathogens, weed
23 invasions, and the costs for continuous forest inventories to support long-term forest management.

24 **Identified lessons** - The elements of sustainability are intertwined with Menominee history, culture,
25 spirituality, and ethics. The balance between the environment, community, and economy for the short
26 term as well as future generations is an example of protecting the entire environment as the Menominee
27 land is a non-fragmented remnant of the prehistoric Lake States forest which has been dramatically
28 reduced all around the reserve (Schabel and Pecore 1997). These and other types of community forest
29 owner associations exist all over the world. Examples are Södra in Sweden (with 52,000 forest owners)
30 (Södra, 2021) or Waldbauernverband in North-Rhine Westphalia (with 150,000 forest owners and
31 covering 585,000 ha) (AGDW-The Forest Owners, 2021). These are ways for small forest owners
32 to educate, jointly put wood on the market, employ better forest management, use machinery together,
33 and apply certification jointly. In this manner and with all their diversity of goals, they manage to
34 maintain carbon sinks and stocks, while preserving biodiversity and producing wood.

35 **[END BOX 7.8 HERE]**

36
37 **Bioenergy targets.** Multiple policies have been enacted at national and supra-national levels to promote
38 the use of bioenergy in the transport sector, and for bioelectricity production. Existing policies mandate
39 or subsidize the production and use of bioenergy. In the past few years, policies have been proposed,
40 put in place or updated in Australia (Renewable Energy Target), Brazil (RenovaBio, Nationally
41 Determined Contribution), Canada (Clean Fuel Standard), China (Biodiesel Industrial Development
42 Policy, Biodiesel Fuel Blend Standard), the European Union (Renewable Energy Directive II), the USA
43 (Renewable Fuel Standards), Japan (FY2030), Russia (Energy Strategy Bill 2035), India (Revised
44 National Policy on Biofuels), and South Africa (Biofuels Regulatory Framework).

45 While current policies focus on bioenergy to decarbonise the energy system, some also contain
46 provisions to minimise the potential environmental and social trade-offs from bioenergy production.
47 For instance, the EU Renewable Energy Directive (EU-REDII) and US Renewable Energy Standard
48 (US-RFS) assign caps on the use of biofuels, which are associated with indirect land-use change and

1 food-security concerns. The Netherlands has a stringent set of 36 sustainability criteria to which the
2 certified biomass needs to comply. The EU-REDII also sets a timeline for the complete phase-out of
3 high-risk biofuels (Section 7.4.4).

4 **7.6.2.3. Voluntary actions and agreements**

5 **Forest certification programs**, such as Forest Sustainability Council (FSC) or Programme for the
6 Endorsement of Forest Certification (PEFC), are consumer driven, voluntary programs that influence
7 timber harvesting practices, and may reduce emissions from forest degradation with reduced impact
8 logging and other approaches (*medium confidence*). Forest certification has expanded globally to over
9 440 Mha (Kraxner et al. 2017). As the area of land devoted to certification has increased, the amount
10 of timber produced from certified land has increased. In 2018, FSC accounted for harvests of 427
11 million m³ and jointly FSC and PEFC accounted for 689 million m³ in 2016 or around 40% of total
12 industrial wood production (FAO 2018c). There is evidence that reduced impact logging can reduce
13 carbon losses in tropical regions (Pearson et al. 2014); (Ellis et al. 2019). However, there is conflicting
14 evidence about whether forest certification reduces deforestation (e.g., Tritsch et al. 2020; Blackman et
15 al. 2018).

16 **Supply chain management** in the food sector encourages more widespread use of conservation
17 measures in agriculture (*high confidence*). The number of private commitments to reduce deforestation
18 from supply chains has greatly increased in recent years, with at least 865 public commitments by 447
19 producers, processors, traders, manufacturers and retailers as of December, 2020 (New York
20 Declaration on Forests 2021). Industry partnerships with NGOs, such as the Roundtable on Sustainable
21 Palm Oil (RSPO), have become more widespread and visible in agricultural production. For example,
22 RSPO certifies members all along the supply chain for palm oil and claims around 19% of total
23 production. Similar sustainability efforts exist for many of the world's major agricultural products,
24 including soybeans, rice, sugar cane, and cattle.

25 There is evidence that the Amazon Soy Moratorium (ASM), an industry-NGO effort whereby large
26 industry consumers agreed voluntarily not to purchase soybeans grown on land deforested after 2006,
27 reduced deforestation in the legal Amazon (Nepstad et al. 2014; Gibbs et al. 2015). However, recent
28 studies have shown that some deforestation from the Amazon was displaced to the Cerrado (Brazilian
29 savannas) region (Moffette and Gibbs 2021). which is a global hotspot for biodiversity, and has
30 significant carbon stocks. These results illustrate the importance of broadening the scope of supply
31 chain management to minimize or eliminate displacement (Lima et al. 2019). In addition, while
32 voluntary efforts may improve environmental outcomes for a time, it is not clear that they are sufficient
33 to deliver long-term reductions in deforestation, given the increases in deforestation that have occurred
34 in the Amazon in recent years (Box 7.9). Voluntary efforts would be more effective at slowing
35 deforestation if they present stronger linkages to regulatory or other approaches (Lambin et al. 2018).

36

37 **[START BOX 7.9 HERE]**

38

Box 7.9 Case study: Deforestation control in the Brazilian Amazon

Summary

39
40 Between 2000 and 2004, deforestation rates in the Brazilian Legal Amazon (is a socio-geographic
41 division containing all nine Brazilian states in the Amazon basin) increased from 18,226 to 27,772 km²
42 yr⁻¹ 2008 (INPE, 2021) . A set of public policies designed in participatory process involving federal
43 government, states, municipalities, and civil society successfully reduced deforestation rates until 2012.
44 However, deforestation rates increased after 2013, and particularly between 2019 and 2020. Successful

1 deforestation control policies are being negatively affected by changes in environmental governance,
2 weak law enforcement, and polarisation of the national politics.

3 **Background**

4 In 2004, the Brazilian federal government started the Action Plan for Prevention and Control of
5 Deforestation in the Legal Amazon (PPCDAm) (Ministry of Environment, Government of Brazil,
6 2018)

7 . The PPCDAm was a benchmark for the articulation of forest conservation policies that included central
8 and state governments, prosecutor offices, and the civil society. The decline in deforestation after 2008
9 is mostly attributed to these policy options. In 2012, deforestation rates decreased to 4,571 km² yr⁻¹.

10 **Case description**

11 Combating deforestation was a theme in several programs, government plans, and projects not being
12 more restricted to the environmental agenda. This broader inclusion resulted from a long process of
13 insertion and articulation in the government dating back to 2003 while elaborating on the Sustainable
14 Amazon Plan. In May 2003, a historic meeting took place in an Amazonian city, with the President of
15 the Republic, State Governors, Ministers, and various business leaders, civil institutions, and social
16 movements. It was presented and approved the document entitled "Sustainable Amazonia - Guidelines
17 and Priorities of the Ministry of Environment for the Sustainable Development of the Amazon
18 Brazilian," containing several guidelines for conservation and sustainable use in the region. At the
19 meeting, the Union and some states signed a Cooperation Agreement aiming to elaborate a plan for the
20 Amazon, to be widely discussed with the various sectors of the regional and national society (Ministerio
21 do Meio Ambiente. MMA 2013).

22 **Interactions and limitations**

23 The PPCDAm had three main lines of action: 1. territorial management and land use; 2. command and
24 control; and 3. promotion of sustainable practices. During the execution of the 1st and 2nd phases of
25 the PPCDAm (2004-2011), important results in the territorial management and land use component
26 included, for example, the creation of 25 Mha of federal Protected Areas (PAs) located mainly in front
27 of the expansion of deforestation, as well as the homologation of 10 Mha of Indigenous Lands. Also,
28 states and municipalities created approximately 25 Mha, so that all spheres of government contributed
29 to the expansion of PAs in the Brazilian Amazon. In the Command and Control component, agencies
30 performed hundreds of inspection operations against illegal activities (e.g., illegal logging) under
31 strategic planning based on technical and territorial priorities. Besides, there was a significant
32 improvement of the environmental monitoring systems, involving the analysis of satellite images to
33 guide actions on the ground. Another policy was the restriction of public credit to enterprises linked to
34 illegal deforestation following a resolution of the Brazilian Central Bank (2008) (Ministerio do Meio
35 Ambiente. MMA 2013). Also, in 2008, Brazil created the Amazon Fund, a REDD+ mechanism
36 (Government of Brazil, n.d).

37 However, the country's political polarisation has gradually eroded environmental governance,
38 especially after the Brazilian Forest Code changes in 2012 (major environmental law in Brazil), the
39 presidential impeachment in 2016, presidential elections in 2018, and the start of the new federal
40 administration in 2019. Successful deforestation control policies are being negatively affected by
41 critical changes in the political context, and weakening the environmental rule of law, forest
42 conservation, and sustainable development programs (for example, changes in the Amazon Fund
43 governance in disagreement with the main donors). In 2019, the annual deforestation rate reached
44 10,129 km² being the first time it surpassed 10,000 km² since 2008 (INPE, 2021) . Besides, there has

1 been no effective transition from the historical economic model to a sustainable one. The lack of clarity
2 in the ownership of land is still a major unresolved issue in the Amazon.

3 **Lessons**

4 The reduction of deforestation in the Brazilian Amazon was possible due to effective political and
5 institutional support for environmental conservation. The initiatives of the Action Plan included the
6 expansion of the protected areas network (conservation unities and indigenous lands), improvement of
7 deforestation monitoring to the enforcement of environmental laws, and the use of economic
8 instruments, for example, by cutting off public credit for municipalities with higher deforestation rates
9 (Souza et al. 2013; Ricketts et al. 2010; Blackman and Veit 2018; Nepstad et al. 2014; Arima et al.
10 2014).

11 The array of public policies and social engagement was a historical and legal breakthrough in global
12 protection. However, the broader political and institutional context and actions to reduce the
13 representation and independent control of civil society movements in decision-making bodies weaken
14 this structure with significant increases in deforestation rates, burnings, and forest fires.

15 **[END BOX 7.9 HERE]**

16

17 **[START BOX 7.10 HERE]**

18

Box 7.10 Regreening the Sahel, Northern Africa

19 **Case description**

20 More than 200 million trees have regenerated on more than 5 Mha in the Sahel (Sendzimir et al. 2011).
21 The Maradi/Zinder region of Niger is the epicentre of experimentation and scale up. This vast
22 geographic extent generates significant mitigation potential despite the relatively modest per unit area
23 increase in carbon of about 0.4 Mg C ha⁻¹ a⁻¹ (Luedeling and Neufeldt 2012). In addition to the carbon
24 benefits, these agroforestry systems decrease erosion, provide animal fodder, recharge groundwater,
25 generate nutrition and income benefits and act as safety nets for vulnerable rural households during
26 climate and other shocks (Bayala et al. 2014, 2015; Binam et al. 2015; Sinare and Gordon 2015; Ilstedt
27 et al. 2016).

28 **Lessons**

29 A mélange of factors contributed to regreening in the Sahel. Increased precipitation, migration,
30 community development, economic volatility and local policy reform have all likely played a role
31 (Haglund et al. 2011; Sendzimir et al. 2011; Brandt et al. 2019a; Garrity and Bayala 2019); the easing
32 of forestry regulations has been particularly critical in giving farmers greater control over the
33 management and use of trees on their land (Garrity et al. 2010). This policy shift was catalysed by
34 greater regional autonomy resulting from economic decline and coincided with successful pilots and
35 NGO-led experimentation, cash-for-work, and training efforts to support changes in land management
36 (Sendzimir et al. 2011). Participation of farmers in planning and implementation helped align actions
37 with local knowledge and goals as well as market opportunities.

38 Regreening takes place when dormant seed or tree stumps sprout and are cultivated through the
39 technique, called Farmer Managed Natural Regeneration (FMNR). Without planting new trees, FMNR
40 is presumed to be cheaper than other approaches to restoration, though comparative economic analysis
41 has yet to be conducted (Chomba et al. 2020). Relatively lower investment costs are believed to have
42 contributed to the replication across the landscape. These factors worked together to contribute to a
43 groundswell of action that affected rights, access, and use of local resources (Tougiani et al. 2009).

1 Regreening in the Sahel and the consequent transformation of the landscape has resulted from the
2 actions of hundreds of thousands of individuals responding to social and biophysical signals (Hanan
3 2018). This is an example for climate change mitigation, where eliminating regulations – versus
4 increasing them - has led to carbon dioxide removal.

5 **[END BOX 7.10 HERE]**

6

7 **7.6.2.4. Mitigation Effectiveness: Additionality, Permanence and Leakage**

8 Additionality, permanence and leakage have been widely discussed in the forestry and agricultural
9 mitigation literature (Murray et al. 2007), including in AR5 (Section 11.3.2 of the WGIII report) and
10 earlier assessment reports. Since the earlier assessment reports, new studies have emerged to provide
11 new insights on the effect of these issues on the credibility of forest and agricultural mitigation. This
12 assessment also provides additional context not considered in earlier assessments.

13 Typically, carbon registries will require that project developers show additionality by illustrating that
14 the project is not undertaken as a result of a legal requirement, and that the project achieves carbon
15 reductions above and beyond a business as usual. The protocols developed by the California Air
16 Resources Board to ensure permanence and additionality are strong standards and may even limit
17 participation (e.g. Ruseva et al. 2017). The business as usual is defined as past management actions by
18 the same entity that can be verified. Additionality can thus be observed in the future as a difference
19 from historical actions. This approach has been used by several countries in their UNFCCC Biennial
20 Update Reports to establish reductions in carbon emissions from avoided deforestation (e.g., Brazil and
21 Indonesia).

22 However, alternative statistical approaches have been deployed in the literature to assess additionality
23 with a quasi-experimental method that rely on developing a counterfactual (e.g. Andam et al. 2008;
24 Blackman 2015; Fortmann et al. 2017; Roopsind et al. 2019; Sills et al. 2015). In several studies,
25 additionality in avoided deforestation was established after the project had been developed by
26 comparing land-use change in treated plots where the policy or program was in effect with land use
27 change in similar untreated plot. Alternatively, synthetic matching statistically compares trends in a
28 treated region (i.e., a region with a policy) to trends in a region without the policy, and has been applied
29 in a region in Brazil (e.g., Sills et al. 2015), and at the country level in Guyana (Roopsind et al. 2019).
30 While these analyses establish that many projects to reduce deforestation have overcome hurdles related
31 to additionality (*high confidence*), there has not been a systematic assessment of the elements of project
32 or program design that lead to high levels of additionality. Such assessment could help developers
33 design projects to better meet additionality criteria.

34 The same experimental methods have been applied to analyse additionality of the adoption of soil
35 conservation and nutrient management practices in agriculture. Claassen et al. (2018) find that programs
36 to promote soil conservation are around 50% additional across the USA (i.e. 50% of the land enrolled
37 in soil conservation programs would not have been enrolled if not for the programme), while Woodward
38 et al. (2016) find that adoption of conservation tillage is rarely additional. Claassen et al. (2018) find
39 that payments for nutrient management plans are nearly 100% additional, although there is little
40 evidence that farmers reduce nutrient inputs when they adopt plans. It is not clear if the same policy
41 approaches would lead to additionality in other regions.

42 Permanence focuses on the potential for carbon sequestered in offsets to be released in the future due
43 to natural or anthropogenic disturbances. Most offset registries have strong permanence requirements,
44 although they vary in their specific requirements. VCS/Verra requires a pool of additional carbon credits
45 that provides a buffer against inadvertent losses. The Climate Action Reserve (CAR) protocol for forests

1 requires carbon to remain on the site for 100 years. The carbon on the site will be verified at pre-
2 determined intervals over the life of the project. If carbon is diminished on a given site, the credits for
3 the site have to be relinquished and the project developer has to use credits from their reserve fund
4 (either other projects or purchased credits) to make up for the loss. Estimates of leakage in forestry
5 projects in the AR5 suggest that it can range from 10% to over 90% in the USA (Murray et al. 2004),
6 and 20-50% in the tropics (Sohngen and Brown 2004) for forest set-asides and reduced harvesting.
7 Carbon offset protocols have made a variety of assumptions. The Climate Action Reserve (CAR)
8 assumes it is 20% in the USA. One of the voluntary protocols (Verra) uses specific information about
9 the location of the project to calculate a location specific leakage factor.

10 More recent literature has developed explicit estimates of leakage based on statistical analysis of carbon
11 projects or programs. The literature suggests that there are two economic pathways for leakage (e.g.
12 (Roopsind et al. 2019), either through a shift in output price that occurs when outputs are affected by
13 the policy or program implementation, as described in (Gan and McCarl 2007; Wear and Murray 2004;
14 Murray et al. 2004; Sohngen and Brown 2004), or through a shift in input prices and markets, such as
15 for labour or capital, as analysed in (Alix-Garcia et al. 2012; Andam et al. 2008; Fortmann et al. 2017;
16 Honey-Rosés et al. 2011). Estimates of leakage through product markets (e.g. timber prices) have
17 suggested leakage of up to 90% (Sohngen and Brown 2004; Murray et al. 2004; Gan and McCarl 2007;
18 I. Kallio and Solberg 2018), while studies that consider shifts in input markets are considerably smaller.
19 The analysis of leakage for the Guyana program by Roopsind et al. (2019) revealed no statistically
20 significant leakage in Suriname. A key design feature for any program to reduce leakage is to increase
21 incentives for complementary mitigation policies to be implemented in areas where leakage may occur.
22 Efforts to continue to draw more forests into carbon policy initiatives will reduce leakage over time
23 Roopsind et al. (2019), suggesting that if NDCs continue to encompass a broader selection of policies,
24 measures and forests over time, leakage will decline.

25 **7.6.3. Assessment of current policies and potential future approaches**

26 The Paris Agreement encourages a wide range of policy approaches, including REDD+, sustainable
27 management of forests, joint mitigation and adaptation, and emphasises the importance of non-carbon
28 benefits and equity for sustainable development (Martius et al. 2016). Around USD 0.7 billion yr⁻¹ has
29 been invested in land-based carbon offsets (Table 7.4), but as noted in Streck (2012), there is a large
30 funding gap between these efforts and the scale of efforts necessary to meet 1.5 or 2.0°C targets outlined
31 in SR1.5. As Box 7.12 discusses, forestry actions could achieve up to 5.8 GtCO₂ yr⁻¹ with costs rising
32 from USD178 billion yr⁻¹ to USD400 billion yr⁻¹ by 2050. Over half of this investment is expected to
33 occur in Latin America, with 13% in SE Asia and 17% in Sub-Saharan Africa (Austin et al. 2020).
34 Other studies have suggested that similar sized programs are possible, although they do not quantify
35 total costs (e.g. Griscom et al. 2017; Busch et al. 2019). The currently quantified efforts to reduce net
36 emissions with forests and agricultural actions are helpful, but society will need to quickly ramp up
37 investments to achieve carbon sequestration levels consistent with high levels of mitigation. Only 2.5%
38 of climate mitigation funding goes to land-based mitigation options, an order of magnitude below the
39 potential proportional contribution (Buchner et al. 2015).

40 To date, there has been significantly less investment in agricultural projects than forestry projects to
41 reduce net carbon emissions (Table 7.4). For example, the economic potential (available up to USD100
42 tCO₂⁻¹) for soil carbon sequestration in croplands is 1.9 (0.4–6.8) GtCO₂ yr⁻¹ (Section 7.4.3.1), however,
43 less than 2% of the carbon in Table 7.4 is derived from soil carbon sequestration projects. While
44 reductions in CH₄ emissions due to enteric fermentation constitute a large share of potential agricultural
45 mitigation reported in Section 7.4, agricultural CH₄ emission reductions so far have been relatively
46 modest compared to forestry sequestration. The protocols to quantify emission reductions in the

1 agricultural sector are available and have been tested, and the main limitation appears to be the lack of
2 available financing or the unwillingness to re-direct current subsidies (*medium confidence*).

3 Although quantified emission reductions in agricultural projects are limited to date, a number of OECD
4 and economy in transition parties have reduced their net emissions through carbon storage in cropland
5 soils since 2000. These reductions in emissions have typically resulted from policy innovations outside
6 of the climate space, or market trends. For example, in the USA, there has been widespread adoption of
7 conservation tillage in the last 30 years as a labour-saving crop management technique. In Europe,
8 agricultural N₂O and CH₄ emissions have declined due to reductions in nutrient inputs and cattle
9 numbers (Henderson et al. 2020). These reductions may be attributed to mechanism within the Common
10 Agricultural Policy (Section 7.6.2.1), but could also be linked to higher nutrient prices in the 2000-2014
11 period. Other environmental policies could play a role, for example, efforts to reduce water pollution
12 from phosphorus in The Netherlands, may ultimately reduce cattle numbers, also lowering CH₄
13 emissions.

14 Numerous developing countries have established policy efforts to abate agricultural emissions or
15 increase carbon storage. Brazil, for instance, developed a subsidy program in 2010 to promote
16 sustainable development in agriculture, and practices that would reduce GHG emissions. Henderson et
17 al. (2020) report that this program reduced GHG emission in agricultural by up to 170 MtCO₂ between
18 2010 and 2018. However, the investments in low-carbon agriculture in Brazil amounted only 2% of the
19 total funds for conventional agriculture in 2019. Programs on deforestation in Brazil had successes and
20 failures, as described in Box 7.9. Indonesia has engaged in a wide range of programs in the REDD+
21 space, including a moratorium implemented in 2011 to prevent the conversion of primary forests and
22 peatlands to oil palm and logging concessions (Henderson et al. 2020) (Tacconi and Muttaqin 2019;
23 Wijaya et al. 2017). Efforts to restore peatlands and forests have also been undertaken. Indonesia reports
24 that results based REDD+ programs have been successful and have led to lower rates of deforestation
25 (Table 7.4).

26 Existing policies focused on GHG management in agriculture and forestry is less advanced in Africa
27 than in Latin American and Asia, however, Henderson et al. (2020) report on 10 countries in Sub
28 Saharan Africa that have included explicit policy proposals for reducing AFOLU GHG emissions
29 through their NDCs. These include efforts to reduce N₂O emission, increase implementation of
30 conservation agriculture, improve livestock management, and implement forestry and grassland
31 practices, including agroforestry (Box 7.10). Within several of the NDCs, countries have explicitly
32 suggested intensification as an approach to reduce emission in the livestock sector. However, it is
33 important to note caveats associated with pursuing mitigation via intensification (Box 7.11)

34 The agricultural sector throughout the world is influenced by many policies that affect production
35 practices, crop choices and land use. It is difficult to quantify the effect of these policies on reference
36 level GHG emissions from the sector, as well as the cost estimates presented in Sections 7.4 and 7.5.
37 The presence of significant subsidy programs intended to improve farmer welfare and rural livelihoods
38 makes it more difficult to implement regulatory programs aimed at reducing net emissions in
39 agriculture, however, it may increase the potential to implement new subsidy programs that encourage
40 practices aimed at reducing net emissions (*medium confidence*). For instance, in the USA, crop
41 insurance can influence both crop choices and land use (Claassen et al. 2017; Miao et al. 2016), both of
42 which will affect emission trends. Regulations to limit nutrient applications have not been widely
43 considered, however, federal subsidy programs have been implemented to encourage farmers to conduct
44 nutrient management planning.

45
46 **[START BOX 7.11 HERE]**

Box 7.11 Sustainable intensification within agriculture: evidence and caveats**Introduction**

Sustainable intensification (SI) has received considerable attention as a suggested means of pursuing increased overall production, reducing associated environmental externalities, and potentially releasing agricultural land for alternative uses, such as forestry or rewilding (Godfray and Garnett 2014; Pretty 2018). The concept was explored within the SRCCL (SRCCL Section 5.6.4.4 and Cross-Chapter Box 6 in Chapter 5; (Mbow et al. 2019)). SI is context specific and dynamic, with no universally prescribed methodology (HLPE 2019). Equal importance is given to enhancing sustainability as to achieving agricultural intensification. The former aspect is often challenging to realise, measure and maintain.

The extent of sustainable intensification

Total global agricultural land area has remained relatively stable while overall production has increased in recent decades (Section 7.3), indicating that agricultural intensification, as judged by production per unit of land (OECD/FAO 2019; Petersen and Snapp 2015) has taken place. Changes in agricultural land use and degradation of natural resources (UN Environment 2019; IPBES 2019) suggests however that not all of this intensification is sustainable. Although agricultural intensification has led to less GHG emissions compared to a scenario where that intensification had not taken place (Burney et al. 2010), absolute agriculture related emissions have continued to increase (Section 7.2). Active pursuit of SI was found to be expanding, with implementation on an increasing area, notably in developing countries (Pretty et al. 2018), yet regional agricultural area expansion at the expense of native habitat also continues in such regions (Section 7.3). Although there are specific examples of SI (Box 7.13) global progress in achieving SI is acknowledged as slow (Cassman and Grassini 2020) with potentially multiple, context specific geophysical and socio-economic barriers to implementation (Silva et al. 2021a; Firbank et al. 2018).

Preconditions to ensure sustainable intensification

Increasing the total amount of product produced by improving production efficiency (output per unit of input) does not guarantee SI. It will only be successful if increased production efficiency translates into reduced environmental and social impacts as well as increased production. For example, AR5 highlighted a growing emphasis on reducing GHG emissions per unit of product via increasing production efficiency (Smith et al. 2014), but reductions in absolute GHG emissions will only occur when production efficiency increases at a greater rate than the rate at which production increases (Clark et al. 2005).

Defined indicators are required. Measurement of SI requires multiple indicators and metrics. It can be assessed at farm, regional or global scales and temporal aspect must be considered. SI may warrant whole system redesign or land reallocation (Garnett et al. 2013; Pretty et al. 2018). Accordingly, there is *high agreement* concerning the need to consider multiple environmental and social outcomes at wider spatial scales, such as catchments or regions (Weltin et al. 2018; Bengochea Paz et al. 2020; Cassman and Grassini 2020). Impacts may be considered in relative terms (per area or product unit), with relationships potentially antagonistic. Both area- and product unit-based metrics are valid, relevant under different contexts and useful in approaching SI, but do not capture overall impacts and trade-offs (Garnett 2014). To reduce the risk of unsustainable intensification, quantitative data and selection of appropriate metrics to identify and guide strategies are paramount (Garnett et al. 2013; Gunton et al. 2016; Cassman and Grassini 2020).

Avoiding unsustainable intensification

1 It is critical that intensification does not drive expansion of unsustainable practices. Increased
2 productivity with associated economic reward could incentivise and reward agricultural land expansion,
3 or environmentally and socially damaging practices on existing and former agricultural land (Phalan
4 2018; Ceddia et al. 2013). Accordingly, coordinated policies are crucial to ensuring desired outcomes
5 (Reddy et al. 2020; Kassam and Kassam 2020; Godfray and Garnett 2014;). Barretto et al. (2013) found
6 that in agriculturally consolidated areas, land-use intensification coincided with either a contraction of
7 both cropland and pasture areas, or cropland expansion at the expense of pastures, both resulting in a
8 stable farmed area. In contrast, in agricultural frontier areas, land-use intensification coincided with
9 expansion of agricultural lands.

10 In conclusion, SI within agriculture is needed given the rising global population and the need to address
11 multiple environmental and social externalities associated with agricultural activities. However,
12 implementation requires strong stakeholder engagement, appropriate regulations, rigorous monitoring
13 and verification and comprehensive outreach and knowledge exchange programmes.

14 **[END BOX 7.11 HERE]**

15

16 A factor that will influence future carbon storage in so-called land-based reservoirs involves considering
17 short- and long-term climate benefits, as well as interactions among various natural climate solution
18 options. The benefits of various natural climate solutions depend on a variety of spatially dependent
19 issues as well as institutional factors, including their management status (managed or unmanaged
20 systems), their productivity, opportunity costs, technical difficulty of implementation, local willingness
21 to consider, property rights and institutions, among other factors. Biomass energy, as described
22 elsewhere in this chapter and in (Cross-Working Group Box 3 in Chapter 12), is a potential example of
23 an option with trade-offs that emerge when policies favour one type of mitigation strategy over another.
24 Bioenergy production needs safeguards to limit negative impacts on carbon stocks on the land base as
25 is already in place in the EU Renewable Energy Directive and several national schemes in Netherlands,
26 UK and Denmark. (DeCicco and Schlesinger 2018; Favero et al. 2020; Buchholz et al. 2016; Khanna
27 et al. 2017). It is argued that a carbon tax on only fossil fuel derived emissions, may lead to massive
28 deployment of bioenergy, although the effects of such a policy can be mitigated when combined with
29 policies that encourage sustainable forest management and protection of forest carbon stocks as well as
30 forest management certification (Favero et al. 2020 and Nabuurs et al. 2017, Baker et al, 2019) (*high*
31 *confidence*).

32 If biomass energy production expands and shifts to carbon capture and storage (e.g. BECCS) during the
33 century, there could be a significant increase in the area of crop and forestland used for biomass energy
34 production (Sections 7.4 and 7.5). BECCS is not projected to be widely implemented for several
35 decades, but in the meantime, policy efforts to advance land based measures including reforestation and
36 restoration activities (Strassburg et al. 2020) combined with sustainable management and provision of
37 agricultural and wood products are widely expected to increase the terrestrial pool of carbon (Cross-
38 Working Group Box 3 in Chapter 12). Carbon sequestration policies, sustainable land management
39 (forest and agriculture), and biomass energy policies can be complementary (Favero et al. 2017; Baker
40 et al. 2019). However, if private markets emerge for biomass and BECCS on the scale suggested in the
41 SR1.5, policy efforts must ramp up to substantially value, encourage, and protect terrestrial carbon
42 stocks and ecosystems to avoid outcomes inconsistent with many SDGs (*high confidence*).

43 **7.6.4. Barriers and opportunities for AFOLU mitigation**

44 The AR5 and other assessments have acknowledged many barriers and opportunities to effective
45 implementation of AFOLU measures. Many of these barriers and opportunities focus on the context in

1 developing countries, where a significant portion of the world's cost-effective mitigation exists, but
2 where domestic financing for implementation is likely to be limited. The SSPs capture some of this
3 context, and as a result, IAMs (Section 7.5) exhibit a wide range of land-use outcomes, as well as
4 mitigation potential. Potential mitigation, however, will be influenced by barriers and opportunities that
5 are not considered by IAMs or by bottom-up studies reviewed here. For example, more efficient food
6 production systems, or sustainable intensification within agriculture, and globalised trade could enhance
7 the extent of natural ecosystems leading to lower GHG emissions from the land system and lower food
8 prices (Popp et al. 2017), but this (or any) pathway will create new barriers to implementation and
9 encourage new opportunities, negating potential benefits (Box 7.11). It is critically important to
10 consider the current context in any country.

11 **7.6.4.1. Socio-economic barriers and opportunities**

12 **Design and coverage of financing mechanisms.** The lack of resources thus far committed to
13 implementing AFOLU mitigation, income and access to alternative sources of income in rural
14 households that rely on agriculture or forests for their livelihoods remains a considerable barrier to
15 adoption of AFOLU (*high confidence*). Section 7.6.1 illustrates that to date only USD0.7 billion yr⁻¹
16 has been spent on AFOLU mitigation, well short of the more than USD400 billion yr⁻¹ that would be
17 needed to achieve the economic potential described in Section 7.4. Despite long-term recognition that
18 AFOLU can play an important role in mitigation, the *economic incentives* necessary to achieve AFOLU
19 aspirations as part of the Paris Agreement or to maintain temperatures below 2.0 °C have not emerged.
20 Without quickly ramping up spending, the lack of funding to implement projects remains a substantial
21 barrier (*high confidence*). Investments are critically important in the livestock sector, which has the
22 highest emissions reduction potential among options because actions in the sector influence agriculture
23 specific activities, such as enteric fermentation, as well as deforestation (Mayberry et al. 2019). In many
24 countries with export-oriented livestock industries, livestock farmers control large swaths of forests or
25 re-forestable areas. Incentive mechanisms and funding can encourage adoption of mitigation strategies,
26 but funding is currently too low to make consistent progress.

27 **Scale and accessibility of financing.** The largest share of funding to date has been for REDD+, and
28 many of the commitments to date suggest that there will be significant funding in this area for the
29 foreseeable future. Funding for conservation programs in OECD countries and China affects carbon,
30 but has been driven by other objectives such as water quality and species protection. Considerably less
31 funding has been available for agricultural projects aimed at reducing carbon emissions, and outside of
32 voluntary markets, there do not appear to be large sources of funding emerging either through
33 international organisations, or national programs. In the agricultural sector, funding for carbon must be
34 obtained by redirecting existing resources from non-GHG conservation to GHG measures, or by
35 developing new funding streams (Henderson et al. 2020).

36 **Risk and uncertainty.** Most approaches to reduce emissions, especially in agriculture, require new or
37 different technologies that involve significant time or financial investments by the implementing
38 landholders. Adoption rates are often slow due to risk aversion among agricultural operators. Many
39 AFOLU measures require carbon to be compensated to generate positive returns, reducing the
40 likelihood of implementation without clear financial incentives. Research to show costs and benefits is
41 lacking in most parts of the world.

42

43 **[START BOX 7.12 HERE]**

44 **Box 7.12 Financing AFOLU mitigation; what are the costs and who pays?**

1 Achieving the large contribution to mitigation that the AFOLU sector can make requires public and
2 private investment. Austin et al. (2020) estimate that in forestry, USD178 billion yr⁻¹ is needed over the
3 next decade to achieve 5 GtCO₂ yr⁻¹, and investments need to ramp up to USD400 billion yr⁻¹ by 2050
4 to expand effort to 6 GtCO₂ yr⁻¹. Other land-based options, such as mangrove protection, peatland
5 restoration, and agricultural options would increase this total cost estimate, but have smaller to
6 negligible opportunity costs.

7 Financing needs in AFOLU, and in particular in forestry, include both the direct effects of any changes
8 in activities – costs of planting or managing trees, net revenues from harvesting, costs of thinning, costs
9 of fire management, etc. – as well as the opportunity costs associated with land use change. Opportunity
10 costs are a critical component of AFOLU finance, and must be included in any estimate of the funds
11 necessary to carry out projects. They are largest, as share of total costs, in forestry because they play a
12 prominent role in achieving high levels of afforestation, avoided deforestation, and improved forest
13 management. In case of increasing soil carbon in croplands through reduced tillage, there are often cost
14 savings associated with increased residues because there is less effort tilling, but the carbon effects per
15 hectare are also modest. There could, however, be small opportunity costs in cases where residues may
16 otherwise be marketed to a biorefinery. The effect of reduced tillage on yields varies considerably across
17 sites and crop types, but tends to enhance yields modestly in the longer-run.

18 Opportunity costs are a direct financing costs for activities that require land uses to change. For instance
19 a government can encourage planting forests on agricultural land by (a) requiring it, (b) setting up a
20 market or market-based incentives, or (c) buying the land and doing it themselves. In each case, the
21 required investment is the same – the planting cost plus the net foregone returns of agricultural rents –
22 even though a different entity pays the cost. Private entities that pay for carbon credits will also bear
23 the direct costs of planting plus the opportunity costs. In the case of avoided deforestation, opportunity
24 costs similarly must be paid to individual actors to avoid the deforestation.

25 **[END BOX 7.12 HERE]**

26

27 **Poverty.** Mitigation and adaptation can have important implications for vulnerable people and
28 communities, for example, mitigation activities consistent with scenarios examined in the SR1.5 could
29 raise food and fiber prices globally (Section. 7.5). In the NDCs, 82 Parties included references to social
30 issues (e.g. poverty, inequality, human well-being, marginalisation), with poverty the most cited factor
31 (70 Parties). The number of hungry and food insecure people in the world is growing, reaching 821
32 million in 2017, or one in every nine people (FAO 2018b), and two-thirds live in rural areas (Laborde
33 Debucquet et al. 2020). Consideration of rural poverty and food insecurity is central in AFOLU
34 mitigation because there are a large number of farms in the world (about 570 million), and most are
35 smaller than 2 hectares. It is important to better understand how different mitigation policies affect the
36 poor.

37 **Cultural values and social acceptance.** Barriers to adoption of AFOLU mitigation will be strongest
38 where historical practices represent long-standing traditions (*high confidence*). Adoption of new
39 mitigation practices, however, may proceed quickly if the technologies can be shown to improve crop
40 yields, reduce costs, or otherwise improve livelihoods (Ranjan 2019). AR6 presents new estimates of
41 the mitigation potential for shifts in diets and reductions in food waste, but given long-standing dietary
42 traditions within most cultures, some of the strongest barriers exist for efforts to change diets (*medium*
43 *confidence*). Furthermore, the large number of undernourished who may benefit from increased calories
44 and meat will complicate efforts to change diets. Regulatory or tax approaches will face strong
45 resistance, while efforts to use educational approaches and voluntary measures have limited potential
46 to slow changes in consumption patterns due to free-riders, rebound effects, and other limitations. Food

1 loss and waste occurs across the supply chain, creating significant challenges to reduce it (FAO 2019c).
2 Where food loss occurs in the production stage, i.e. in fields at harvest, there may be opportunities to
3 align reductions in food waste with improved production efficiency, however, adoption of new
4 production methods often requires new investments or changes in labour practices, both of which are
5 barriers.

6 **7.6.4.2. Institutional barriers and opportunities**

7 **Transparent and accountable governance.** Good governance and accountability are crucial for
8 implementation of forest and agriculture mitigation. Effective nature-based mitigation will require
9 large-scale estimation, modelling, monitoring, reporting and verification of GHG inventories,
10 mitigation actions, as well as their implications for sustainable development goals and their interactions
11 with climate change impacts and adaptation. Efforts must be made to integrate the accounting from
12 projects to the country level. While global datasets have emerged to measure forest loss, at least
13 temporarily (e.g. Hansen et al., 2013), similar datasets do not yet exist for forest degradation and
14 agricultural carbon stocks or fluxes. Most developing countries have insufficient capacity to address
15 research needs, modelling, monitoring, reporting and data requirements (e.g. Ravindranath et al. 2017),
16 compromising transparency, accuracy, completeness, consistency and comparability.

17 Opportunity for political participation of local stakeholders is barrier in most places where forest
18 ownership rights are not sufficiently documented (Essl et al. 2018). Since incentives for self-
19 enforcement can have an important influence on deforestation rates (Fortmann et al. 2017), weak
20 governance and insecure property rights are significant barriers to introduction of forest carbon offset
21 projects in developing countries, where many of the low-cost options for such projects exist (Gren and
22 Zeleke 2016). Governance challenges exist at all levels of government, with poor coordination,
23 insufficient information sharing, and concerns over accountability playing a prominent role within
24 REDD+ projects and programs (Ravikumar et al. 2015). In some cases, governments are increasingly
25 centralising REDD+ governance and limiting the distribution of governance functions between state
26 and non-state actors (Zelli et al. 2017; Phelps et al. 2010). Overlap and duplication in FLEGT and
27 REDD+ also limits governance effectiveness (Gupta et al. 2016).

28 **Clear land tenure and land-use rights.** Unclear property rights and tenure insecurity undermine the
29 incentives to improve forest and agricultural productivity, lead to food insecurity, undermine REDD+
30 objectives, discourage adoption of farm conservation practices, discourage tree planting and forest
31 management, and exacerbate conflict between different land users (Sunderlin et al. 2018; Antwi-Agyei
32 et al. 2015; Borras and Franco 2018; Felker et al. 2017; Riggs et al. 2018; Kansanga and Luginaah
33 2019). Some positive signs exist as over 500 million hectares of forests have been converted to
34 community management with clear property rights in the past two decades (Rights and Resources
35 Initiative 2018), but adoption of forest and agricultural mitigation practices will be limited in large
36 remaining areas with unclear property rights (Gupta et al. 2016).

37 **Lack of institutional capacity.** Institutional complexity, or lack thereof, represents a major challenge
38 when implementing large and complex mitigation programs (e.g., REDD+) in agriculture, forest and
39 other land uses (Bäckstrand et al. 2017). Without sufficient capacity, many synergies between
40 agricultural and forest programs, or mitigation and adaptation opportunities, may be missed (Duguma
41 et al. 2014). Another aspect of institutional complexity is the different biophysical and socio-economic
42 circumstances as well as the public and private financial means involved in the architecture and
43 implementation of REDD+ and other initiatives (Zelli et al. 2017).

44 **7.6.4.3. Ecological barriers and opportunities**

45 **Availability of land and water.** Climate mitigation scenarios in the two recent special reports (SR1.5C
46 and SRLCC) that aim to limit global temperature increase to 2°C or less involve carbon dioxide (CO₂)

1 removal from the atmosphere. To support large-scale CDR, these scenarios involve significant land-use
2 change, due to afforestation/reforestation, avoided deforestation, and deployment of Biomass Energy
3 with Carbon Capture and Storage (BECCS). While a considerable amount of land is certainly available
4 for new forests or new bioenergy crops, that land has current uses that will affect not only the costs, but
5 also the willingness of current users or owners, to shift uses. Regions with private property rights and a
6 history of market-based transactions may be the most feasible for land use change or land management
7 change to occur. Areas with less secure tenure or a land market with fewer transactions in general will
8 likely face important hurdles that limit the feasibility of implementing novel nature-based solutions.

9 Implementation of nature-based solution may have local or regionally important consequences for other
10 ecosystem services, some of which may be negative (*high confidence*). Land use change has important
11 implications for the hydrological cycle, and the large land use shifts suggested for BECCS when not
12 carried out in a carefully planned manner, are expected to increase water demands substantially across
13 the globe (Stenzel et al. 2019; Rosa et al. 2020). Afforestation can have minor to severe consequences
14 for surface water acidification, depending on site-specific factors and exposure to air pollution and sea-
15 salts (Futter et al. 2019). The potential effects of coastal afforestation on sea-salt related acidification
16 could lead to re-acidification and damage on aquatic biota.

17 ***Specific soil conditions, water availability, GHG emission-reduction potential as well as natural***
18 ***variability and resilience.*** Recent analysis by (Cook-Patton et al. 2020) illustrates large variability in
19 potential rates of carbon accumulation for afforestation and reforestation options, both within
20 biomes/ecozones and across them. Their results suggest that while there is large potential for
21 afforestation and reforestation, the carbon uptake potential in land-based climate change mitigation
22 efforts is highly dependent on the assumptions related to climate drivers, land use and land management,
23 and soil carbon responses to land-use change. Less analysis has been conducted on bioenergy crop
24 yields, however, bioenergy crop yields are also likely to be highly variable, suggesting that bioenergy
25 supply could exceed or fall short of expectations in a given region, depending on site conditions.

26 The effects of climate change on ecosystems, including changes in crop yields, shifts in terrestrial
27 ecosystem productivity, vegetation migration, wildfires, and other disturbances also will affect the
28 potential for AFOLU mitigation. Climate is expected to reduce crop yields, increase crop and livestock
29 prices, and increase pressure on undisturbed forest land for food production creating new barriers and
30 increasing costs for implementation of many nature-based mitigation techniques (IPCC WGII AR6
31 Chapter 5) (*medium confidence*).

32 The observed increase in the terrestrial sink over the past half century can be linked to changes in the
33 global environment, such as increased atmospheric CO₂ concentrations, N deposition, or changes in
34 climate (Ballantyne et al. 2012), though not always proven from ground-based information
35 (Vandersleen et al. 2015). While the terrestrial sink relies on regrowth in secondary forests (Houghton
36 and Nassikas 2017), there is emerging evidence that the sink will slow in the northern hemisphere as
37 forests age (Nabuurs et al. 2013), although saturation may take decades (Zhu et al. 2018). Forest
38 management through replanting, variety selection, fertilisation, and other management techniques, has
39 increased the terrestrial carbon sink over the last century (Mendelsohn and Sohngen 2019). Saturation
40 of the sink in situ may not occur when e.g. substitution effects of timber usage are also
41 considered.

42 Increasing concentrations of CO₂ are expected to increase carbon stocks globally, with the strongest
43 effects in the tropics (Kim et al. 2017a; Schimel et al. 2015; AR6 WGI, Fig SPM7)) and economic
44 models suggest that future sink potential may be robust to the impacts of climate change (Tian et al.
45 2018). However, it is uncertain if this large terrestrial carbon sink will continue in the future (e.g.
46 Aragão et al. 2018), as it is increasingly recognized that gains due to CO₂ fertilization are constrained

1 by climate and increasing disturbances (Schurgers et al. 2018; Duffy et al. 2021; IPCC WGII AR6
2 Chapter 5). Further, negative synergies between local impacts like deforestation and forest fires may
3 interact with global drivers like climate change and lead to tipping points (Lovejoy and Nobre 2018;).
4 Factors that reduce permanence or slow forest growth will drive up costs of forest mitigation measures,
5 suggesting that climate change presents a formidable challenge to implementation of nature-based
6 solutions beyond 2030 (*high confidence*).

7 In addition to climate change, Dooley and Kartha (2018) also note that technological and social factors
8 could ultimately limit the feasibility of agricultural and forestry mitigation options, especially when
9 deployed at large-scale. Concern is greatest with widespread use of bioenergy crops, which could lead
10 to forest losses (Harper et al. 2018). Deployment of BECCS and forest-based mitigation can be
11 complementary (Favero et al. 2017; Baker et al. 2019), but inefficient policy approaches could lead to
12 net carbon emissions if BECCS replaces high-carbon content ecosystems with crops.

13 ***Adaptation benefits and biodiversity conservation.*** Biodiversity may improve resilience to climate
14 change impacts as more-diverse systems could be more resilient to climate change impacts, thereby
15 maintaining ecosystem function and preserving biodiversity (Hisano et al. 2018). However, losses in
16 ecosystem functions due species shifts or reductions in diversity may impair the positive effects of
17 biodiversity on ecosystems. Forest management strategies based on biodiversity and ecosystems
18 functioning interactions can augment the effectiveness of forests in reducing climate change impacts on
19 ecosystem functioning (*high confidence*). In spite of the many synergies between climate policy
20 instruments and biodiversity conservation, however, current policies often fall short of realising this
21 potential (Essl et al. 2018).

22 ***7.6.4.4. Technological barriers and opportunities***

23 ***Monitoring, reporting, and verification.*** Development of satellite technologies to assess potential
24 deforestation has grown in recent years with the release of 30 m data by Hansen et al. (2013), however,
25 this data only captures tree cover loss, and increasing accuracy over time may limit its use for trend
26 analysis (Ceccherini et al. 2020; Palahí et al. 2021). Datasets on forest losses are less well developed
27 for reforestation and afforestation. As Mitchell et al. (2017) point out, there has been significant
28 improvement in the ability to measure changes in tree and carbon density on sites using satellite data,
29 but these techniques are still evolving and improving and they are not yet available for widespread use.

30 Ground-based forest inventory measurements have been developed in many countries, most
31 prominently in the northern hemisphere, but more and more countries are starting to develop and collect
32 national forest inventories. Training and capacity building is going on in many developing countries
33 under UNREDD and FAO programmes. Additional efforts to harmonize data collection methods and
34 to make forest inventory data available to the scientific community would improve confidence in forest
35 statistics, and changes in forest statistics over time. To some extent the Global Forest Biodiversity
36 Initiative fills in this data gap (<https://gfbi.udl.cat/>).

37 **7.6.5. Linkages to ecosystem services, human well-being and adaptation (incl. SDGs)**

38 The linkage between biodiversity, ecosystem services, human well-being and sustainable development
39 is widely acknowledged (Millennium Ecosystem Assessment 2005; UN Environment 2019). Loss of
40 biodiversity and ecosystem services will have an adverse impact on quality of life, human well-being
41 and sustainable development (Díaz et al. 2019). Such losses will not only affect current economic
42 growth but also impede the capacity for future economic growth.

43 Population growth, economic development, urbanisation, technology, climate change, global trade and
44 consumption, policy and governance are key drivers of global environmental change over recent
45 decades (Kram et al. 2014; UN Environment 2019; WWF 2020). Changes in biodiversity and ecosystem

1 services are mainly driven by habitat loss, climate change, invasive species, over-exploitation of natural
2 resources, and pollution (Millennium Ecosystem Assessment 2005). The relative importance of these
3 drivers varies across biomes, regions, and countries. Climate change is expected to be a major driver of
4 biodiversity loss in the coming decades, followed by commercial forestry and bioenergy production
5 (OECD 2012; UN Environment 2019). Population growth along with rising incomes and changes in
6 consumption and dietary patterns, will exert immense pressure on land and other natural resources
7 (IPCC. 2019a). Current estimates suggest that 75% of the land surface has been significantly
8 anthropogenically altered, with 66% of the ocean area experiencing increasing cumulative impacts and
9 over 85% of wetland area lost (Díaz et al. 2019). As discussed, in section 7.3, land-use change is driven
10 amongst others by agriculture, forestry (logging and fuelwood harvesting), infrastructural development
11 and urbanisation, all of which may also generate localised air, water, and soil pollution (Díaz et al.
12 2019). Over a third of the world's land surface and nearly three-quarters of available freshwater
13 resources are devoted to crop or livestock production (Díaz et al. 2019). Despite a slight reduction in
14 global agricultural area since 2000, regional agricultural area expansion has occurred in Latin America
15 and the Caribbean, Africa and the Middle East (FAO 2019; (OECD/FAO 2019). The degradation of
16 tropical forests and biodiversity hotspots, endangers habitat for many threatened and endemic species,
17 and reduces valuable ecosystem services. However, trends vary considerably by region. As noted in
18 Section 7.3, global forest area declined by roughly 178 Mha between 1990 and 2020 (FAO 2020a),
19 though the rate of net forest loss has decreased over the period, due to reduced deforestation in some
20 countries and forest gains in others. Between 1990 to 2015, forest cover fell by almost 13% in Southeast
21 Asia, largely due to an increase in timber extraction, large-scale biofuel plantations and expansion of
22 intensive agriculture and shrimp farms, whereas in Northeast Asia and South Asia it increased by 23%
23 and 6% respectively, through policy instruments such as joint forest management, payment for
24 ecosystem services, and restoration of degraded forests (IPBES 2018b). It is lamenting that the area
25 under natural forests which are rich in biodiversity and provide diverse ecosystem services decreased
26 by 301 Mha between 1990 and 2020, decreasing in most regions except Europe and Oceania with largest
27 losses reported in Sub-Saharan Africa (FAO 2020a). The increasing trend of mining in forest and coastal
28 areas, and in river basins for extracting has had significant negative impacts on biodiversity, air and
29 water quality, water distribution, and on human health (Section 7.3). Freshwater ecosystems equally
30 face a series of combined threats including from land-use change, water extraction, exploitation,
31 pollution, climate change and invasive species (Díaz et al. 2019).

32 **7.6.5.1. Ecosystem services**

33 An evaluation of eighteen ecosystem services over the past five decades (1970-2019) found only four
34 (agricultural production, fish harvest, bioenergy production and harvest of materials) to demonstrate
35 increased performance, while the remaining fourteen, mostly concerning regulating and non-material
36 contributions, were found to be in decline (Díaz et al. 2019). The value of global agricultural output
37 (over USD3.54 trillion in 2018) had increased approximately threefold since 1970, and roundwood
38 production (industrial roundwood and fuelwood) by 27%, between 1980 to 2018, reaching some 4
39 billion m³ in 2018. However, the positive trends in these four ecosystem services does not indicate long-
40 term sustainability. If increases in agricultural production are realised through forest clearance or
41 through increasing energy-intensive inputs, gains are likely to be unsustainable in the long run.
42 Similarly, an increase in fish production may involve overfishing, leading to local species declines
43 which also impacts fish prices, fishing revenues, and the well-being of coastal and fishing communities
44 (Sumaila and Lam 2020). Climate change and other drivers are likely to affect future fish catch
45 potential, although impacts will differ across regions (Sumaila et al. 2017; IPCC 2019b).

46 The increasing trend in aquaculture production especially in South and Southeast Asia through intensive
47 methods affects existing food production and ecosystems by diverting rice fields or mangroves

1 (Bhattacharya and Ninan 2011). Although extensive traditional fish farming of carp in central Europe
2 can contribute to landscape management, enhance biodiversity and provide ecosystem services, there
3 are several barriers to scale up production due to strict EU environmental regulations, vulnerability to
4 extreme weather events, and to avian predators that are protected by EU laws, and disadvantages faced
5 by small-scale enterprises that dominate the sector (European-Commission 2021). Bioenergy
6 production may have high opportunity costs in land-scarce areas and compete with land used for food
7 production which threatens food security and affects the poor and vulnerable. But these impacts will
8 differ across scale, contexts and other factors.

9 Currently, land degradation is estimated to have reduced productivity in 23% of the global terrestrial
10 area, and between USD235 billion and USD577 billion in annual global crop output is at risk because
11 of pollinator loss (Díaz et al. 2019). The global trends reviewed above are based on data from 2,000
12 studies. It is not clear whether the assessment included a quality control check of the studies evaluated
13 and suffer from aggregation bias. For instance, a recent meta-analysis of global forest valuation studies
14 noted that many studies reviewed had shortcomings such as failing to clearly mention the methodology
15 and prices used to value the forest ecosystem services, double counting, data errors, etc, (Ninan and
16 Inoue 2013). Furthermore the criticisms against the paper by (Costanza et al. 1997), such as ignoring
17 ecological feedbacks and non-linearities that are central to the processes that link all species to each
18 other and their habitats, ignoring substitution effects may also apply to the global assessment (Smith
19 1997); Bockstael et al. 2000; Loomis et al. 2000). Land degradation has had a pronounced impact on
20 ecosystem functions worldwide (Scholes et al. 2018). Net primary productivity of ecosystem biomass
21 and of agriculture is presently lower than it would have been under a natural state on 23% of the global
22 terrestrial area, amounting to a 5% reduction in total global net primary productivity (Scholes et al.
23 2018). Over the past two centuries, soil organic carbon, an indicator of soil health, has seen an estimated
24 8% loss globally (176 GtC) from land conversion and unsustainable land management practices
25 (Scholes et al. 2018). Projections to 2050 predict further losses of 36 GtC from soils, particularly in
26 Sub-Saharan Africa. These losses are projected to come from the expansion of agricultural land into
27 natural areas (16 GtC), degradation due to inappropriate land management (11 GtC) and the draining
28 and burning of peatlands (9 GtC) and melting of permafrost (Scholes et al. 2018). Trends in biodiversity
29 measured by the global living planet index between 1970 to 2016 indicate a 68% decline in monitored
30 population of mammals, birds, amphibians, reptiles, and fish WWF 2020). FAO's recent report on the
31 state of the world's biodiversity for food and agriculture points to an alarming decline in biodiversity
32 for food and agriculture including associated biodiversity such as pollination services, micro-organisms
33 which are essential for production systems (FAO 2019d). These suggest that overall ecosystem health
34 is consistently declining with adverse consequences for good quality of life, human well-being, and
35 sustainable development.

36 Although numerous studies have estimated the value of ecosystem services for different sites,
37 ecosystems, and regions, these studies mostly evaluate ecosystem services at a single point in time See
38 (Costanza et al. 1997; Nahuelhual et al. 2007; de Groot et al. 2012; Ninan and Kontoleon 2016; Xue
39 and Tisdell 2001). The few studies that have assessed the trends in the value of ecosystem services
40 provided by different ecosystems across regions and countries indicate a declining trend (Costanza et
41 al. 2014; Kubiszewski et al. 2017). Land use change is a major driver behind loss of biodiversity and
42 ecosystem services in most regions (Archer et al. 2018; Rice et al. 2018; IPBES 2018b; M. Fischer et
43 al. 2018). Projected impacts of land use change and climate change on biodiversity and ecosystem
44 services (material and regulating services) between 2015 to 2050 were assessed to have relatively less
45 negative impacts under global sustainability scenarios as compared to regional competition and
46 economic optimism scenarios (Díaz et al. 2019). The projected impacts were based on a subset of
47 Shared Socioeconomic Pathway (SSP) scenarios and GHG emissions trajectories (RCP) developed in

1 support of IPCC assessments. There are synergies, trade-offs and co-benefits between ecosystem
2 services and mitigation options with impacts on ecosystem services differing by scale and contexts
3 (*high confidence*). Measures such as conservation agriculture, agroforestry, soil and water conservation,
4 afforestation, adoption of silvopastoral systems, can help minimise trade-offs between mitigations
5 options and ecosystem services (Duguma et al. 2014). Climate smart agriculture (CSA) is being
6 promoted to enable farmers to make agriculture more sustainable and adapt to climate change (Box
7 7.4). However, experience with CSA in Africa has not been encouraging. For instance, a study of
8 climate smart cocoa production in Ghana shows that due to lack of tenure (tree) rights, bureaucratic and
9 legal hurdles in registering trees in cocoa farms, and other barriers small cocoa producers could not
10 realise the project benefits (Box 7.13). Experience of CSA in some other Sub-Saharan African countries
11 and other countries such as Belize too has been constrained by weak extension systems and policy
12 implementation, and other barriers (Arakelyan et al. 2017; Kongsager 2017).

13

14 **START BOX 7.13 HERE**

15

Box 7.13 Case study: climate smart cocoa production in Ghana

16 **Policy Objectives**

- 17 **1.** To promote sustainable intensification of cocoa production and enhance the adaptive capacity of
18 small cocoa producers.
- 19 **2.** To reduce cocoa-induced deforestation and GHG emissions.
- 20 **3.** To improve productivity, incomes, and livelihoods of smallholder cocoa producers.

21 **Policy Mix**

22 The climate smart cocoa (CSC) production programme in Ghana involved distributing shade tree
23 seedlings that can protect cocoa plants from heat and water stress, enhance soil organic matter and water
24 holding capacity of soils, and provide other assistance with agroforestry, giving access to extension
25 services such as agronomic information and agro-chemical inputs. The shade tree seedlings were
26 distributed by NGOs, government extension agencies, and the private sector free of charge or at
27 subsidised prices and was expected to reduce pressure on forests for growing cocoa plants. The CSC
28 programme was mainly targeted at small farmers who constitute about 80% of total farm holdings in
29 Ghana. Although the government extension agency (Cocobod) undertook mass spraying or pruning of
30 cocoa farms they found it difficult to access the 800,000 cocoa smallholders spread across the tropical
31 south of the country. The project brought all stakeholders together i.e., the government, private sector,
32 local farmers and civil society or NGOs to facilitate the sustainable intensification of cocoa production
33 in Ghana. Creation of a community-based governance structure was expected to promote benefit
34 sharing, forest conservation, adaptation to climate change, and enhanced livelihood opportunities.

35 **Governance Context**

36 *Critical enablers*

37 The role assigned to local government mechanisms such as Ghana's Community Resource Management
38 Area Mechanisms (CREMAs) was expected to give a voice to smallholders who are an important
39 stakeholder in Ghana's cocoa sector. CREMAs are inclusive because authority and ownership of natural
40 resources are devolved to local communities who can thus have a voice in influencing CSC policy
41 thereby ensuring equity and adapting CSC to local contexts. However, ensuring the long-term
42 sustainability of CREMAs will help to make them a reliable mechanism for farmers to voice their

1 concerns and aspirations, and ensure their independence as a legitimate governance structure in the long
2 run. The private sector was assigned an important role to popularise climate smart cocoa production in
3 Ghana. However, whether this will work to the advantage of smallholder cocoa producers needs to be
4 seen.

5 *Critical barriers*

6 The policy intervention overlooks the institutional constraints characteristic of the cocoa sector in
7 Ghana where small farmers are dominant and have skewed access to resources and markets. Lack of
8 secure tenure (tree rights) where the ownership of shade trees and timber vests with the state,
9 bureaucratic and legal hurdles to register trees in their cocoa farms are major constraints that impede
10 realisation of the expected benefits of the CSC programme. This is a great disincentive for small cocoa
11 producers to implement CSC initiatives and nurture the shade tree seedlings and undertake land
12 improvement measures. The state marketing board has the monopoly in buying and marketing of cocoa
13 beans including exports which impeded CREMAs or farming communities from directly selling their
14 produce to MNCs and traders. However, many MNCs have been involved in setting up of CREMA or
15 similar structures, extending premium prices and non-monetary benefits (access to credit, shade tree
16 seedlings, agro-chemicals) thus indirectly securing their cocoa supply chains. A biased ecological
17 discourse about the benefits of climate smart agriculture and sustainable intensive narrative,
18 complexities regarding the optimal shade levels for growing cocoa, and dependence on agro-chemicals
19 are issues that affect the success and sustainability of the project intervention. Dominance of private
20 sector players especially MNCs in the sector may be detrimental to the interests of smallholder cocoa
21 producers.

23 **END BOX 7.13 HERE**

25 **7.6.5.2. Human well-being and Sustainable Development Goals**

26 Conservation of biodiversity and ecosystem services is part of the larger objective of building climate
27 resilience and promoting good quality of life, human well-being and sustainable development. While
28 two of the 17 SDGs directly relate to nature (SDGs 14 and 15 covering marine and terrestrial ecosystems
29 and biodiversity), most other SDGs relating to poverty, hunger, inequality, health and well-being, clean
30 sanitation and water, energy, etc., are directly or indirectly linked to nature (Blicharska et al. 2019). A
31 survey among experts to assess how 16 ecosystem services could help in achieving the SDGs relating
32 to good environment and human well-being suggested that ecosystem services could contribute to
33 achieving about 41 targets across 12 SDGs (Wood et al. 2018). They also indicated cross-target
34 interactions and synergetic outcomes across many SDGs. Conservation of biodiversity and ecosystem
35 services is critical to sustaining the well-being and livelihoods of poor and marginalised people, and
36 indigenous communities who depend on natural resources (high confidence). Nature provides a broad
37 array of goods and services that are critical to good quality of life and human well-being. Healthy and
38 diverse ecosystems can play an important role in reducing vulnerability and building resilience to
39 disasters and extreme weather events (SCBD) Secretariat of the Convention on Biological Diversity
40 2009; The Royal Society Science Policy Centre 2014; Ninan and Inoue 2017).

41 Current negative trends in biodiversity and ecosystem services will undermine progress towards
42 achieving 80% (35 out of 44) of the assessed targets of SDGs related to poverty, hunger, health, water,
43 cities, climate, oceans and land (Díaz et al. 2019). However, Reyers and Selig (2020) note that the
44 assessment by (Díaz et al. 2019) could only assess the consequences of trends in biodiversity and

1 ecosystem services for 35 out of the 169 SDG targets due to data and knowledge gaps, and lack of
2 clarity about the relationship between biodiversity, ecosystem services and SDGs.

3 Progress in achieving the 20 Aichi Biodiversity targets which are critical for realising the SDGs has
4 been poor with most of the targets not being achieved or only partially realised (SCBD 2020). There
5 could be synergies and trade-offs between ecosystem services and human well-being. For instance, a
6 study notes that although policy interventions and incentives to enhance supply of provisioning services
7 (e.g., agricultural production) have led to higher GDP, it may have an adverse effect on the regulatory
8 services of ecosystems (Kirchner et al. 2015). However, we are aware of the inadequacies of traditional
9 GDP as an indicator of well-being. In this context the Dasgupta Biodiversity Review argues for using
10 the inclusive wealth approach to accurately measure social well-being by tracking the changes in
11 produced, human and natural capital (Dasgupta 2021). Targets for nature (biodiversity and ecosystem
12 services) should be refined so as to fit in with the metrics tracked by the SDGs (Ferrier et al. 2016; Rosa
13 et al. 2017).

14 **7.6.5.3. Land-based mitigation and adaptation**

15 Combined mitigation and adaptation approaches have been highlighted throughout Section 7.4
16 regarding specific measures. Land-based mitigation and adaptation to the risks posed by climate change
17 and extreme weather events can have several co-benefits as well as help promote development and
18 conservation goals. Land-based mitigation and adaptation will not only help reduce GHG emissions in
19 the AFOLU sector, but measures are required to closely link up with adaptation. In the central 2°C
20 scenario, improved management of land and more efficient forest practices, a reduction in deforestation
21 and an increase in afforestation, would account for 10% of the total mitigation effort over 2015–2050
22 (Keramidas et al. 2018). If managed and regulated appropriately, the Land sector could become carbon-
23 neutral as early as 2030–2035, being a key sector for emissions reductions beyond 2025 (Keramidas et
24 al. 2018). Nature-based solutions (NbS) with safeguards has immense potential for cost-effective
25 adaptation to climate change; but their impacts will vary by scale and contexts (*high confidence*).
26 Griscom et al. 2017 estimate this potential to provide 37% of cost-effective CO₂ mitigation until 2030
27 needed to meet 2°C goals with likely co-benefits for biodiversity. However, due to the time lag for
28 technology deployment and natural carbon gain this mitigation potential of NbS by 2030 or 2050 can
29 be delayed or much lower than the estimated potential (Qin et al. 2021).

30 **7.7. Knowledge gaps**

31 Closing knowledge gaps and narrowing uncertainties are crucial to advance AFOLU mitigation.
32 Knowledge gaps exist across a range of areas, from emissions accounting and mitigation measure
33 development to integration of scientific and traditional knowledge and development and sustainable
34 implementation strategies. The following are identified as priorities:

- 35 • Uncertainty in contemporary emissions and sinks within AFOLU is still high. There is on-going
36 need to develop and refine emission factors, improve activity data and facilitate knowledge
37 exchange, concerning inventories and accounting. For example, insufficient knowledge on CO₂
38 emissions relating to forest management and burning or draining of organic soils (wetlands and
39 peatlands), limits certainty on CO₂ and CH₄ fluxes.
- 40 • Improved monitoring of the land CO₂ balance is urgently needed, including impacts of land
41 degradation and restoration efforts (e.g., in tropical and boreal regions), making use of
42 combined remote sensing, artificial intelligence, ground-based and modelling tools (Grassi et
43 al. 2021). Improved estimates would provide more reliable projections of nationally determined

- 1 contributions to emissions reduction and enhancement of sinks, and reconciliation of national
2 accounting and modelling results (Nabuurs et al. 2019).
- 3 • The future impacts of climate change on land systems are highly uncertain, for example, the
4 role of permafrost thaw, tipping points, increased disturbances and enhanced CO₂ fertilization
5 (Friedlingstein et al. 2020). Further research into these mechanisms is critical to better
6 understand the permanence of mitigation measures in land sector.
 - 7 • There is need to understand the role of forest management, carbon and nitrogen fertilization
8 and associated interactions in the current forest carbon sink that has emerged in the last 50 to
9 70 years. These aspects are likely to explain much of the difference between bookkeeping
10 models and other methodologies.
 - 11 • Continued research into novel and emerging mitigation measures and associated cost efficiency
12 (e.g. CH₄ inhibitors or vaccines for ruminants) is required. In addition to developing specific
13 measures, research is also needed into best practice regarding implementation and optimal
14 agricultural land and livestock management at regional and country level. Further research into
15 the feasible mitigation potential of sustainable intensification in terms of absolute GHG
16 emissions and appropriate policy mechanisms, is required to implement and advance this
17 strategy.
 - 18 • Research into accounting systems and policy options that will enable agricultural soil and forest
19 carbon to be utilized as offsets (voluntary or regulatory) is needed to increase financing for
20 land-based CDR. Design of incentives that consider local institutions and novel frameworks for
21 cooperation between private finance and public governance can encourage investment. Equally,
22 research to adjust or remove regulations and subsidy schemes that may hamper land-based
23 mitigation efforts, is urgently required.
 - 24 • Improving mitigation potential estimates, whether derived from sectoral studies or IAMs to
25 account for biophysical climate effects, and impacts of future climate change (e.g. mitigation
26 permanence), biodiversity loss and corresponding feedbacks is needed. IAM ‘usability’ can be
27 enhanced by integrating a wider set of measures and incorporating sustainability considerations.
 - 28 • Research into the feasibility of improving and enhancing sustainable agricultural and forestry
29 value chains, provision of renewable products (building with wood) and the sustainability of
30 bioenergy is critically important. Modelled scenarios do not examine many poverty,
31 employment and development trade-offs, which are highly context specific and vary
32 enormously by region. Trade-off analysis and cost-benefit analysis can assist decision making
33 and policy.
 - 34 • In-depth understanding of mitigation-SDG interactions is critical for identifying mitigation
35 options that maximize synergies and minimize trade-offs. Mitigation measures have important
36 synergies, trade-offs and co-benefits, impacting biodiversity and resource-use, human well-
37 being, ecosystem services, adaptation capacity and many SDGs. In addition to exploring
38 localised economic implementation costs, studies are needed to understand how measures will
39 impact and interact with wider environmental and social factors across localities and contexts.

40

41 **Frequently Asked Questions (FAQs)**

42 **FAQ 7.1 Why is the Agriculture, Forestry and Other Land Uses (AFOLU) sector unique when**
43 **considering GHG mitigation?**

- 1 There are three principal reasons that make the AFOLU sector unique in terms of mitigation;
- 2 1. In contrast to other sectors, AFOLU can facilitate mitigation in several different ways.
3 Specifically, AFOLU can (a) reduce emissions as a sector in its own right, (b) remove
4 meaningful quantities of carbon from the atmosphere and relatively cheaply, and (c) provide
5 raw materials to enable mitigation within other sectors, such as energy, industry or the built
6 environment.
 - 7 2. The emissions profile of AFOLU differs from other sectors, with a greater proportion of non-
8 CO₂ gases (N₂O and CH₄). The impacts of mitigation efforts within AFOLU can vary according
9 to which gases are targeted, as a result of the differing atmospheric lifetime of the gases and
10 differing global temperature responses to the accumulation of the specific gases in the
11 atmosphere.
 - 12 3. In addition to tackling climate change, AFOLU mitigation measures have capacity, where
13 appropriately implemented, to help address some critical, wider challenges, as well as
14 contributing to climate change adaptation. AFOLU is inextricably linked with some of the most
15 serious challenges that are suggested to have ever faced humanity, such as large-scale
16 biodiversity loss, environmental degradation and the associated consequences. As AFOLU
17 concerns land management and utilises a considerable portion of the Earth's terrestrial area, the
18 sector greatly influences soil, water and air quality, biological and social diversity, the provision
19 of natural habitats, and ecosystem functioning, consequently impacting many SDGs.

20 **FAQ 7.2 What AFOLU measures have the greatest economic mitigation potential?**

21 Economic mitigation potential refers to the mitigation estimated to be possible at an annual cost of up
22 to USD100 tCO₂⁻¹ mitigated. This cost is deemed the price at which society is willing to pay for
23 mitigation and is used as a proxy to estimate the proportion of technical mitigation potential that could
24 realistically be implemented. Between 2020 and 2050, measures concerning forests and other ecosystem
25 are estimated to have an average annual mitigation potential of 7.3 (3.9 - 13.1) GtCO₂-eq yr⁻¹ at
26 USD100 tCO₂⁻¹. At the same cost, agricultural measures are estimated to have a potential of 4.1 (1.7-
27 6.7) GtCO₂-eq yr⁻¹. Emerging technologies, such as CH₄ vaccines and inhibitors, could sustainably
28 increase agricultural mitigation potential in future. The diverted production effects of changes in
29 demand (reduced food losses, diet changes and improved and enhanced wood products use), is
30 estimated to have an economic potential of 2.2 (1.1–3.6) GtCO₂-eq yr⁻¹. However, cost forms only one
31 constraint to mitigation, with realization of economic potential dependent on multiple context-specific
32 environmental and socio-cultural factors.

33 **FAQ 7.3 What are potential impacts of large-scale establishment of dedicated bioenergy 34 plantations and crops and why is it so controversial?**

35 The potential of bioenergy with carbon capture and storage (BECCS) remains a focus of debate with
36 several studies evaluating the level at which BECCS could be sustainably implemented, published since
37 AR5. BECCS involves sequestering carbon through plant growth (i.e. in trees or crops) and capturing
38 the carbon generated when this biomass is processed for power or fuel. The captured carbon then
39 requires long-term storage in for example, geological, terrestrial or ocean reservoirs, or in products.
40 While appearing to create a net removal of carbon from the atmosphere, BECCS requires land, water
41 and energy which can create adverse side-effects at scale. Controversy has arisen because some of the
42 models calculating the energy mix required to keep the temperature to 1.5°C have included BECCS at
43 very large scales as a means of both providing energy and removing carbon from the atmosphere to
44 offset emissions from industry, power, transport or heat. For example, studies have calculated that for
45 BECCS to achieve 11.5 GtCO₂-eq per year of carbon removal in 2100, as envisaged in one scenario,
46 380-700 Mha or 25-46% of all the world's arable and cropland would be needed. In such a situation,

1 competition for agricultural land seriously threatens food production and food security, while also
2 impacting biodiversity, water and soil quality, and landscape aesthetic value. More recently however,
3 the scenarios for BECCS have become much more realistic, though concerns regarding impacts on food
4 security and the environment remain, while the reliability of models is uncertain due to methodological
5 flaws. Improvements to models are required to better capture wider environmental and social impacts
6 of BECCS in order to ascertain its sustainable contribution in emissions pathways. Additionally, the
7 opportunity for other options that could negate very large-scale deployment of BECCS, such as other
8 carbon dioxide removal measures or more stringent emission reductions in other sectors, could be
9 explored within models.

Chapter 8: Urban Systems and Other Settlements

Coordinating Lead Authors: Shuaib Lwasa (Uganda), Karen C. Seto (the United States of America)

Lead Authors: Xuemei Bai (Australia), Hilda Blanco (the United States of America), Kevin Gurney (the United States of America), Şiir Kilkış (Turkey), Oswaldo Lucon (Brazil), Jin Murakami (Japan), Jiahua Pan (China), Ayyoob Sharifi (Japan/Iran), Yoshiki Yamagata (Japan)

Contributing Authors: Vanesa Castan Broto (United Kingdom/Spain), Winston Chow (Singapore), Galina Churkina (the Russian Federation,/Germany), Felix Creutzig (Germany), David Dodman (Jamaica/United Kingdom), Rafiq Hamdi (Belgium), Burak Güneralp (Turkey/ the United States of America), Bronwyn Hayward (New Zealand), Angel Hsu (the United States of America), Lucy Hutyra (the United States of America), Nadja Kabisch (Germany), Meredith Keller (the United States of America), Timon McPhearson (the United States of America), Peter Newman (Australia), David Nowak (the United States of America), Alan Organschi (the United States of America), Minal Pathak (India), Mark Pelling (United Kingdom), Clara Pregitzer (the United States of America), Anu Ramaswami (the United States of America), Mia Reback (the United States of America), Diana Reckien (Germany), Jen Shin (the United States of America), Michael Westphal (the United States of America), Lee White (Australia)

Review Editors: Carolina Dubeux (Brazil), Diana Ürge-Vorsatz (Hungary)

Chapter Scientists: Meredith Keller (the United States of America), Enock Ssekuubwa (Uganda)

Date of Draft: 27/11/2021

2 **Table of Contents**

3	Chapter 8: Urban Systems and Other Settlements	8-1
4	Executive summary	8-4
5	8.1 Introduction	8-8
6	8.1.1 What is new since AR5	8-8
7	8.1.2 Preparing for the Special Report on Cities and Climate Change in AR7	8-10
8	8.1.3 The scope of the chapter: a focus on urban systems	8-10
9	8.1.4 The urban century	8-11
10	8.1.5 Urbanization in developing countries	8-15
11	8.1.6 Urban carbon footprint	8-15
12	8.2 Co-Benefits and trade-offs of urban mitigation strategies	8-18
13	8.2.1 Sustainable development	8-18
14	8.2.2 Economic development, competitiveness, and equity	8-23
15	8.2.3 Coupling mitigation and adaptation	8-24
16	Cross-Working Group Box 2: Cities and Climate Change	8-25
17	8.3 Urban systems and GHG emissions	8-30
18	8.3.1 Trends in urban land use and the built environment	8-30
19	8.3.2 Informal urban settlements	8-35
20	8.3.3 Trends in urban GHG emissions	8-36

1 Executive summary

2 **Although urbanization is a global trend often associated with increased incomes and higher**
3 **consumption, the growing concentration of people and activities is an opportunity to increase**
4 **resource efficiency and decarbonize at scale** (*very high confidence*). The same urbanization level can
5 have large variations in per capita urban carbon emissions. For most regions, per capita urban emissions
6 are lower than per capita national emissions. {8.1.4, 8.3.3, 8.4, Box 8.1}

7
8 **Most future urban population growth will occur in developing countries, where per capita**
9 **emissions are currently low but expected to increase with the construction and use of new**
10 **infrastructure and the built environment, and changes in incomes and lifestyles** (*very high*
11 *confidence*). The drivers of urban Greenhouse Gas (GHG) emissions are complex and include an
12 interplay of population size, income, state of urbanization, and how cities are laid out. How new cities
13 and towns are designed, constructed, managed, and powered will lock-in behaviour, lifestyles, and
14 future urban GHG emissions. Low-emission urbanization can improve well-being while minimizing
15 impact on GHG emissions, but there is risk that urbanization can lead to increased global GHG
16 emissions through increased emissions outside the city's boundaries. {8.1.4, 8.3, Box 8.1, 8.4, 8.6}

17
18 **The urban share of global GHG emissions (including CO₂ and CH₄) is substantive and continues**
19 **to increase** (*high confidence*). Total urban emissions based on consumption-based accounting were
20 estimated to be 24.5 GtCO₂-eq, or 62% of the global total in 2015, excluding aviation, shipping and
21 biogenics, and increased to an estimated 28.5 ± 0.1 GtCO₂-eq in 2020, representing about 67-72% of
22 global emissions. About 100 of the highest emitting urban areas account for approximately 18% of the
23 global carbon footprint. {8.1.6, 8.3.3}

24
25 **The urban share of regional GHG emissions increased between 2000 and 2015, with much inter-**
26 **region variation in the magnitude of the increase** (*high confidence*). Globally, the urban share of
27 national emissions increased 6 percentage points, from 56% in 2000 to 62% in 2015. For 2000 to 2015,
28 the urban emissions share across WGIII AR6 regions increased from 28% to 38% in Africa, from 46%
29 to 54% in Asia and Developing Pacific, from 62% to 72% in Developed Countries, from 57% to 62%
30 in Eastern Europe and West-Central Asia, from 55% to 66% in Latin America and Caribbean, and from
31 68% to 69% in the Middle East. {8.1.6, 8.3.3}

32
33 **Per capita urban GHG emissions increased between 2000 and 2015, with cities in the Developed**
34 **Countries region producing nearly seven times more per capita than the lowest emitting region**
35 (*medium confidence*). From 2000 to 2015, the global urban GHG emissions per capita increased from
36 5.5 to 6.2 tCO₂-eq/person (an increase of 11.8%); Africa increased from 1.3 to 1.5 tCO₂-eq per person
37 (22.6%); Asia and Developing Pacific increased from 3.0 to 5.1 tCO₂-eq per person (71.7%); Eastern
38 Europe and West-Central Asia increased from 6.9 to 9.8 tCO₂-eq/person (40.9%); Latin America and
39 the Caribbean increased from 2.7 to 3.7 tCO₂-eq/person (40.4%); and Middle East increased from 7.4
40 to 9.6 tCO₂-eq/person (30.1%). Albeit starting from the highest level, Developed Countries had a
41 decline of 11.4 to 10.7 tCO₂-eq/person (-6.5%). {8.3.3}

42
43 **The global share of future urban GHG emissions is expected to increase through 2050 with**
44 **moderate to no mitigation efforts due to growth trends in population, urban land expansion and**
45 **infrastructure and service demands, but the extent of the increase depends on the scenario and**
46 **the scale and timing of urban mitigation action** (*medium confidence*). With aggressive and immediate
47 mitigation policies to limit global warming below 1.5°C by the end of the century, including high levels
48 of electrification, energy and material efficiency, renewable energy preferences, and socio-behavioural
49 responses, urban GHG emissions could approach net zero and reach a maximum of 3 GtCO₂-eq in 2050.

1 Under a scenario with aggressive but not immediate urban mitigation policies to limit global warming
2 to 2°C, urban emissions could reach 17 GtCO₂-eq in 2050. With no urban mitigation efforts, urban
3 emissions could more than double from 2020 levels and reach 65 GtCO₂-eq in 2050, while being limited
4 to 34 GtCO₂-eq in 2050 with only moderate mitigation efforts. {8.3.4}

5
6 **Urban land areas could triple between 2015 and 2050, with significant implications for future**
7 **carbon lock-in.** There is a large range in the forecasts of urban land expansion across scenarios and
8 models, which highlights an opportunity to shape future urban development towards low- or net zero
9 GHG emissions and minimize the loss of carbon stocks and sequestration in the AFOLU sector due to
10 urban land conversion (*medium confidence*). By 2050, urban areas could increase up to 211% over the
11 2015 global urban extent, with the median projected increase ranging from 43% to 106%. While the
12 largest absolute amount of new urban land is forecasted to occur in Asia and Developing Pacific, and
13 in Developed Countries, the highest rate of urban land growth is projected to occur in Africa, Eastern
14 Europe and West-Central Asia, and in the Middle East. The infrastructure that will be constructed
15 concomitant with urban land expansion will lock-in patterns of energy consumption that will persist for
16 decades if not generations. Furthermore, given past trends, the expansion of urban areas is likely to take
17 place on agricultural lands and forests, with implications for the loss of carbon stocks and sequestration.
18 {8.3.1, 8.3.4, 8.4.1, 8.6}

19
20 **The construction of new, and upgrading of, existing urban infrastructure through 2030 will result**
21 **in significant emissions** (*very high confidence*). The construction of new and upgrading of existing
22 urban infrastructure using conventional practices and technologies can result in significant committed
23 CO₂ emissions, ranging from 8.5 GtCO₂ to 14 GtCO₂ annually up to 2030 and more than double annual
24 resource requirements for raw materials to about 90 billion tonnes per year by 2050, up from 40 billion
25 tonnes in 2010 (*medium evidence, high agreement*).{8.4.1, 8.6}

26
27 **Given the dual challenges of rising urban GHG emissions and future projections of more frequent**
28 **extreme climate events, there is an urgent need to integrate urban mitigation and adaptation**
29 **strategies for cities to address climate change and withstand its effects** (*very high confidence*).
30 Mitigation strategies can enhance resilience against climate change impacts while contributing to social
31 equity, public health, and human well-being. Urban mitigation actions that facilitate economic
32 decoupling can have positive impacts on employment and local economic competitiveness.{8.2, Cross-
33 Working Group Box 2, 8.4}

34
35 **Cities can only achieve net zero or near net zero GHG emissions through deep decarbonisation**
36 **and systemic transformation** (*very high confidence*). Urban deep decarbonisation entails
37 implementing three broad strategies concurrently: (1) reducing urban energy consumption across all
38 sectors, including through compact and efficient urban forms and supporting infrastructure; (2)
39 electrification and switching to net zero emissions resources; and (3) enhancing carbon uptake and
40 stocks (*medium evidence, high agreement*). Given the regional and global reach of urban supply chains,
41 a city cannot achieve net zero GHG emissions by only focusing on reducing emissions within its
42 administrative boundaries. {8.1.6, 8.3.4, 8.4, 8.6}

43
44 **Packages of mitigation policies that implement multiple urban-scale interventions can have**
45 **cascading effects across sectors, reduce GHG emissions outside of a city's administrative**
46 **boundaries, and reduce more emissions than the net sum of individual interventions, particularly**
47 **if multiple scales of governance are included** (*high confidence*). Cities have the ability to implement
48 policy packages across sectors using an urban systems approach, especially those that affect key
49 infrastructure based on spatial planning, electrification of the urban energy system, and urban green and
50 blue infrastructure. The institutional capacity of cities to develop, coordinate, and integrate sectoral

1 mitigation strategies within their jurisdiction varies by context, particularly those related to governance,
2 the regulatory system, and budgetary control. {8.4, 8.5, 8.6}

3
4 **Integrated spatial planning to achieve compact and resource-efficient urban growth through co-**
5 **location of higher residential and job densities, mixed land use, and transit-oriented development**
6 **could reduce GHG emissions between 23-26% by 2050 compared to the business-as-usual**
7 **scenario** (*robust evidence, high agreement, very high confidence*). Compact cities with shortened
8 distances between housing and jobs, and interventions that support a modal shift away from private
9 motor vehicles towards walking, cycling, and low-emissions shared and public transportation, passive
10 energy comfort in buildings, and urban green infrastructure can deliver significant public health benefits
11 and have lower GHG emissions. {8.2, 8.3.4, 8.4, 8.6}

12
13 **Urban green and blue infrastructure can mitigate climate change through carbon sequestration,**
14 **avoided emissions, and reduced energy use while offering multiple co-benefits** (*robust evidence,*
15 *high agreement*). Urban green and blue infrastructure, including urban forests and street trees,
16 permeable surfaces, and green roofs offer potentials to mitigate climate change directly through
17 sequestering and storing carbon, and indirectly by inducing a cooling effect that reduces energy demand
18 and reducing energy use for water treatment. Global urban trees store approximately 7.4 billion tonnes
19 of carbon, and sequester approximately 217 million tonnes of carbon annually, although urban tree
20 carbon storage and sequestration are highly dependent on biome. Among the multiple co-benefits of
21 green and blue infrastructure are reducing the urban heat island (UHI) effect and heat stress, reducing
22 stormwater runoff, improving air quality, and improving mental and physical health of urban dwellers.
23 {8.2, 8.4.4}

24
25 **The potentials and sequencing of mitigation strategies to reduce GHG emissions will vary**
26 **depending on a city's land use and spatial form and its state of urbanization, whether it is an**
27 **established city with existing infrastructure, a rapidly growing city with new infrastructure, or**
28 **an emerging city with infrastructure build-up** (*medium confidence*). The long lifespan of urban
29 infrastructures locks in behaviour and committed emissions. Urban infrastructures and urban form can
30 enable socio-cultural and lifestyle changes that can significantly reduce carbon footprints. Rapidly
31 growing cities can avoid higher future emissions through urban planning to co-locate jobs and housing
32 to achieve compact urban form, and by leapfrogging to low-carbon technologies. Established cities will
33 achieve the largest GHG emissions savings by replacing, repurposing, or retrofitting the building stock,
34 strategic infilling and densifying, as well as through modal shift and the electrification of the urban
35 energy system. New and emerging cities have unparalleled potential to become low or net zero GHG
36 emissions while achieving high quality of life by creating compact, co-located, and walkable urban
37 areas with mixed land use and transit-oriented design, that also preserve existing green and blue assets
38 {8.2, 8.4, 8.6}

39
40 **With over 880 million people living in informal settlements, there are opportunities to harness**
41 **and enable informal practices and institutions in cities related to housing, waste, energy, water,**
42 **and sanitation to reduce resource use and mitigate climate change** (*low evidence, medium*
43 *agreement*). The upgrading of informal settlements and inadequate housing to improve resilience and
44 well-being offers a chance to create a low-carbon transition. However, there is limited quantifiable data
45 on these practices and their cumulative impacts on GHG emissions. {8.1.4, 8.2.2, Cross-Working Group
46 Box 2, 8.3.2, 8.4, 8.6, 8.7}

47
48 **Achieving transformational changes in cities for climate change mitigation and adaptation will**
49 **require engaging multiple scales of governance, including governments and non-state actors, and**
50 **in connection with substantive financing beyond sectoral approaches** (*very high confidence*). Large

1 and complex infrastructure projects for urban mitigation are often beyond the capacity of local
2 municipality budgets, jurisdictions, and institutions. Partnerships between cities and international
3 institutions, national and region governments, transnational networks, and local stakeholders play a
4 pivotal role in mobilizing global climate finance resources for a range of infrastructure projects with
5 low-carbon emissions and related spatial planning programs across key sectors. {8.4, 8.5}

8.1 Introduction

8.1.1 What is new since AR5

The Fifth Assessment Report (AR5) of the Intergovernmental Panel on Climate Change (IPCC) was the first IPCC report that had a standalone chapter on urban mitigation of climate change. The starting point for that chapter was how the spatial organization of urban settlements affects greenhouse gas (GHG) emissions and how urban form and infrastructure could facilitate mitigation of climate change. A main finding in AR5 was that urban form shapes urban energy consumption and GHG emissions.

Since AR5, there has been growing scientific literature and policy foci on urban strategies for climate change mitigation. There are three possible reasons for this. First, according to AR5 Working Group III (WGIII) Chapter 12 on Human Settlements, Infrastructure, and Spatial Planning, urban areas generate between 71–76% of carbon dioxide (CO₂) emissions from global final energy use and between 67–76% of global energy (Seto et al. 2014). Thus, focusing on ‘urban systems’ (see Glossary and Figure 8.15) addresses one of the key drivers of emissions. Second, more than half of the world population lives in urban areas, and by mid-century 7 out of 10 people on the planet will live in a town or a city (UN DESA 2019). Thus, coming up with mitigation strategies that are relevant to urban settlements is critical for successful mitigation of climate change. Third, beyond climate change, there is growing attention on cities as major catalysts of change and to help achieve the objectives outlined in multiple international frameworks and assessments.

Cities are also gaining traction within the work of the IPCC. The IPCC Special Report on Global Warming of 1.5°C (SR1.5 Chapter 4) identified four systems that urgently need to change in fundamental and transformative ways: urban infrastructure, land use and ecosystems, industry, and energy. Urban infrastructure was singled out but urban systems form a pivotal part of the other three systems requiring change (IPCC 2018a) (see ‘infrastructure’ in Glossary). The IPCC Special Report on Climate Change and Land (SRCCL) identified cities not only as spatial units for land-based mitigation options but also places for managing demand for natural resources including food, fibre, and water (IPCC 2019).

Other international frameworks are highlighting the importance of cities. For example, the Intergovernmental Science-Policy Platform on Biodiversity and Ecosystem Services (IPBES) report on nature’s contribution to people is clear: cities straddle the biodiversity sphere in the sense that they present spatial units of ecosystem fragmentation and degradation while at the same time contain spatial units where the concentration of biodiversity compares favourably with some landscapes (IPBES 2019a). Cities are also featured as a key element in the transformational governance to tackle both climate change and biodiversity and ecosystem challenges in the first-ever IPCC-IPBES co-sponsored workshop report (Pörtner et al. 2021) (see Section 8.5 and ‘governance’ in Glossary).

The UN Sustainable Development Goals (SDGs) further underscore the importance of cities in the international arena with the inclusion of SDG 11 on Sustainable Cities and Communities for ‘inclusive, safe, resilient and sustainable’ cities and human settlements (United Nations 2015; Queiroz et al. 2017; United Nations 2019). Additionally, UN-Habitat’s New Urban Agenda (NUA) calls for various measures, including integrated spatial planning at the city-regional scale, to address the systemic challenges included in greening cities, among which is emissions reduction and avoidance (United Nations 2017).

Since AR5, there has also been an increase in scientific literature on urban mitigation of climate change, including more diversity of mitigation strategies than were covered during AR5 (Lamb et al. 2018), as well as a growing focus on how strategies at the urban scale can have compounding or additive effects beyond urban areas (e.g., in rural areas, land use planning, and the energy sector).

1 There is also more literature on using a systems approach to understand the interlinkages between
2 mitigation and adaptation, and situating GHG emissions reduction targets within broader social,
3 economic, and human well-being context and goals (Bai et al. 2018; Ürge-Vorsatz et al. 2018; Lin et
4 al. 2021). In particular, the nexus approach, such as the water and energy nexus and the water-energy-
5 food nexus, is increasingly being used to understand potential emissions and energy savings from cross-
6 sectoral linkages that occur in cities (Wang and Chen 2016; Engström et al. 2017; Valek et al. 2017).
7 There is also a growing literature that aims to quantify transboundary urban GHG emissions and carbon
8 footprint beyond urban and national administrative boundaries (Chen et al. 2016; Hu et al. 2016). Such
9 a scope provides a more complete understanding of how local urban emissions or local mitigation
10 strategies can have effects on regions' carbon footprint or GHG emissions.

11 *City Climate Action*

12 Moreover, cities around the world are putting increasing focus on tackling climate change. Since AR5:

- 13 • Climate leadership at the local scale is growing with commitment from city decision-makers
14 and policymakers to implement local-scale mitigation strategies (GCoM 2018, 2019; ICLEI
15 2019a; C40 Cities 2020a).
- 16 • More than 360 cities announced at the Paris Climate Conference that the collective impact of
17 their commitments will lead to reducing up to 3.7 GtCO₂-eq (CO₂-equivalent) of urban
18 emissions annually by 2030 (Cities for Climate 2015).
- 19 • The Global Covenant of Mayors (GCoM), a transnational network comprised of more than
20 10,000 cities, have made commitments to reduce urban GHG emissions up to 1.4–2.3 GtCO₂-
21 eq annually by 2030 and 2.8–4.2 GtCO₂-eq annually by 2050, compared to business-as-usual
22 (GCoM 2018, 2019).
- 23 • More than 800 cities have made commitments to achieve net zero GHG emissions (see
24 Glossary), either economy-wide or in a particular sector (NewClimate Institute and Data-
25 Driven EnviroLab 2020).

26 Although most cities and other subnational actors (see Glossary) are yet to meet their net zero GHG or
27 CO₂ emissions commitments, the growing numbers of those commitments, alongside organizations
28 enabled to facilitate reaching those targets, underscore the growing support for climate action by city
29 and other subnational leaders.

30 *Historical and future urban emissions*

31 One major innovation in this assessment report is the inclusion of historical and future urban GHG
32 emissions. Urban emissions based on consumption-based accounting by regions has been put forth for
33 the timeframe 1990–2100 using multiple datasets with projections given in the framework of the Shared
34 Socioeconomic Pathway (SSP) - Representative Concentration Pathway (RCP) scenarios. This advance
35 has provided a time dimension to urban footprints considering different climate scenarios with
36 implications for urban mitigation, allowing a comparison of the way urban emissions and their reduction
37 can evolve given different scenario contexts (see Glossary for definitions of various 'pathways' and
38 'scenarios' in the context of climate change mitigation, including 'SSPs' and 'RCPs').

39 *Sustainable development linkages and feasibility assessment*

40 Special emphasis is placed on the co-benefits of urban mitigation options, including an evaluation of
41 linkages with the SDGs based on synergies and/or trade-offs. Urban mitigation options are further
42 evaluated based on multiple dimensions according to the feasibility assessment (see Section 8.5.5,
43 Figure 8.19, and SM 8.2) indicating the enablers and barriers of implementation. These advances
44 provide additional guidance for urban mitigation.

8.1.2 Preparing for the Special Report on Cities and Climate Change in AR7

At the 43rd Session of the IPCC in 2016, the IPCC approved a Special Report on Climate Change and Cities during the Seventh Assessment Cycle of the IPCC (AR7). To stimulate scientific research knowledge exchange, the IPCC and nine global partners co-sponsored the IPCC Cities and Climate Change Science Conference, which brought together over 700 researchers, policymakers, and practitioners from 80 countries.

The conference identified key research priorities including the need for an overarching systems approach to understanding how sectors interact in cities as drivers for GHG emissions and the relationship between climate and other urban processes, as well as achieving transformation towards low-carbon and resilient futures (Bai et al. 2018). The subsequent report on global research and action agenda identifies scale, informality, green and blue infrastructure, governance and transformation, as well as financing climate action, as areas for scientific research during the AR6 cycle and beyond (WCRP 2019).

8.1.3 The scope of the chapter: a focus on urban systems

This chapter takes an urban systems approach and covers the full range of urban settlements, including towns, cities, and metropolitan areas. By ‘urban system’ (see Figure 8.15), this chapter refers to two related concepts. First, an urban systems approach recognizes that cities do not function in isolation. Rather, cities exhibit strong interdependencies across scales, whether it is within a region, a country, a continent, or worldwide. Cities are embedded in broader ecological, economic, technical, institutional, legal, and governance structures that often constrain their systemic function, which cannot be separated from wider power relations (Bai et al. 2016).

The notion of a system of cities has been around for nearly 100 years and recognizes that cities are interdependent, in that significant changes in one city, such as economic activities, income, or population, will affect other cities in the system (Christaller 1933; Berry 1964; Marshall 1989). This perspective of an urban system emphasizes the connections between a city and other cities, as well as between a city and its hinterlands (Hall and Hay 1980; Ramaswami et al. 2017b; Xu et al. 2018c). An important point is that growth in one city affects growth in other cities in the global, national or regional system of cities (Gabaix 1999; Scholvin et al. 2019; Knoll 2021).

Moreover, there is a hierarchy of cities (Taylor 1997; Liu et al. 2014), with very large cities at the top of the hierarchy concentrating political power and financial resources, but of which there are very few. Rather, the urban system is dominated by small- and medium-sized cities and towns. With globalization and increased interconnectedness of financial flows, labour, and supply chains, cities across the world today have long-distance relationships on multiple dimensions but are also connected to their hinterlands for resources.

The second key component of the urban systems lens identifies the activities and sectors within a city as being inter-connected—that cities are ecosystems (Rees 1997; Grimm et al. 2000; Newman and Jennings 2008; Acuto et al. 2019; Abdullah and Garcia-Chueca 2020; Acuto and Leffel 2021). This urban systems perspective emphasizes linkages and interrelations within cities. The most evident example of this is urban form and infrastructure, which refer to the patterns and spatial arrangements of land use, transportation systems, and urban design. Changes in urban form and infrastructure can simultaneously affect multiple sectors, such as buildings, energy, and transport.

This chapter assesses urban systems beyond simply jurisdictional boundaries. Using an urban systems lens has the potential to accelerate mitigation beyond a single sector or purely jurisdictional approach (see Section 8.4). An urban systems perspective presents both challenges and opportunities for urban mitigation strategies. It shows that any mitigation option potentially has positive or negative

1 consequences in other sectors, other settlements, cities, or other parts of the world, and requires more
2 careful and comprehensive considerations on the broader impacts, including equity and social justice
3 (see Glossary for a comprehensive definition of ‘equity’ in the context of mitigation and adaption). This
4 chapter focuses on cities, city regions, metropolitan regions, megalopitans, mega-urban regions, towns,
5 and other types of urban configurations because they are the primary sources of urban GHG emissions
6 and tend to be where mitigation action can be most impactful.

7 There is no internationally agreed upon definition of urban, urban population, or urban area. Countries
8 develop their own definitions of urban, often based on a combination of population size or density, and
9 other criteria including the percentage of population not employed in agriculture, the availability of
10 electricity, piped water, or other infrastructures, and characteristics of the built environment, such as
11 dwellings and built structures. This chapter assesses urban systems, which includes cities and towns. It
12 uses a similar framework as Chapter 6 of AR6 IPCC WGII, referring to cities and urban settlements as
13 ‘concentrated human habitation centres that exist along a continuum’ (Dodman et al. 2022) (for further
14 definitions of ‘urban,’ ‘cities,’ ‘settlements,’ and related terms, see Glossary, and WGII Chapter 6).

16 **8.1.4 The urban century**

17 The 21st century will be the urban century, defined by a massive increase in global urban populations
18 and a significant building up of new urban infrastructure stock to accommodate the growing urban
19 population. Six trends in urbanization are especially important in the context of climate change
20 mitigation.

21 First, the size and relative proportion of the urban population is unprecedented and continues to increase.
22 As of 2018, approximately 55% of the global population lives in urban areas (about 4.3 billion people)
23 (UN DESA 2019). It is predicted that 68% of the world population will live in urban areas by 2050.
24 This will mean adding 2.5 billion people to urban areas between 2018 and 2050, with 90% of this
25 increase taking place in Africa and Asia. There is a strong correlation between the level of urbanization
26 and the level of national income, with considerable variation and complexity in the relationship between
27 the two (UN DESA 2019). In general, countries with levels of urbanization of 75% or greater all have
28 high national incomes, whereas countries with low levels of urbanization under 35% have low national
29 incomes (UN DESA 2019). In general, there is a clear positive correlation between the level of
30 urbanization and income levels (see Figure 8.1, also Box 8.1).

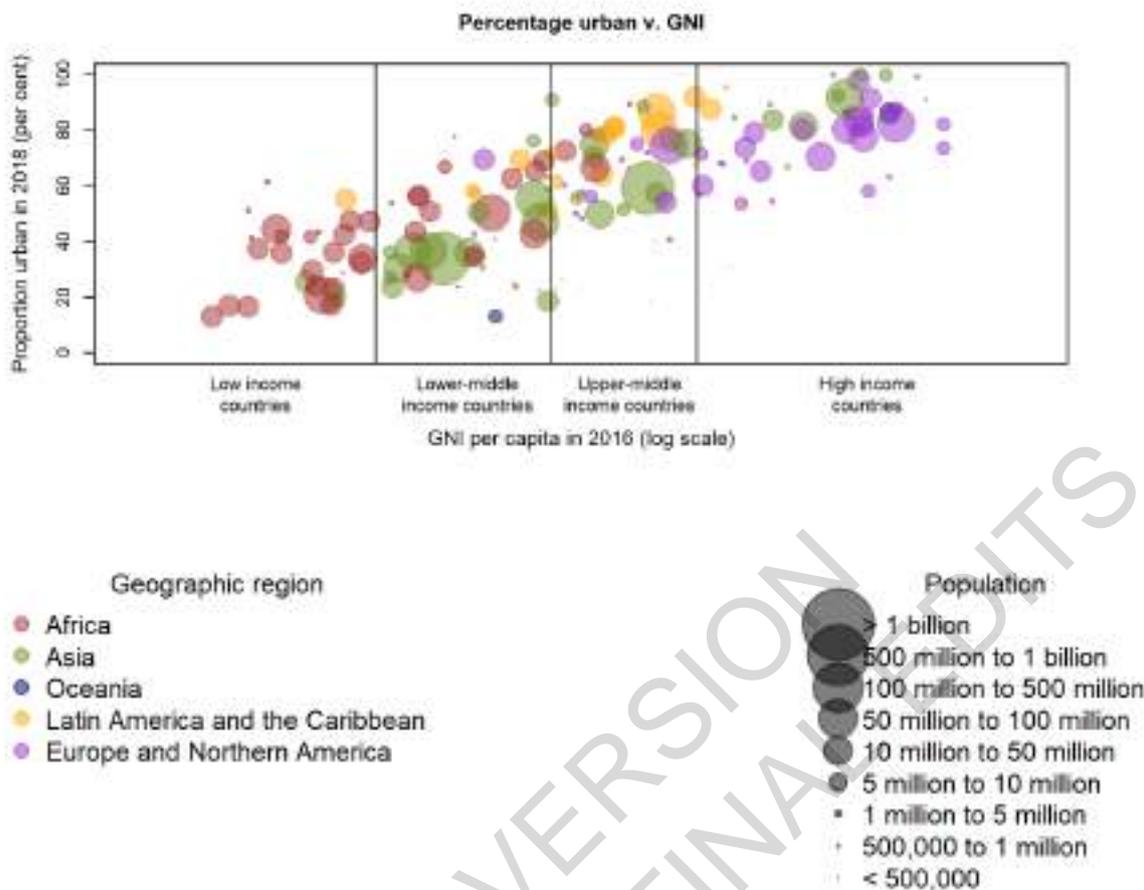

Figure 8.1¹ Relationship between urbanization level and Gross National Income

There is a positive and strong correlation between the urbanization level and gross national income. High income countries have high levels of urbanization, on average 80%. Low-income countries have low levels of urbanization, on average 30%.

Source: UN DESA 2019, p. 42

Second, the geographic concentration of the world's current urban population is in emerging economies, and the majority of future urban population growth will take place in developing countries and Least-Developed Countries (LDCs). About half of the world's urban population in 2018 lived in just seven countries, and about half of the increase in urban population through 2050 is projected to be concentrated in eight countries (UN DESA 2019) (see Figure 8.2). Of these eight, seven are emerging economies where there will be a need for significant financing to construct housing, roads, and other urban infrastructure to accommodate the growth of the urban population. How these new cities of tomorrow will be designed and constructed will lock-in patterns of urban energy behaviour for decades if not generations (see Section 8.3.4 and 8.4). Thus, it is essential that urban climate change mitigation strategies include solutions appropriate for cities of varying sizes and typologies (see Section 8.6 and Figure 8.21).

FOOTNOTE¹ The countries and areas classification in the underlying report for this figure deviates from the standard classification scheme adopted by WGIII as set out in Annex II, section 1.

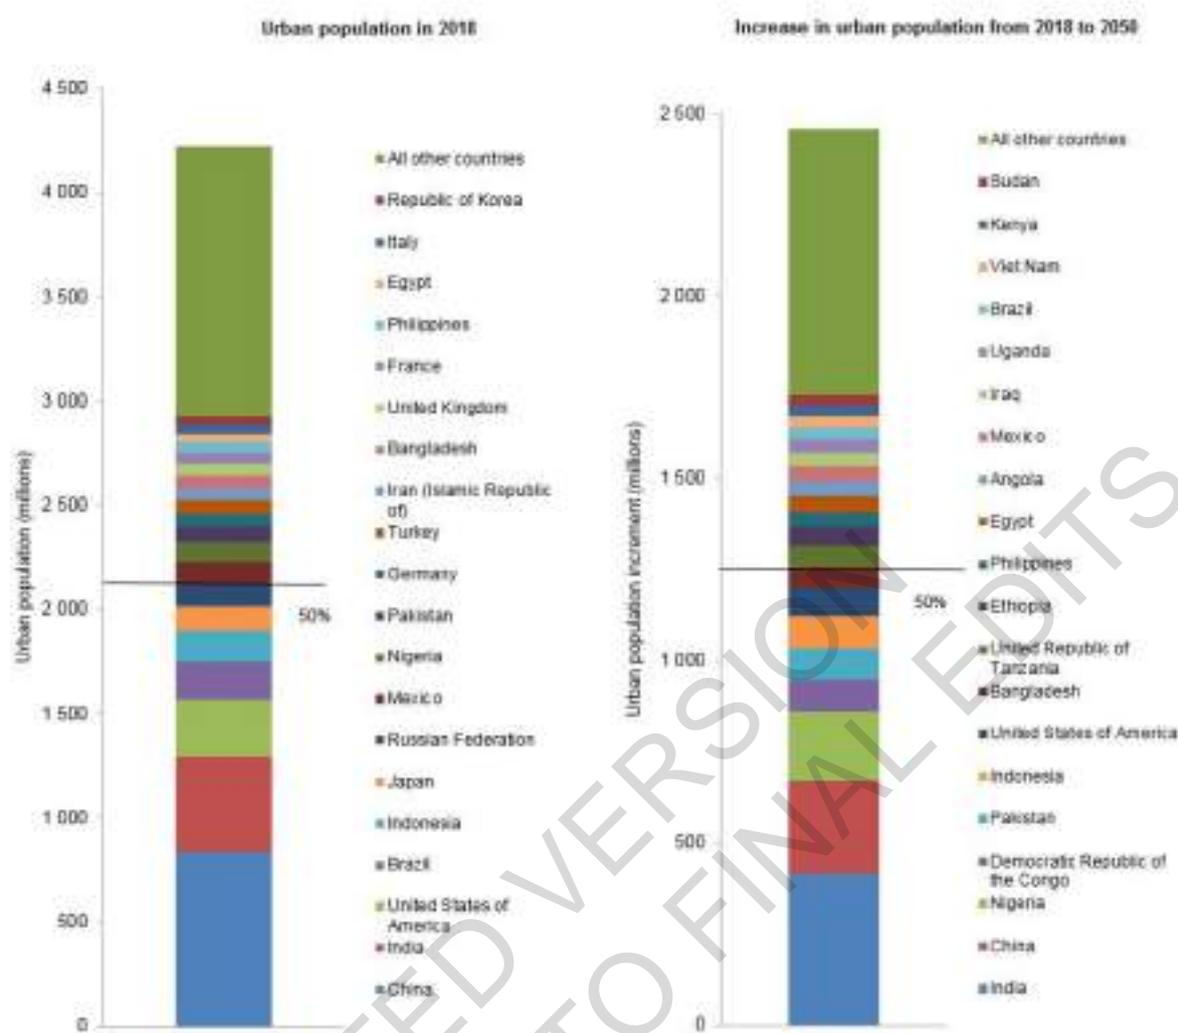

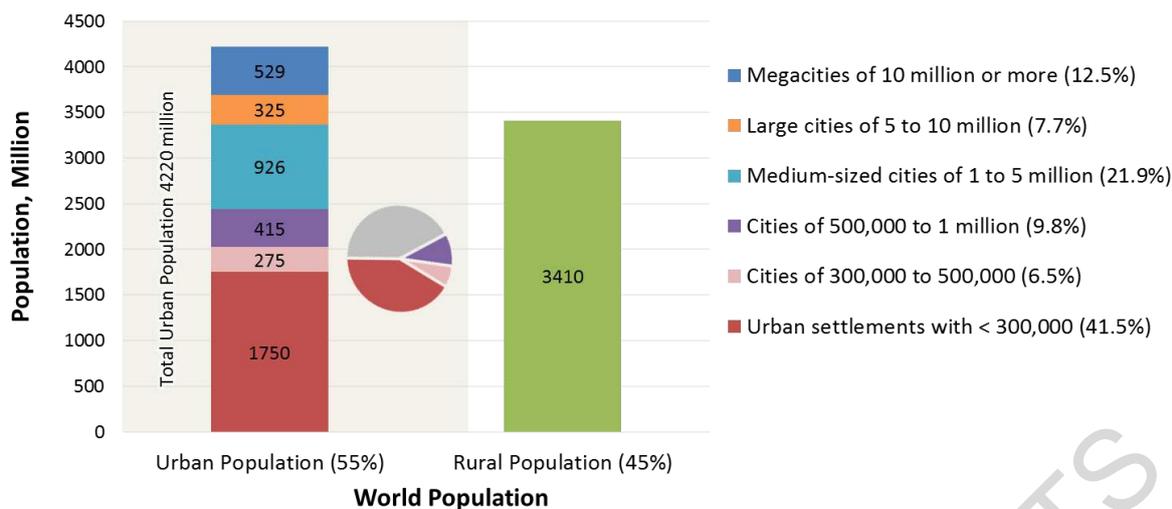

Figure 8.2 Urban population size in 2018 and increase in the projected urban population.

In 2018, about half of the world's urban population lived in seven countries, and about half of the increase in urban population through 2050 is forecasted to concentrate in eight countries.

Source: UN DESA 2019, p. 44

Third, small and medium-sized cities and towns are a dominant type of urban settlement. In 2018, more than half (58%) of the urban population lived in cities and towns with fewer than 1 million inhabitants and almost half of the world's urban population (48%) lived in settlements with fewer than 500,000 inhabitants (see Figure 8.3). Although megacities receive a lot of attention, only about 13% of the urban population worldwide lived in a megacity—an urban area with at least 10 million inhabitants (UN DESA 2019). Thus, there is a need for a wide range of strategies for urban mitigation of climate change that are appropriate for cities of varying levels of development, sizes, especially smaller cities which often have lower levels of financial capacities than large cities.

1

2

3 **Figure 8.3 Population of the world, by area of residence and size class of urban settlement for 2018**

4

5 As of 2018, 4.2 billion people or 55% of the world population reside in urban settlements while 45%
 6 reside in rural areas. The coloured stacked bars for the urban population represent the total number of
 7 inhabitants for a given size class of urban settlements. Megacities of 10 million or more inhabitants have a
 8 total of only 529 million inhabitants that corresponded to 12.5% of the urban population. In contrast,
 9 about 1.8 billion inhabitants reside in urban settlements with fewer than 300,000 inhabitants that
 10 corresponded to 41.5% of the urban population. The pie chart represents the respective shares for 2018,
 11 with 42% of the urban population residing in settlements with more than 1 million inhabitants, and 58%
 12 of the urban population residing in settlements with fewer than 1 million inhabitants. Almost half of the
 13 world's urban population (48%) live in settlements with fewer than 500,000 inhabitants.

14

15

Source: adapted from UN DESA 2019, p. 56.

16

17 Fourth, another trend is the rise of megacities and extended metropolitan regions. The largest cities
 18 around the world are becoming even larger, and there is a growing divergence in economic power
 19 between megacities and other large cities (Kourtit et al. 2015; Hoornweg and Pope 2017; Zhao et al.
 20 2017b). Moreover, there is evidence that the largest city in each country has an increasing share of the
 21 national population and economy.

22 Fifth, population declines have been observed for cities and towns across the world, including in Poland,
 23 Republic of Korea, Japan, United States, Germany, and Ukraine. The majority of cities that have
 24 experienced population declines are concentrated in Europe. Multiple factors contribute to the decline
 25 in cities, including declining industries and the economy, declining fertility, and outmigration to larger
 26 cities. Shrinking urban populations could offer retrofitting opportunities (UNEP 2019) and increasing
 27 greenspaces (Jarzebski et al. 2021), but the challenges for these cities differ in scope and magnitude
 28 from rapidly expanding cities.

29 Sixth, urbanization in many emerging economies is characterized by informality and an informal
 30 economy (Brown and McGranahan 2016). The urban informal economy includes a wide array of
 31 activities, including but not limited to street vending, home-based enterprises, unreported income from
 32 self-employment, informal commerce, domestic service, waste-picking, and urban agriculture. The
 33 urban informal economy is large and growing. Globally, about 44% of the urban economy is informal,
 34 although there is much variation between countries and regions (ILO 2018). Emerging and developing
 35 economies have the highest percentage of the urban informal economy, with Africa (76%) and the Arab
 36 States (64%) with the largest proportion (ILO 2018). Urban informality also extends to planning,

1 governance and institutions (Roy 2009; EU 2016; Lamson-Hall et al. 2019). Given its prevalence, it is
2 important for urban climate change mitigation strategies to account for informality, especially in
3 emerging and developing countries (see Section 8.3.2).

5 **8.1.5 Urbanization in developing countries**

6 Urbanization in the 21st century will be dominated by population and infrastructure growth in
7 developing countries, and as such it is important to highlight three aspects that are unique and especially
8 relevant for climate change mitigation. First, urbanization will increase in speed and magnitude. Given
9 their significant impact on emissions, mitigation action in Asian cities, especially the large and rapidly
10 growing cities, will have significant implications on global ambitions (see Section 8.3.4).

11 Second, a number of cities in developing countries lack institutional, financial and technical capacities
12 to enable local climate change action (Sharifi et al. 2017; Fuhr et al. 2018). While these capacities differ
13 across contexts (Hickmann et al. 2017), several governance challenges are similar across cities
14 (Gouldson et al. 2015). These factors also influence the ability of cities to innovate and effectively
15 implement mitigation action (Nagendra et al. 2018) (see Chapter 17).

16 Third, there are sizable economic benefits in developing country cities that can provide an opportunity
17 to enhance political momentum and institutions (Colenbrander et al. 2016). The co-benefits approach
18 (see Section 8.2), which frames climate objectives alongside other development benefits, is increasingly
19 seen as an important concept justifying and driving climate change action in developing countries (Sethi
20 and Puppim de Oliveira 2018).

21 Large-scale system transformations are also deeply influenced by factors outside governance and
22 institutions such as private interests and power dynamics (Jaglin 2014; Tyfield 2014). In some cases,
23 these private interests are tied up with international flows of capital. In India, adaptation plans involving
24 networks of private actors and related mitigation actions have resulted in the dominance of private
25 interests. This has led to trade-offs and adverse impacts on the poor (Chu 2016; Mehta et al. 2019).

26 When planning and implementing low-carbon transitions, it is important to consider the socio-economic
27 context. An inclusive approach emphasizes the need to engage non-state actors, including businesses,
28 research organizations, non-profit organizations and citizens (Lee and Painter 2015; Hale et al. 2020).
29 For example, engaging people in defining locally relevant mitigation targets and actions has enabled
30 successful transformations in China (Engels 2018), Africa (Göpfert et al. 2019) and Malaysia (Ho et al.
31 2015). An active research and government collaboration through multiple stakeholder interactions in a
32 large economic corridor in Malaysia led to the development and implementation of a low-carbon
33 blueprint for the region (Ho et al. 2013). Many cities in LDCs and developing countries lack adequate
34 urban infrastructure and housing. An equitable transformation in these cities entails prioritizing energy
35 access and basic services including safe drinking water and sanitation, to meet basic needs of their
36 populations.

37 **8.1.6 Urban carbon footprint**

39 Urban areas concentrate GHG fluxes because of the size of the urban population, the size and nature of
40 the urban economy, the energy and GHGs embodied in the infrastructure (see Glossary for a definition
41 of ‘embodied emissions’), and the goods and services imported and exported to and from cities
42 (USGCRP 2018).

43 **8.1.6.1 Urban carbon cycle**

44 In cities, carbon cycles through natural (e.g., vegetation and soils) and managed (e.g., reservoirs and
45 anthropogenic—buildings, transportation) pools. The accumulation of carbon in urban pools, such as

1 buildings or landfills, results from the local or global transfer of carbon-containing energy and raw
2 materials used in the city (Churkina 2008; Pichler et al. 2017; Chen et al. 2020b). Quantitative
3 understanding of these transfers and the resulting emissions and uptake with an urban area is essential
4 for accurate urban carbon accounting (USGCRP 2018). Currently, urban areas are a net source of carbon
5 because they emit more carbon than they uptake. Thus, urban mitigation strategies require a twofold
6 strategy: reducing urban emissions of carbon into the atmosphere, and enhancing uptake of carbon in
7 urban pools (Churkina 2012) (for a broader definition of ‘carbon cycle’ and related terms such as
8 ‘carbon sink,’ carbon stock,’ ‘carbon neutrality,’ ‘GHG neutrality,’ and others, see Glossary).

9 Burning fossil fuels to generate energy for buildings, transportation, industry, and other sectors is a
10 major source of urban GHG emissions (Gurney et al. 2015). At the same time, most cities do not
11 generate within their boundaries all of the resources they use, such as electricity, gasoline, cement,
12 water, and food needed for local homes and businesses to function (Jacobs 1969), requiring
13 consideration of GHG emissions embodied in supply chains serving cities. Furthermore, urban
14 vegetation, soils, and aquatic systems can both emit or remove carbon from the urban atmosphere and
15 are often heavily managed. For example, urban parks, forests, and street trees actively remove carbon
16 from the atmosphere through growing season photosynthesis. They can become a net source of carbon
17 most often during the dormant season or heat waves. Some of the sequestered carbon can be stored in
18 the biomass of urban trees, soils, and aquatic systems. Urban infrastructures containing cement also
19 uptake carbon through the process of carbonation. The uptake of carbon by urban trees is at least two
20 orders of magnitude faster than by cement-containing infrastructures (Churkina 2012) (see Section
21 8.4.4, and Figures 8.17 and 8.18).

22 **8.1.6.2 Urban emissions accounting**

23 Urban GHG emissions accounting can determine critical conceptual and quantitative aspects of urban
24 GHG emissions. The accounting framework chosen can therefore predetermine the emissions
25 responsibility, the mitigation options available, and the level of effort required to correctly account for
26 emissions (Afionis et al. 2017).

27 Two main urban carbon accounting advances have occurred since AR5. The first includes efforts to
28 better understand and clarify how the different urban GHG accounting frameworks that have emerged
29 over the past 15 years are inter-related, require different methodological tools, and reflect differing
30 perspectives on emissions responsibility and quantification effort. The second main advance lies in a
31 series of methodological innovations facilitating practical implementation, emissions verification, and
32 scaling-up of the different GHG accounting approaches. This section provides an overview of the most
33 used GHG urban accounting frameworks followed by a review of the advances since AR5.

34 Numerous studies have reviewed urban GHG accounting frameworks and methods with somewhat
35 different nomenclatures and categorical divisions (Lin et al. 2015; Lombardi et al. 2017; Chen et al.
36 2019b; Arioli et al. 2020; Heinonen et al. 2020; Hachaichi and Baouni 2021; Ramaswami et al. 2021).
37 Furthermore, accounting frameworks are reflected in multiple protocols used by urban practitioners
38 (BSI 2013; Fong et al. 2014; ICLEI 2019b). Synthesis of these reviews and protocols, as well as the
39 many individual methodological studies available, point to four general frameworks of urban GHG
40 accounting: (1) territorial accounting (TA); (2) communitywide infrastructure supply chain foot-
41 printing (CIF); and (3 and 4) consumption-based carbon footprint accounting (CBCF) (Wiedmann and
42 Minx 2008). The last, CBCF, can be further divided into accounting with a focus on household or
43 personal consumption—(3) the personal carbon footprint (PCF)—and an approach in which one
44 includes final consumption in an area by all consumers—(4) the areal carbon footprint (ACF) (Heinonen
45 et al. 2020). A number of small variations to these general categories are found in the literature (Lin et
46 al. 2015; Chen et al. 2020a), but these four general frameworks capture the important distinctive (i.e.,
47 policy-relevant) features of urban GHG accounting.

1 All these approaches are foundationally rooted in the concept of urban metabolism that is, the tracking
2 of material and energy flows into, within, and out of cities (Wolman 1965). These frameworks all aim
3 to quantify urban GHG emissions but reflect different perspectives on where the emission responsibility
4 is allocated in addition to how much and which components of the GHG emissions associated with the
5 import and export of good and services to and from a city (‘transboundary embedded/embody GHG
6 emissions’) are included in a given urban emissions account. The four frameworks share some common,
7 overlapping GHG emission quantities and their inter-relationships have been defined mathematically
8 (Chavez and Ramaswami 2013).

9 A key advance since AR5 lies in understanding the different GHG accounting frameworks in terms of
10 what they imply for responsibility—shared or otherwise—and what they imply for the depth and
11 breadth of GHG emission reductions. TA focuses on in-city direct emission of GHGs to the atmosphere
12 (e.g., combustion, net ecosystem exchange, methane – CH₄ – leakage) within a chosen geographic area
13 (Sovacool and Brown 2010; Gurney et al. 2019). CIF connects essential infrastructure use and demand
14 activities in cities with their production, by combining TA emissions with the transboundary supply
15 chain emissions associated with imported electricity, fuels, food, water, building materials, and waste
16 management services used in cities (Ramaswami et al. 2008; Kennedy et al. 2009; Chavez and
17 Ramaswami 2013).

18 CBCF considers not only the supply-chain-related GHG emissions of key infrastructure, but also
19 emissions associated with all goods and services across a city, often removing emissions associated
20 with goods and services exported from a city (Wiedmann et al. 2016, 2021). The distinction between
21 the PCF and ACF variants of the CBCF are primarily associated with whether the agents responsible
22 for the final demand are confined to only city residents (PCF) or all consumers in a city (ACF), which
23 can include government consumers, capital formation, and other final demand categories (Heinonen et
24 al. 2020).

25 A recent synthesis of these frameworks in the context of a net zero GHG emissions target suggests that
26 the four frameworks contribute to different aspects of decarbonization policy and can work together to
27 inform the overall process of decarbonization (Ramaswami et al. 2021). Furthermore, the relative
28 magnitude of GHG emissions for a given city resulting from the different frameworks is often a
29 reflection of the city’s economic structure as a ‘consumer-’ or producer city’ (Chavez and Ramaswami
30 2013; Sudmant et al. 2018).

31 The TA framework is unique in that it can be independently verified through direct measurement of
32 GHGs in the atmosphere, offering a check on the integrity of emission estimates (Lauvaux et al. 2020;
33 Mueller et al. 2021). It is traditionally simpler to estimate by urban practitioners given the lower data
34 requirements, and it can be relevant to policies aimed specifically at energy consumption and mobility
35 activities within city boundaries. However, it will not reflect electricity imported for use in cities or
36 lifecycle emissions associated with in-city consumption of goods and services.

37 The CIF framework adds to the TA framework by including GHG emissions associated with electricity
38 imports and the lifecycle GHG emissions associated with key infrastructure provisioning activities in
39 cities, serving all homes, businesses, and industries. This widens both the number of emitting categories
40 and the responsibility for those emissions by including infrastructure-related supply chain emissions.
41 The CIF framework enables individual cities to connect communitywide demand for infrastructure
42 and food with their transboundary production, strategically aligning their net zero emissions plans with
43 larger-scale net zero efforts (Ramaswami and Chavez 2013; Ramaswami et al. 2021; Seto et al. 2021).

44 The PCF version of the CBCF shifts the focus of the consumption and associated supply chain emissions
45 to only household consumption of goods and services (Jones and Kammen 2014). This both reduces
46 the TA emissions considered and the supply chain emissions, excluding all emissions associated with
47 government, capital formation, and exports. The ACF, by contrast, widens the perspective considerably,

1 including the TA and supply chain emissions of all consumers in a city, but often removing emissions
2 associated with exports.

3 An additional distinction is the ability to sum up accounts from individual cities in a region or country,
4 for example, directly to arrive at a regional or national total. This can only be done for the TA and PCF
5 frameworks. The ACF and CIF frameworks would require adjustment to avoid double-counting
6 emissions (Chen et al. 2020a).

7 A second major area of advance since AR5 has been in methods to implement, verify and scale up the
8 different GHG foot-printing approaches. Advances have been made in six key areas: (1) advancing
9 urban metabolism accounts integrating stocks and flows, and considering biogenic and fossil-fuel-based
10 emissions (Chen et al. 2020b); (2) improving fine-scale and near-real-time urban use-activity data
11 through new urban data science (Gately et al. 2017; Gurney et al. 2019; Turner et al. 2020; Yadav et al.
12 2021); (3) using atmospheric monitoring from the ground, aircraft, and satellites combined with inverse
13 modelling to independently quantify TA emissions (Lamb et al. 2016; Lauvaux et al. 2016, 2020; Davis
14 et al. 2017; Mitchell et al. 2018; Sargent et al. 2018; Turnbull et al. 2019; Wu et al. 2020a); (4)
15 improving supply chain and input-output modelling, including the use of physically based input-output
16 models (Wachs and Singh 2018); (5) establishing the global multi-region input-output models (Lenzen
17 et al. 2017; Wiedmann et al. 2021); and (6) generating multi-sector use and supply activity data across
18 all cities in a nation, in a manner where data aggregate consistently across city, province, and national
19 scales (Tong et al. 2021) (see Section 8.3).

20

21 **8.2 Co-Benefits and trade-offs of urban mitigation strategies**

22 Co-benefits are ‘the positive effects that a policy or measure aimed at one objective might have on other
23 objectives, thereby increasing the total benefits to the society or environment’ (Matthews et al. 2018).
24 AR5 WGIII Chapter 12 reported a range of co-benefits associated with urban climate change mitigation
25 strategies, including public savings, air quality and associated health benefits, and productivity
26 increases in urban centres (Seto et al. 2014). Since AR5, evidence continues to mount on the co-benefits
27 of urban mitigation. Highlighting co-benefits could make a strong case for driving impactful mitigation
28 action (Bain et al. 2016), especially in developing countries, where development benefits can be the
29 argument for faster implementation (Sethi and Puppim de Oliveira 2018). Through co-benefits, urban
30 areas can couple mitigation, adaptation, and sustainable development while closing infrastructure gaps
31 (Thacker et al. 2019; Kamiya et al. 2020).

32 The urgency of coupling mitigation and adaptation is emphasized through a special Cross-Working
33 Group Box on ‘Cities and Climate Change’ (see Section 8.2.3 and Cross-Working Group Box 2). This
34 section further addresses synergies and trade-offs for sustainable development with a focus on linkages
35 with the SDGs and perspectives for economic development, competitiveness, and equity.

36 **8.2.1 Sustainable development**

37 Sustainable development is a wide concept, encompassing socioeconomic and environmental
38 dimensions, envisaging long-term permanence and improvement. Whilst long-term effects are more
39 related to resilience—and hence carry co-benefits and synergies with the mitigation of GHG
40 emissions—some short-term milestones were defined by the post-2015 UN Sustainable Development
41 Agenda SDGs, including a specific goal on climate change (SDG 13) and one on making cities
42 inclusive, safe, resilient and sustainable (SDG 11) (United Nations 2015). The SDGs and related
43 indicators can be an opportunity to improve cities by using science-based decision-making and
44 engaging a diverse set of stakeholders (Simon et al. 2016; Klopp and Petretta 2017; Kutty et al. 2020).

1 There are multiple ways that development pathways can be shifted towards sustainability (see Section
2 4.3.3, Cross-Chapter Box 5 in Chapter 4, Chapter 17, and Figure 17.1). Urban areas can work to redirect
3 development pathways towards sustainability while increasing co-benefits for urban inhabitants. Figure
4 8.4 indicates that mitigation options for urban systems can provide synergistic linkages across a wide
5 range of SDGs, and some cases where linkages can produce both synergies and trade-offs. While
6 linkages are based on context and the scale of implementation, synergies can be most significant when
7 urban areas pursue integrated approaches where one mitigation option supports the other (see also
8 Sections 8.4 and 8.6).

Integrating sectors, strategies and innovations																			

List of SDGs

- SDG 1: No Poverty
- SDG 2: Zero Hunger
- SDG 3: Good Health and Well-being
- SDG 4: Quality Education
- SDG 5: Gender Equality
- SDG 6: Clean Water and Sanitation
- SDG 7: Affordable and Clean Energy
- SDG 8: Decent Work and Economic Growth
- SDG 9: Industry, Innovation and Infrastructure

- SDG 10: Reduced Inequalities
- SDG 11: Sustainable Cities and Communities
- SDG 12: Responsible Consumption and Production
- SDG 13: Climate Action
- SDG 14: Life Below Water
- SDG 15: Life on Land
- SDG 16: Peace, Justice and Strong Institutions
- SDG 17: Partnerships for the Goals

Confidence levels

- Low confidence
- Medium confidence
- High confidence

Figure 8.4 Co-benefits of urban mitigation actions.

The first column lists urban mitigation options. The second column indicates synergies with the SDGs. The third column indicates both synergies and/or trade-offs. The dots represent confidence levels with the number of dots representing levels from low to high. In the last column, confidence levels for synergies and/or trade-offs are provided separately. A plus sign (+) represents synergy and a minus sign (-) represents a trade-off. Supplementary Material SM8.1 provides 64 references and extends the SDG mappings that are provided in Thacker et al. (2019) and Fuso Nerini et al. (2018). Please see Supplementary Material Table 17.1 for details and Annex II for the methodology of the SDG assessment.

Figure 8.4 summarizes an evaluation of the synergies and/or trade-offs with the SDGs for the mitigation options for urban systems based on Supplementary Material (SM) 8.1 (SM8.1). The evaluations depend on the specific urban context with synergies and/or trade-offs being more significant in certain contexts than others. Urban mitigation with a view of the SDGs can support shifting pathways of urbanization towards greater sustainability. The feasibility of urban mitigation options is also malleable and can increase with more ‘enabling conditions’ (see Glossary), provided, perhaps, though institutional (i.e., financial or governmental) support (see Section 8.5). Strengthened institutional capacity that supports the coordination of mitigation options can increase linkages with the SDGs and their synergies. For example, urban land use and spatial planning for walkable and co-located densities together with electrification of the urban energy system can hold more benefits for the SDGs than any one of the mitigation options alone (see Sections 8.4.2.2, 8.4.3.1, and 8.6).

Evidence on the co-benefits of urban mitigation measures for human health has increased significantly since AR5, especially through the use of health impact assessments, where energy savings and cleaner energy supply structures based on measures for urban planning, heating, and transport have reduced CO₂, nitrogen oxides (NO_x), and coarse particulate matter (PM₁₀) emissions (Diallo et al. 2016). Some measures, especially those related to land-use planning and transportation, have also increased opportunities for physical activity for improved health (Diallo et al. 2016). In developing countries, the co-benefits approach has been effective in justifying climate change mitigation actions at the local level (Puppim de Oliveira and Doll 2016). Mixed-use compact development with sufficient land use diversity can have a positive influence on urban productivity (see Section 8.4.2). Conversely, urban spatial structures that increase walking distances and produce car dependency have negative impacts on urban productivity considering congestion as well as energy costs (Salat et al. 2017).

There is increasing evidence that climate mitigation measures can lower health risks that are related to energy poverty, especially among vulnerable groups such as the elderly and in informal settlements (Monforti-Ferrario et al. 2018). Measures such as renewable energy-based electrification of the energy system not only reduce outdoor air pollution, but also enhance indoor air quality by promoting smoke-free heating and cooking in buildings (Kjellstrom and McMichael 2013). The environmental and ecological benefits of electrification of the urban energy system include improved air quality based on a shift to non-polluting energy sources (Jacobson et al. 2018; Ajanovic and Haas 2019; Bagheri et al. 2019; Gai et al. 2020). Across 74 metropolitan areas around the world, an estimated 408,270 lives per year are saved due to air quality improvements that stem from a move to 100% renewable energy (Jacobson et al. 2020). Other studies indicate that there is potential to reduce premature mortality by up to 7,000 people in 53 towns and cities, to create 93,000 new jobs, and to lower global climate costs and personal energy costs, through renewable energy transformations (Jacobson et al. 2018).

Across 146 signatories of a city climate network, local energy-savings measures led to 6,596 avoided premature deaths and 68,476 years of life saved due to improved air quality (Monforti-Ferrario et al. 2018). Better air quality further reinforces the health co-benefits of climate mitigation measures based on walking and bicycling since evidence suggests that increased physical activity in urban outdoor settings with low levels of black carbon improves lung function (Laeremans et al. 2018). Physical activity can also be fostered through urban design measures and policies that promote the development of ample and well-connected parks and open spaces, and can lead to physical and mental health benefits (Kabisch et al. 2016) (see Section 8.4.4 and Figure 8.18).

Cities in India, Indonesia, Vietnam, and Thailand show that reducing emissions from major sources (e.g., transport, residential burning, biomass open burning and industry) could bring substantial co-benefits of avoided deaths from reduced PM_{2.5} (fine inhalable particulates) emissions and radiative

1 forcing from black carbon (Pathak and Shukla 2016; Dhar et al. 2017; Permadi et al. 2017; Karlsson et
2 al. 2020), reduced noise, and reduced traffic injuries (Kwan and Hashim 2016). Compact city policies
3 and interventions that support a modal shift away from private motor vehicles towards walking, cycling,
4 and low-emission public transport delivers significant public health benefits (Creutzig 2016; Ürges-
5 Vorsatz et al. 2018). Trade-offs associated with compact development include the marginal health costs
6 of transport air pollution (Lohrey and Creutzig 2016) and stress from traffic noise (Gruebner et al. 2017)
7 (Section 8.4.2.2).

8 Urban green and blue infrastructure—a subset of nature-based solutions (NBS)—acts as both climate
9 mitigation and adaptation measures by reducing heat stress (Kim and Coseo 2018; Privitera and La
10 Rosa 2018; Herath et al. 2021) improving air quality, reducing noise (Scholz et al. 2018; De la Sota et
11 al. 2019), improving urban biodiversity (Hall et al. 2017b), and enhancing well-being, including
12 contributions to local development (Lwasa et al. 2015). Health benefits from urban forestry and green
13 infrastructure include reduced cardiovascular morbidity, improved mental health (van den Bosch and
14 Ode Sang 2017; Vujcic et al. 2017; Al-Kindi et al. 2020; Sharifi et al. 2021), raised birth weight
15 (Dzhambov et al. 2014), and increased life expectancy (Jonker et al. 2014). Urban agriculture, including
16 urban orchards, roof-top gardens, and vertical farming contribute to enhancing food security and
17 fostering healthier diets (Cole et al. 2018; Petit-Boix and Apul 2018; De la Sota et al. 2019) (see Section
18 8.4.4, Figure 8.18, and Box 8.2).

19 20 **8.2.2 Economic development, competitiveness, and equity**

21 Sustainable management of urban ecosystems entails addressing economic growth, equity, and good
22 governance. In total, 102 SDG targets (99 synergies and 51 trade-offs) are identified with published
23 evidence of relationships with urban ecosystems—out of the 169 in the 2030 Agenda (Maes et al. 2019).
24 The targets require action in relation to urban ecosystem management, environmental improvements,
25 equality related to basic services, long-term economic growth, economic savings, stronger governance,
26 and policy development at multiple scales.

27 Mitigation measures related to different sectors can provide co-benefits and reduce social inequities.
28 Transport-related measures, such as transportation demand management, transit-oriented development
29 (TOD), and promotion of active transport modes provide economic co-benefits through, for example,
30 reducing healthcare costs linked with pollution and cardiovascular diseases, improving labour
31 productivity, and decreasing congestion costs (including waste of time and money) (Sharifi et al. 2021).
32 As a case-in-point, data from cities such as Bangkok, Kuala Lumpur, Jakarta, Manila, Beijing, Mexico
33 City, Dakar, and Buenos Aires indicate that economic costs of congestion account for a considerable
34 share of their gross domestic product (GDP) (ranging from 0.7% to 15.0%) (Dulal 2017) (see Section
35 8.4.2).

36 Since policy interventions can result in negative impacts or trade-offs with other objectives, fostering
37 accessibility, equity, and inclusivity for disadvantaged groups is essential (Viguié and Hallegatte 2012;
38 Sharifi 2020; Pörtner et al. 2021). Anti-sprawl policies that aim to increase density or introduction of
39 large green areas in cities could increase property prices, resulting in trade-offs with affordable housing
40 and pushing urban poor further away from cities (Reckien et al. 2017; Alves et al. 2019). Deliberate
41 strategies can improve access of low income populations to jobs, and gender-responsive transport
42 systems that can enhance women’s mobility and financial independence (Viguié and Hallegatte 2012;
43 Lecompte and Juan Pablo 2017; Reckien et al. 2017; Priya Uteng and Turner 2019).

44 Low-carbon urban development that triggers economic decoupling and involves capacity building
45 measures could have a positive impact on employment and local competitiveness (Dodman 2009;
46 Kalmykova et al. 2015; Chen et al. 2018b; García-Gusano et al. 2018; Hu et al. 2018; Shen et al. 2018).
47 Sustainable and low-carbon urban development that integrates issues of equity, inclusivity, and

1 affordability while safeguarding urban livelihoods, providing access to basic services, lowering energy
2 bills, addressing energy poverty, and improving public health, can also improve the distributional
3 effects of existing and future urbanization (Friend et al. 2016; Claude et al. 2017; Colenbrander et al.
4 2017; Ma et al. 2018; Mrówczyńska et al. 2018; Pukšec et al. 2018; Wiktorowicz et al. 2018;
5 Ramaswami 2020).

6 Depending on the context, green and blue infrastructure can also offer considerable economic co-
7 benefits. For example, green roofs and facades and other urban greening efforts such as urban
8 agriculture and greening streets can improve microclimatic conditions and enhance thermal comfort,
9 thereby reducing utility and healthcare costs. The presence of green and blue infrastructure may also
10 increase the economic values of nearby properties (Votsis 2017; Alves et al. 2019) (see Section 8.4.4
11 and Figure 8.18).

12 Studies in the UK show that beneficiaries are willing to pay (WTP) an additional fee (up to 2% more in
13 monthly rent) for proximity to green and blue infrastructure, with the WTP varying depending on the
14 size and nature of the green space (Mell et al. 2013, 2016). Urban agriculture can not only reduce
15 household food expenditure, but also provide additional sources of revenue for the city (Ayerakwa
16 2017; Alves et al. 2019). Based on the assessed literature, there is *high agreement* on the economic co-
17 benefits of green and blue infrastructure, but supporting evidence is still limited (see Section 8.7).

18 Implementing waste management and wastewater recycling measures can provide additional sources of
19 income for citizens and local authorities. Wastewater recycling can minimize the costs associated with
20 the renewal of centralized wastewater treatment plants (Bernstad Saraiva Schott and Cánovas 2015;
21 Gharfalkar et al. 2015; Gonzalez-Valencia et al. 2016; Herrero and Vilella 2018; Matsuda et al. 2018;
22 Nisbet et al. 2019). Waste management and wastewater recycling is also a pathway for inclusion of the
23 informal sector into the urban economy with *high agreement* and *medium evidence* (Sharifi 2021).
24 Additionally, authorities can sell energy generated from wastewater recycling to compensate for the
25 wastewater management costs (Colenbrander et al. 2017; Gondhalekar and Ramsauer 2017). Another
26 measure that contributes to reducing household costs is the promotion of behavioural measures such as
27 dietary changes that can decrease the demand for costly food sources and reduce healthcare costs
28 through promoting healthy diets (Hoppe et al. 2016) (see Sections 8.4.5 and 8.4.6).

29 In addition to cost savings, various measures such as stormwater management and urban greening can
30 enhance social equity and environmental justice. For example, the thermal comfort benefits provided
31 by green and blue infrastructure and passive design measures can address issues related to energy
32 poverty and unaffordability of expensive air conditioning systems for some social groups (Sharma et
33 al. 2018; He et al. 2019). To achieve such benefits, however, the costs of integrating green and blue
34 infrastructure and passive design measures into building design would need to be minimized. Another
35 example is the flood mitigation benefits of stormwater management measures that can reduce impacts
36 on urban poor who often reside in flood-prone and low-lying areas of cities (Adegun 2017; He et al.
37 2019). Generally, the urban poor are expected to be disproportionately affected by climate change
38 impacts. Carefully designed measures that reduce such disproportionate impacts by involving experts,
39 authorities and citizens would enhance social equity (Pandey et al. 2018; He et al. 2019; Mulligan et al.
40 2020).

42 **8.2.3 Coupling mitigation and adaptation**

43 There are numerous synergies that come from coupling urban adaptation and mitigation. A number of
44 studies have developed methods to assess the synergies between mitigation and adaptation strategies,
45 as well as their co-benefits (Solecki et al. 2015; Buonocore et al. 2016; Chang et al. 2017; Helgenberger
46 and Jänicke 2017). Co-benefits occur when implementing mitigation (or adaptation) measures that have
47 positive effects on adaptation (or mitigation) (Sharifi 2021). In contrast, the trade-offs emerge when

1 measures aimed at improving mitigation (adaptation) undermine the ability to pursue adaptation
2 (mitigation) targets (Sharifi 2020). The magnitude of such co-benefits and trade-offs may vary
3 depending on various factors. A systematic review of over 50 climate change articles provides evidence
4 that mitigation can contribute to resilience—especially to temperature changes and flooding—with
5 varying magnitudes depending on factors, such as the type of mitigation measure and the scale of
6 implementation (Sharifi 2019).

7 Measures from different sectors that can provide both mitigation and adaptation benefits involve urban
8 planning (see Section 8.4.2), buildings (Sections 8.4.3.2 and 8.4.4), energy (Section 8.4.3), green and
9 blue infrastructure (Section 8.4.4), transportation (Section 8.4.2), socio-behavioural aspects (Section
10 8.4.5), urban governance (Section 8.5), waste (Section 8.4.5.2), and water (Section 8.4.6). In addition
11 to their energy-saving and carbon-sequestration benefits, many measures can also enhance adaptation
12 to climate threats, such as extreme heat, energy shocks, floods, and droughts (Sharifi 2021). Existing
13 evidence is mainly related to urban green infrastructure, urban planning, transportation, and buildings.
14 There has been more emphasis on the potential co-benefits of measures, such as proper levels of density,
15 building energy efficiency, distributed and decentralized energy infrastructure, green roofs and facades,
16 and public/active transport modes. Renewable-based distributed and decentralized energy systems
17 improve resilience to energy shocks and can enhance adaptation to water stress considering the water-
18 energy nexus. By further investment on these measures, planners and decision makers can ensure
19 enhancing achievement of mitigation/adaptation co-benefits at the urban level (Sharifi 2021).

20 As for trade-offs, some mitigation efforts may increase exposure to stressors such as flooding and the
21 urban heat island (UHI) effect (see Glossary), thereby reducing the adaptive capacity of citizens. For
22 instance, in some contexts, high-density areas that lack adequate provision of green and open spaces
23 may intensify the UHI effect (Pierer and Creutzig 2019; Xu et al. 2019). There are also concerns that
24 some mitigation efforts may diminish adaptive capacity of urban poor and marginalized groups through
25 increasing costs of urban services and/or eroding livelihood options. Environmental policies designed
26 to meet mitigation targets through phasing out old vehicles may erode livelihood options of poor
27 households, thereby decreasing their adaptive capacity (Colenbrander et al. 2017). Ambitious mitigation
28 and adaptation plans could benefit private corporate interests resulting in adverse effects on the urban
29 poor (Chu et al. 2018; Mehta et al. 2019).

30 Urban green and blue infrastructure such as urban trees, greenspaces, and urban waterways can
31 sequester carbon and reduce energy demand, and provide adaptation co-benefits by mitigating the UHI
32 effect (Berry et al. 2015; Wamsler and Pauleit 2016; WCRP 2019) (see Section 8.4.4, Figure 8.18, and
33 Box 8.2).

34

44 **Introduction**

45 This Cross-Working Group Box on Cities and Climate Change responds to the critical role of
46 urbanization as a mega-trend impacting climate adaptation and mitigation. Issues associated with cities

1 and urbanization are covered in substantial depth within all three Working Groups (including WGI Box
2 TS.14, WGII Chapter 6 ‘Cities, settlements and key infrastructure,’ WGII regional chapters, WGII
3 Cross-Chapter Paper ‘Cities and settlements by the sea’, and WGIII Chapter 8 ‘Urban systems and other
4 settlements’). This Box highlights key findings from WGII and III and substantial gaps in literature
5 where more research is urgently needed relating to policy action in cities. It describes methods of
6 addressing mitigation and adaptation in an integrated way across sectors and cities to advance
7 sustainable development and equity outcomes and assesses the governance and finance solutions
8 required to support climate resilient responses.

9 *Urbanization: A megatrend driving global climate risk and potential for low-carbon and resilient*
10 *futures*

11 Severe weather events, exacerbated by anthropogenic emissions, are already having devastating impacts
12 on people who live in urban areas, on the infrastructure that supports these communities, as well as
13 people living in distant places (*high confidence*) (Cai et al. 2019; Folke et al. 2021). Between 2000 and
14 2015, the global population in locations that were affected by floods grew by 58–86 million (Tellman
15 et al. 2021). The direct economic costs of all extreme events reached USD 210–268 billion in 2020 (Aon
16 2021; Munich RE 2021; WMO 2021) or about USD 0.7 billion per day; this figure does not include
17 knock-on costs in supply chains (Kii 2020) or lost days of work, implying that the actual economic
18 costs could be far higher. Depending on RCP, between half (RCP2.6) and three-quarters (RCP8.5) of
19 the global population could be exposed to periods of life-threatening climatic conditions arising from
20 coupled impacts of extreme heat and humidity by 2100 (Mora et al. 2017; Huang et al. 2019) (see WGII
21 Section 6.2.2.1, WGII Figure 6.3, and WGIII Sections 8.2 and 8.3.4).

22 Urban systems are now global, as evidenced by the interdependencies between infrastructure, services,
23 and networks driven by urban production and consumption; remittance flows and investments reach
24 into rural places shaping natural resource use far from the city and bring risk to the city when these
25 places are impacted by climate change (see WGIII Sections 8.4 and WGIII Figure 8.15). This megatrend
26 (Kourtit et al. 2015) amplifies as well as shapes the potential impacts of climate events and integrates
27 the aims and approaches for delivering mitigation, adaptation, and sustainable development (*medium*
28 *evidence, high agreement*) (Dawson et al. 2018; Tsavdaroglou et al. 2018; Zscheischler et al. 2018). For
29 cities facing flood damage, wide-ranging impacts have been recorded on other urban areas near and far
30 (Carter et al. 2021; Simpson et al. 2021) as production and trade is disrupted (Shughrue et al. 2020). In
31 the absence of integrated mitigation and adaptation across and between infrastructure systems and local
32 places, impacts that bring urban economies to a standstill can extend into supply chains and across
33 energy networks causing power outages.

34 Urban settlements contribute to climate change, generating about 70% of global CO₂-eq emissions (*high*
35 *confidence*) (see WGI Box TS.14, WGII Sections 6.1 and 6.2, and WGIII Section 8.3). This global
36 impact feeds back to cities through the exposure of infrastructure, people, and business to the impacts
37 of climate-related hazards. Particularly in larger cities, this climate feedback is exacerbated by local
38 choices in urban design, land use, building design, and human behaviour (Viguié et al. 2020) that shape
39 local environmental conditions. Both the local and global combine to increase hazardousness. Certain
40 configurations of urban form and their elements can add up to 2°C to warming; concretisation of open
41 space can increase run-off, and building height and orientation influences wind direction and strength
42 (see WGII Section 6.3 and WGIII Section 8.4.2).

43 Designing for resilient and low-carbon cities today is far easier than retrofitting for risk reduction
44 tomorrow. As urbanization unfolds, its legacy continues to be the locking-in of emissions and
45 vulnerabilities (*high confidence*) (Seto et al. 2016; Ürge-Vorsatz et al. 2018) (see WGIII Section 8.4
46 and Figure 8.15). Retrofitting, disaster reconstruction, and urban regeneration programmes offer scope
47 for strategic direction changes to low-carbon and high-resilience urban form and function, so long as
48 they are inclusive in design and implementation. Rapid urban growth means new investment, new

1 buildings and infrastructure, new demands for energy and transport and new questions about what a
2 healthy and fulfilling urban life can be. The USD 90 trillion expected to be invested in new urban
3 development by 2030 (NCE 2018) is a global opportunity to place adaptation and mitigation directly
4 into urban infrastructure and planning, as well as to consider social policy including education,
5 healthcare, and environmental management (Ürge-Vorsatz et al. 2018). If this opportunity is missed,
6 and business-as-usual urbanization persists, social and physical vulnerability will become much more
7 challenging to address.

8 The benefits of actions taken to reduce GHG emissions and climate stressors diminish with delayed
9 action, indicating the necessity for rapid responses. Delaying the same actions for increasing the
10 resilience of infrastructure from 2020 to 2030 is estimated to have a median cost of at least USD 1
11 trillion (Hallegatte et al. 2019) while also missing the carbon emissions reductions required in the
12 narrowing window of opportunity to limit global warming to 1.5°C (WGI). In contrast, taking integrated
13 actions towards mitigation, adaptation, and sustainable development will provide multiple benefits for
14 the health and well-being of urban inhabitants and avoid stranded assets (see WGII Section 6.3, WGII
15 Chapter 17, Cross-Chapter Box FEASIBILITY in WGII Chapter 18, WGIII Chapter 5, and WGIII
16 Section 8.2).

17 *The policy-action gap: urban low-carbon and climate resilient development*

18 Cities are critical places to realize both adaptation and mitigation actions simultaneously with potential
19 co-benefits that extend far beyond cities (*medium evidence high agreement*) (Göpfert et al. 2019;
20 Grafakos et al. 2020). Given rapid changes in the built environment, transforming the use of materials
21 and the land intensiveness of urban development, including in many parts of the Global South, will be
22 critical in the next decades, as well as mainstreaming low-carbon development principles in new urban
23 development in all regions. Much of this development will be self-built and ‘informal’—and new modes
24 of governance and planning will be required to engage with this. Integrating mitigation and adaptation
25 now rather than later, through reshaping patterns of urban development and associated decision-making
26 processes, is a prerequisite for attaining resilient and zero-carbon cities (see WGIII Sections 8.4 and
27 8.6, and WGIII Figure 8.21).

28 While more cities have developed plans for climate adaptation and mitigation since AR5, many remain
29 to be implemented (*limited evidence, high agreement*) (Araos et al. 2017; Aguiar et al. 2018; Olazabal
30 and Ruiz De Gopegui 2021). A review of local climate mitigation and adaptation plans across 885 urban
31 areas of the European Union suggests mitigation plans are more common than adaptation plans—and
32 that city size, national legislation, and international networks can influence the development of local
33 climate and adaptation plans with an estimated 80% of those cities with above 500,000 inhabitants
34 having a mitigation and/or an adaptation plan (Reckien et al. 2018).

35 Integrated approaches to tackle common drivers of emissions and cascading risks provide the basis for
36 strengthening synergies across mitigation and adaptation, and help manage possible trade-offs with
37 sustainable development (*limited evidence, medium agreement*) (Grafakos et al. 2019; Landauer et al.
38 2019; Pierer and Creutzig 2019). An analysis of 315 local authority emission reduction plans reveals
39 that the most common policies cover municipal assets and structures (Palermo et al. 2020a). Estimates
40 of emission reductions by non-state and sub-state actors in ten high-emitting economies projected GHG
41 emissions in 2030 would be 1.2–2.0 GtCO₂-eq per year or 3.8–5.5% lower compared to scenario
42 projections for current national policies (31.6–36.8 GtCO₂-eq per year) if the policies are fully
43 implemented and do not change the pace of action elsewhere (Kuramochi et al. 2020). The value of
44 integrating mitigation and adaptation is underscored in the opportunities for decarbonizing existing
45 urban areas, and investing in social, ecological, and technological infrastructure resilience (WGII
46 Section 6.4). Integrating mitigation and adaptation is challenging (Landauer et al. 2019) but can provide
47 multiple benefits for the health and well-being of urban inhabitants (Sharifi 2021) (See WGIII Section
48 8.2.3).

1 Effective climate strategies combine mitigation and adaptation responses, including through linking
2 adaptive urban land use with GHG emission reductions (*medium evidence, high agreement*) (Xu et al.
3 2019; Patterson 2021). For example, urban green and blue infrastructure can provide co-benefits for
4 mitigation and adaptation (Ürge-Vorsatz et al. 2018) and is an important entry point for integrating
5 adaptation and mitigation at the urban level (Frantzeskaki et al. 2019) (see WGIII Section 8.4.4 and
6 WGIII Figure 8.18). Grey and physical infrastructure, such as sea defences can immediately reduce
7 risk, but also transfer risk and limit future options. Social policy interventions including social safety
8 nets provide financial security for the most at-risk and can manage vulnerability determined by specific
9 hazards or independently.

10 Hazard-independent mechanisms for vulnerability reduction—such as population-wide social
11 security—provide resilience in the face of unanticipated cascading impacts or surprise and novel
12 climate-related hazard exposure. Social interventions can also support or be led by ambitions to reach
13 the SDGs (Archer 2016). Climate-resilient development invites planners to develop interventions and
14 monitor the effectiveness of outcomes beyond individual projects and across wider remits that consider
15 sustainable development. Curbing the emission impacts of urban activities to reach net zero emissions
16 in the next decades, while improving the resilience of urban areas, necessitates an integrated response
17 now.

18 Key gaps in knowledge include: urban-enabling environments; the role of smaller settlements, low-
19 income communities, and informal settlements, as well as those in rental housing spread across the city;
20 and the ways in which actions to reduce supply chain risk can be supported to accelerate equitable and
21 sustainable adaptation in the face of financial and governance constraints (Birkmann et al. 2016; Shi et
22 al. 2016; Rosenzweig et al. 2018; Dulal 2019).

23 *Enabling action*

24 Innovative governance and finance solutions are required to manage complex and interconnected risks
25 across essential key infrastructures, networks, and services, as well as to meet basic human needs in
26 urban areas (*medium confidence*) (Colenbrander et al. 2018a; Moser et al. 2019). There are many
27 examples of ‘ready-to-use’ policy tools, technologies, and practical interventions for policymakers
28 seeking to act on adaptation and mitigation (Bisaro and Hinkel 2018; Keenan et al. 2019; Chirambo
29 2021) (see WGIII Section 8.5.4). Tax and fiscal incentives for businesses and individuals can help
30 support city-wide behaviour change towards low-carbon and risk reducing choices. Change can start
31 where governments have most control—often in public sector institutions and investment—but the
32 challenge ahead requires partnership with private sector and community actors acting at scale and with
33 accountability. Urban climate governance and finance needs to address urban inequalities at the
34 forefront if the urban opportunity is to realize the ambition of the SDGs.

35 Increasing the pace of investments will put pressure on governance capability, transparency, and
36 accountability of decision-making (*medium confidence*) (see WGII Section 6.4.5). Urban climate action
37 that actively includes local actors is more likely to avoid unintended, negative maladaptive impacts and
38 mobilize a wide range of local capacities. In the long run, this is also more likely to carry public support,
39 even if some experiments and investments do not deliver the intended social benefits. Legislation,
40 technical capacity, and governance capability is required to be able to absorb additional finance.

41 In recent years, about USD 384 billion of climate finance has been invested in urban areas per year.
42 This remains at about 10% of the annual climate finance that would be necessary for low-carbon and
43 resilient urban development at a global scale (Negreiros et al. 2021). Rapid deployment of funds to
44 stimulate economies in the recovery from COVID-19 has highlighted the pitfalls of funding expansion
45 ahead of policy innovation and capacity building. The result can be an intensification of existing carbon-
46 intensive urban forms—exactly the kinds of ‘carbon lock-in’ (see WGIII Glossary and WGIII Section

1 8.4.1) that have contributed to risk creation and its concentration amongst those with little public voice
2 or economic power.

3 Iterative and experimental approaches to climate adaptation and mitigation decision-making grounded
4 in data and co-generated in partnership with communities can advance low-carbon climate resilience
5 (*medium evidence, high confidence*) (Culwick et al. 2019; Caldarice et al. 2021; van der Heijden and
6 Hong 2021). Conditions of complexity, uncertainty, and constrained resources require innovative
7 solutions that are both adaptive and anticipatory. Complex interactions among multiple agents in times
8 of uncertainty makes decision-making about social, economic, governance, and infrastructure choices
9 challenging and can lead decision-makers to postpone action. This is the case for those balancing
10 household budgets, residential investment portfolios, and city-wide policy responsibilities. Living with
11 climate change requires changes to business-as-usual design-making. Co-design and collaboration with
12 communities through iterative policy experimentation can point the way towards climate resilient
13 development pathways (Ataöv and Peker 2021). Key to successful learning is transparency in
14 policymaking, inclusive policy processes, and robust local modelling, monitoring, and evaluation,
15 which are not yet widely undertaken (Sanchez Rodriguez et al. 2018; Ford et al. 2019).

16 The diversity of cities' experiences of climate mitigation and adaptation strategies brings an advantage
17 for those city governments and other actors willing to 'learn together' (*limited evidence, high*
18 *confidence*) (Bellinson and Chu 2019; Haupt and Coppola 2019). While contexts are varied, policy
19 options are often similar enough for the sharing of experiments and policy champions. Sharing expertise
20 can build on existing regional and global networks, many of which have already placed knowledge,
21 learning, and capacity-building at the centre of their agendas. Learning from innovative forms of
22 governance and financial investment, as well as strengthening coproduction of policy through inclusive
23 access to knowledge and resources, can help address mismatches in local capacities and strengthen
24 wider SDGs and COVID-19 recovery agendas (*limited evidence, medium agreement*). Perceptions of
25 risk can greatly influence the reallocation of capital and shift financial resources (Battiston et al. 2021).
26 Coupling mitigation and adaptation in an integrated approach offers opportunities to enhance efficiency,
27 increases the coherence of urban climate action, generates cost savings, and provides opportunities to
28 reinvest the savings into new climate action projects to make all urban areas and regions more resilient.

29 Local governments play an important role in driving climate action across mitigation and adaptation as
30 managers of assets, regulators, mobilizers, and catalysts of action, but few cities are undertaking
31 transformative climate adaptation or mitigation actions (*limited evidence, medium confidence*)
32 (Heikkinen et al. 2019). Local actors are providers of infrastructure and services, regulators of zoning,
33 and can be conveners and champions of an integrated approach for mitigation and adaptation at multiple
34 levels (*limited evidence high confidence*). New opportunities in governance and finance can enable
35 cities to pool resources together and aggregate interventions to innovate ways of mobilizing urban
36 climate finance at scale (Colenbrander et al. 2019; Simpson et al. 2019; White and Wahba 2019).
37 However, research increasingly points towards the difficulties faced during the implementation of
38 climate financing in situ, such as the fragmentation of structures of governance capable of managing
39 large investments effectively (Mohammed et al. 2019) (see WGIII Section 8.5 and WGIII Chapter 13).

40 Scaling up transformative place-based action for both adaptation and mitigation requires enabling
41 conditions, including land-based financing, intermediaries, and local partnerships (*medium evidence,*
42 *high agreement*) (Chu et al. 2019; Chaudhuri, 2020) supported by a new generation of big data
43 approaches. Governance structures that combine actors working at different levels with a different mix
44 of tools are effective in addressing challenges related to implementation of integrated action while
45 cross-sectoral coordination is necessary (Singh et al. 2020). Joint institutionalization of mitigation and
46 adaptation in local governance structures can also enable integrated action (Göpfert et al. 2020;
47 Hurlimann et al. 2021). However, the proportion of international finance that reaches local recipients
48 remains low, despite the repeated focus of climate policy on place-based adaptation and mitigation

1 (Manuamorn et al. 2020). Green financing instruments that enable local climate action without
2 exacerbating current forms of inequality can jointly address mitigation, adaptation, and sustainable
3 development. Climate finance that also reaches beyond larger non-state enterprises (e.g., small and
4 medium-sized enterprises, local communities, non-governmental organizations—NGOs, etc.), and is
5 inclusive in responding to the needs of all urban inhabitants (e.g., disabled individuals, citizens of
6 different races or ethnicities, etc.) is essential for inclusive and resilient urban development
7 (Colenbrander et al. 2019; Gabaldón-Estevan et al. 2019; Frenova 2021). Developing networks that can
8 exert climate action at scale is another priority for climate finance.

9 The urban megatrend is an opportunity to transition global society. Enabling urban governance to avert
10 cascading risk and achieve low-carbon, resilient development will involve the coproduction of policy
11 and planning, rapid implementation and greater cross sector coordination, and monitoring and
12 evaluation (*limited evidence, medium agreement*) (Di Giulio et al. 2018; Grafakos et al. 2019). New
13 constellations of responsible actors are required to manage hybrid local-city or cross-city risk
14 management and decarbonization initiatives (*limited evidence, medium agreement*). These may
15 increasingly benefit from linkages across more urban and more rural space as recognition of cascading
16 and systemic risk brings recognition of supply chains, remittance flows, and migration trends as vectors
17 of risk and resilience. Urban governance will be better prepared in planning, prioritizing, and financing
18 the kind of measures that can reduce GHG emissions and improve resilience at scale when they consider
19 a view of cascading risks and carbon lock-ins globally, while also acting locally to address local
20 limitations and capacities, including the needs and priorities of urban citizens (Colenbrander et al.
21 2018a; Rodrigues 2019).

22 **END CROSS-WORKING GROUP BOX 2 HERE**

23 **8.3 Urban systems and GHG emissions**

24 This section assesses trends in urban land use, the built environment, and urban GHG emissions, as well
25 as forecasts for urban land use and emissions under certain scenarios to 2050 or 2100. These trends and
26 scenarios hold implications for optimizing the approaches to urban climate change mitigation discussed
27 in Section 8.4 and 8.6.

28 **8.3.1 Trends in urban land use and the built environment**

29 Urban land use is one of the most intensive human impacts on the planet (Pouyat et al. 2007; Grimm et
30 al. 2008). Urban land expansion to accommodate a growing urban population has resulted in the
31 conversion of agricultural land (Pandey et al. 2018; Liu et al. 2019), deforestation (van Vliet 2019),
32 habitat fragmentation (Liu et al. 2016b), biodiversity loss (McDonald et al. 2018, 2020), and the
33 modification of urban temperatures and regional precipitation patterns (Li et al. 2017; Krayenhoff et al.
34 2018; Liu and Niyogi 2019; Zhang et al. 2019).

35 Urban land use and the associated built environment and infrastructure shape urban GHG emissions
36 through the demand for materials and the ensuing energy-consuming behaviours. In particular, the
37 structure of the built environment (i.e., its density, form, and extent) have long-lasting influence on
38 urban GHG emissions, especially those from transport and building energy use, as well as the embodied
39 emissions of the urban infrastructure (Butler et al. 2014; Salat et al. 2014; Ramaswami et al. 2016; Seto
40 et al. 2016; d'Amour et al. 2017). Thus, understanding trends in urban land use is essential for assessing
41 energy behaviour in cities as well as long-term mitigation potential (see Sections 8.4 and 8.6, and Figure
42 8.21).

43 This section draws on the literature to discuss three key trends in urban land expansion, and how those
44 relate to GHG emissions.

1 First, urban land areas are growing rapidly all around the world. From 1975 to 2015, urban settlements
2 expanded in size approximately 2.5 times, accounting for 7.6% of the global land area (Pesaresi et al.
3 2016). Nearly 70% of the total urban expansion between 1992 and 2015 occurred in Asia and North
4 America (Liu et al. 2020a). By 2015, the extent of urban and built-up lands was between 0.5–0.6% of
5 the total 130 Mkm² global ice-free land use, taking up other uses such as fertile cropland and natural
6 ecosystems.

7 Second, as Figure 8.5 shows, urban population densities are declining, with significant implications for
8 GHG emissions. From 1970 to 2010, while the global urban settlement extent doubled in size (Pesaresi
9 et al. 2016), most regions (grouped by the WGIII AR6 10-region aggregation) exhibited a trend of
10 decreasing urban population densities suggesting expansive urban growth patterns. Urban population
11 densities have consistently declined in the Asia-Pacific Developed, Europe, North America, and
12 Southern Asia regions, across all city sizes. North America consistently had the lowest urban population
13 densities. Notably, the Middle East region appears to be the only region exhibiting an overall increasing
14 trend across all city-size groups, while Latin America and Caribbean appears to be relatively stable for
15 all city sizes. While the larger cities in Africa and South-East Asia and Developing Pacific exhibit
16 slightly stable urban population densities, the small- and medium-sized cities in those regions trend
17 toward lower urban population densities. In large urban centres of Eastern Asia and North America,
18 rapid decreases in earlier decades seem to have tapered. Compared to larger cities, small-medium urban
19 areas with populations of less than 2 million have more declines in urban population densities and
20 higher rates of urban land expansion (Güneralp et al. 2020).

21

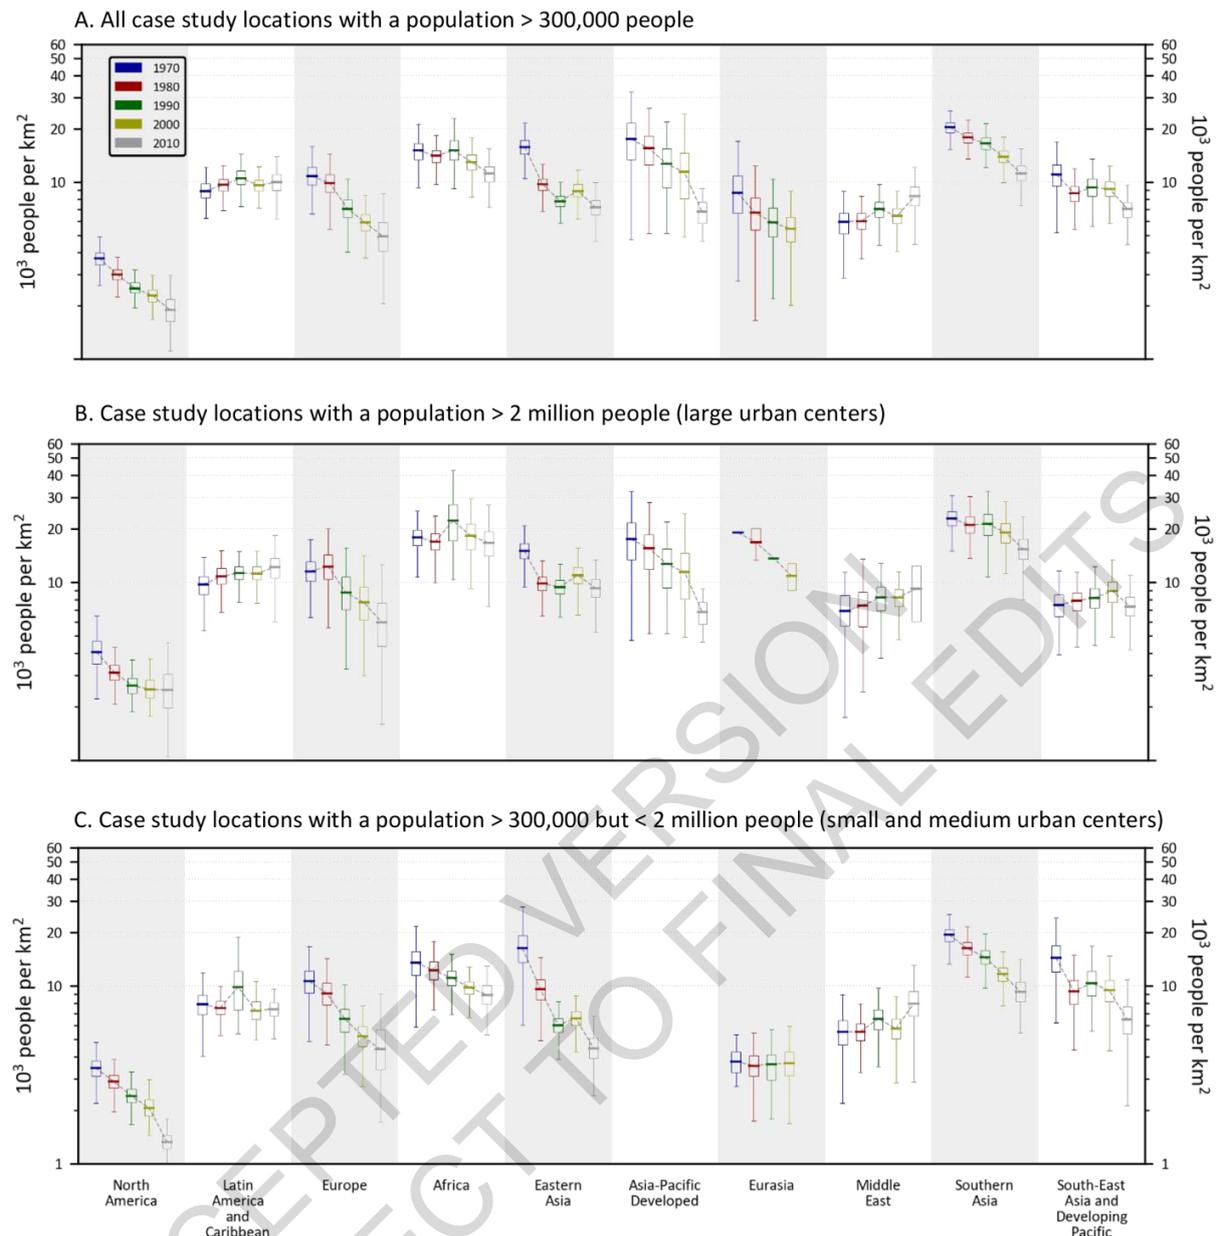

Figure 8.5 Urban population density by decade (1970-2010) grouped by the WGIII AR6 10-region aggregation.

The first panel (a) displays the results from all case study locations with a population >300,000. Panels (b) and (c) show results grouped by city size: (b) cities with a population >2 million (large urban centres), and (c) those with a population >300,000 but <2 million (small and medium urban centres). Box plots show the median, first and third quartiles, and lower and upper mild outlier thresholds of bootstrapped average urban population densities at the turn of each decade. The estimates are shown on a logarithmic scale. The data shows an overall trend of declining urban population densities among all but one region in the last four decades, at varying rates—although the Latin America and Caribbean region indicates relatively constant urban population density over time. The Middle East region is the only region to present with an increase in urban population density across all city sizes.

Source: Adapted from Güneralp et al. (2020, p. 7)

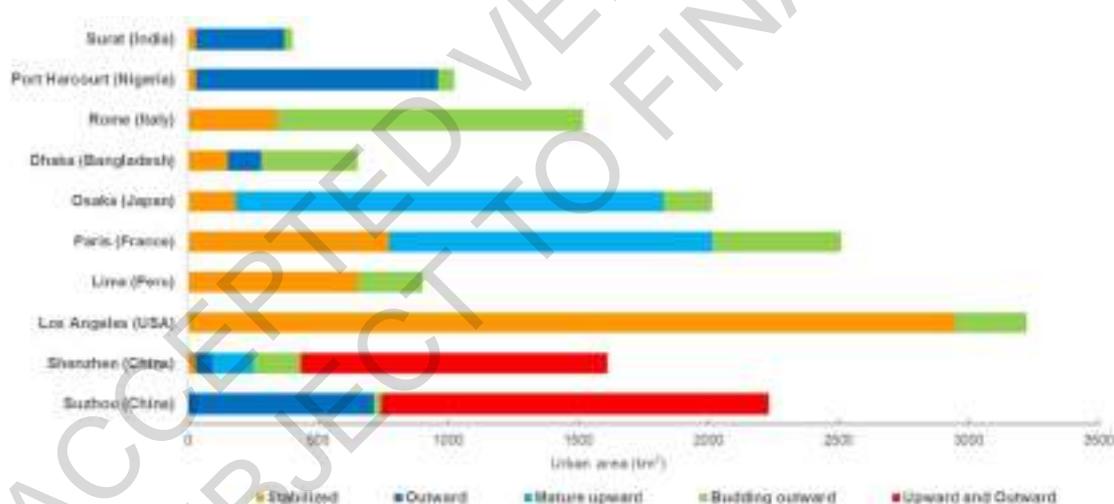

This decline in urban densities is paralleled by an increase in ‘sprawl’, or ‘outward’ urban development. Urban expansion occurs in either one of three dimensions: (1) outward in a horizontal manner; (2) upward, by way of vertical growth; or (3) infill development, where unused, abandoned,

1 or underutilized lands within existing urban areas are developed or rehabilitated (see, also, Figure
2 8.20). Outward expansion results in more urban land area and occurs at the expense of other land uses
3 (i.e., the conversion and loss of cropland, forests, etc.). Vertical expansion results in more multi-story
4 buildings and taller buildings, more floor space per area, and an increase in urban built-up density.

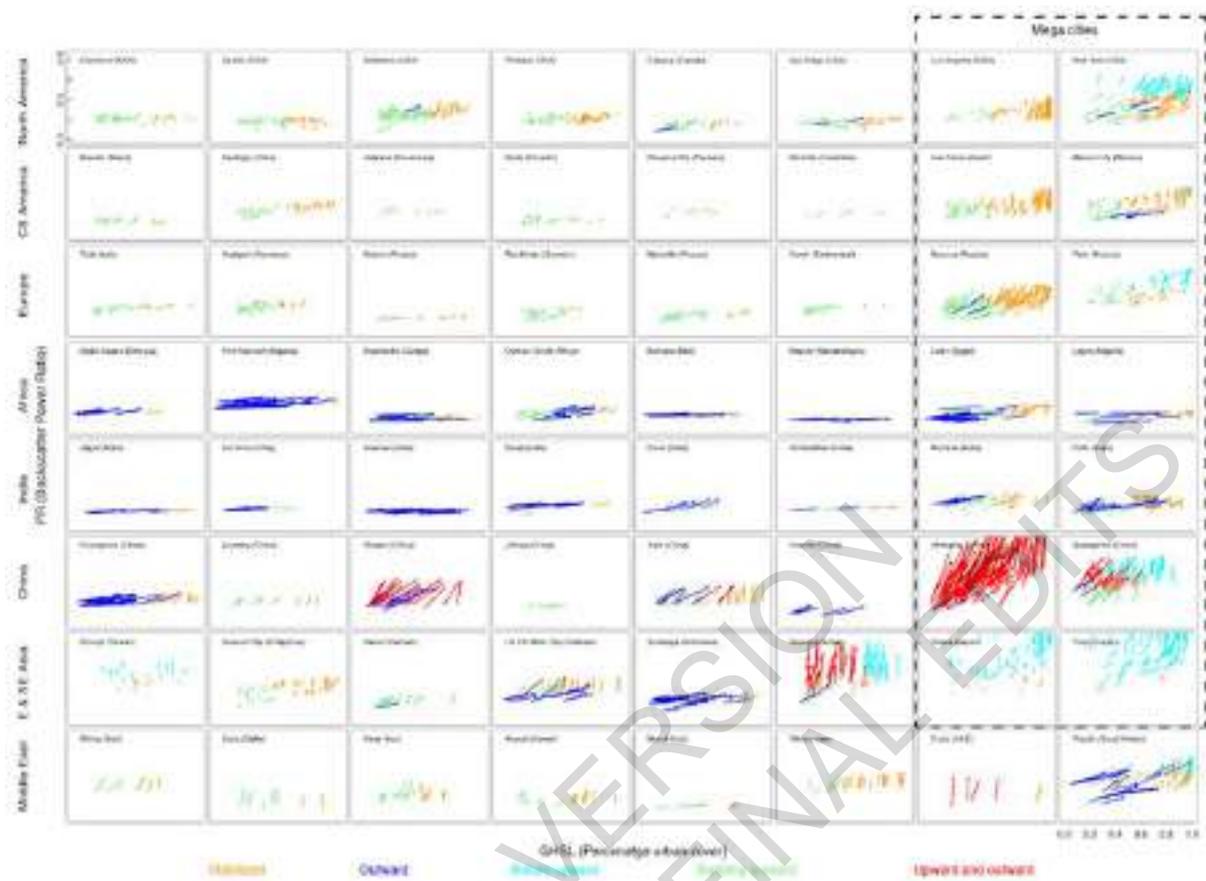

5 Every city has some combination of outward and upward growth in varying degrees (Mahtta et al.
6 2019) (see Figure 8.6). That each city is comprised of different and multiple urban growth typologies
7 suggests the need for differentiated mitigation strategies for different parts of a single city (see Section
8 8.6 and Figure 8.21). Recent research shows that the relative combination of outward versus upward
9 growth is a reflection of its economic and urban development (Lall et al. 2021). That is, how a city
10 grows—whether upward or outward—is a function of its economic development level. Upward
11 growth, or more tall buildings, is a reflection of higher land prices (Ahlfeldt and McMillen 2018;
12 Ahlfeldt and Barr 2020).

13 An analysis of 478 cities with populations of more than 1 million people found that the predominant
14 urban growth pattern worldwide is outward expansion, suggesting that cities are becoming more
15 expansive than dense (Mahtta et al. 2019) (see Figure 8.6). The study also found that cities within a
16 geographic region exhibit remarkably similar patterns of urban growth. Some studies have found a mix
17 of urban forms emerging around the world; an analysis of 194 cities identified an overall trend (from
18 1990 to 2015) toward urban forms that are a mixture of fragmented and compact (Lemoine-Rodriguez
19 et al. 2020). The exception to this trend is a group of large cities in Australia, New Zealand, and the
20 United States that are still predominantly fragmented. The same study also identified small- to medium-
21 sized cities as the most dynamic in terms of their expansion and change in their forms.

9 **outward (green), and upward and outward (red). Note that with few exceptions, each city is comprised of**
10 **multiple typologies of urban growth.**

11
12 Source: Mahtta et al., 2019

13
14 A third trend in is urban land growth taking place on agricultural land, carbon stocks, and other land
15 uses (see ‘carbon stocks’ and ‘AFOLU’—agriculture, forestry, and other land uses—in Glossary). As
16 Figure 8.7 shows, over 60% of the reported urban expansion (nearly 40,000 km²) from 1970 to 2010
17 was formerly agricultural land (Güneralp et al. 2020). This percentage increased to about 70% for global
18 urban expansion that occurred between 1992 and 2015, followed by grasslands (about 12%) and forests
19 (about 9%) (Liu et al. 2020a). In terms of percent of total urban land expansion, the largest conversion
20 of agricultural lands to urban land uses from 1970 to 2010 took place in the Eastern Asia, and South-
21 East Asia and Developing Pacific regions; the largest proportional losses of natural land cover were
22 reported for the North America and Asia-Pacific Developed regions (Güneralp et al. 2020). At a sub-
23 regional level, agricultural land constituted the largest proportion of land converted to urban areas in
24 China, India, Europe, Southeast Asian countries and the central United States between 1995 and 2015;
25 in the eastern United States, most of new urban land was converted from forests (Liu et al. 2020a).
26 Urban expansion through 2040 may lead to the loss of almost 65 Mtonnes of crop production—a

1 scenario that underscores the ongoing relationship between urbanization and AFOLU (van Vliet et al.
2 2017) (see, also, Chapter 7).

3

4

5 **Figure 8.7** Percent of total urban land expansion from other land covers, sorted by the WGIII AR6 10-
6 region aggregation (1970–2010)

7

8

9 As urban land has expanded outward, other forms of land cover, including agriculture, ‘nature’ (e.g.,
10 forest, grassland, shrubland, water, and bare soil), all of which are disaggregated to the bottom half of the
11 plot), and other land covers, have been displaced. Globally, agriculture comprises the majority (about
12 60%) of the land displaced by urban expansion since 1970. Forests and shrubland vegetation—important
13 carbon stocks—also make up a significant proportion of displacement. The loss of carbon-sequestering
14 land like forests and shrubland independently impacts climate change by reducing global carbon stocks.
15 Eurasia is omitted because there are no case studies from that region that report land conversion data.

16

17

18

8.3.2 Informal urban settlements

19 About 880 million people currently live in informal settlements—defined as unplanned areas operating
20 outside of legal and regulatory systems, where residents have no legal claim over their property and
21 have inadequate basic services and infrastructure (United Nations 2018). Furthermore, upgrading
22 informal settlements and inadequate housing is essential for improving resilience to climate change and
23 well-being. Given the ubiquity of informal settlements in developing countries and LDCs, there is
24 potential to harness informality to accelerate transitions to low-carbon urban development. There are
25 several key reasons for their potential to mitigate GHG emissions. First, informal urban areas may not
26 require large investments in retrofitting as they have developed with minimal investment in large-scale
27 infrastructure. Second, these areas exhibit flexibility of development and can potentially be transformed

1 into an urban form that supports low- or carbon-neutral infrastructure for transportation, energy use in
2 residential buildings, and other sectors (Baurzhan and Jenkins 2016; Henneman et al. 2016; Byrne et
3 al. 2017; Oyewo et al. 2019).

4 Informal urban areas can avoid the conventional trajectory of urban development by utilizing large-
5 scale strategies, such as micro-scale technologies, modal shifts towards compact, walkable urban form,
6 as well as decentralized or meso-scale utilities of water, sanitation, and service centres,—thereby
7 mitigating emissions associated with transport and treating wastes (Tongwane et al. 2015; Yang et al.
8 2018). Some specific mitigation options include spatial adjustments for walkability of neighbourhoods,
9 low-energy-intensive mobility, low-energy-intensive residential areas, low-carbon energy sources at
10 city-scale, off-grid utilities, and electrification and enhancement of the urban ecology—all of which
11 have multiple potential benefits (Colenbrander et al. 2017; Fang et al. 2017; Laramée et al. 2018; van
12 der Zwaan et al. 2018; Wu et al. 2018; Silveti and Andersson 2019). Some of the co-benefits of the
13 various mitigation options include more job opportunities and business start-ups, increased incomes,
14 air quality improvement, and enhanced health and well-being (Gebregziabher et al. 2014; Dagnachew
15 et al. 2018; Keramidas et al. 2018; Adams et al. 2019; Ambole et al. 2019; Boltz et al. 2019; Moncada
16 et al. 2019; Weimann and Oni 2019; Manga et al. 2020) (see Section 8.2).

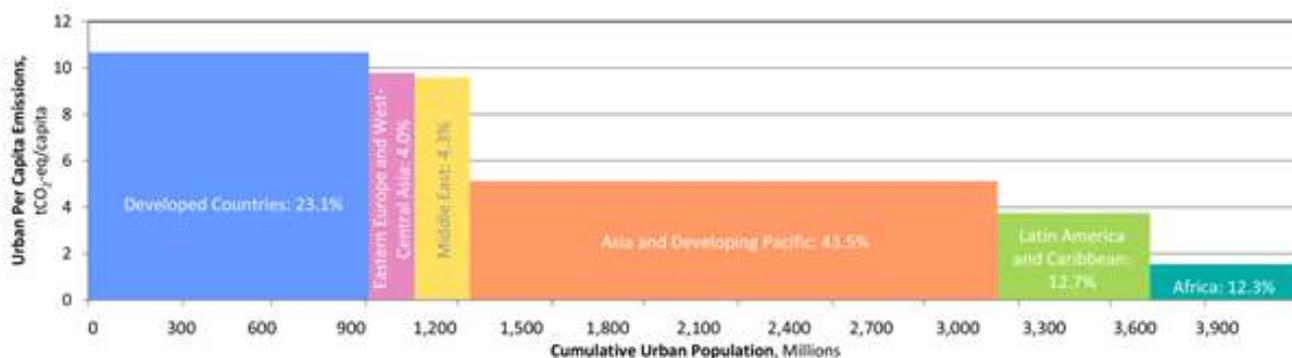

17 Non-networked and non-centralized urban services and infrastructure in informal settlements, including
18 sanitation, waste, water, and electricity, serve over 60% of the urban population in developing country
19 cities (Lawhon et al. 2018). The alternatives of disruptive, hybrid, largely non-networked multiplicity
20 of technologies applicable at micro- to meso-scales have potential for low-emissions development in
21 urban areas of developing countries (Narayana 2009; Dávila and Daste 2012; Radomes Jr and Arango
22 2015; Potdar et al. 2016; Grové et al. 2018). These technologies can be applied in the short-term as
23 responses with long-term influence on emissions reduction. The cumulative impact of the disruptive
24 technologies can reduce emissions by 15–25% through enhanced emissions sinks in small- and medium-
25 sized cities (Tongwane et al. 2015; du Toit et al. 2018; Nero et al. 2018, 2019; Frantzeskaki et al. 2019;
26 Mantey and Sakyi 2019; Singh and G. 2019).

27 **8.3.3 Trends in urban GHG emissions**

29 One major innovation presented in AR6—particularly in this chapter—is the inclusion of trend data on
30 urban GHG emissions. Using multiple datasets in conjunction with the SSP and RCP scenarios, this
31 chapter provides an estimate of urban GHG emissions from 1990 through 2100, based on a
32 consumption-based approach. This innovation provides, for the first time, a temporal dimension to
33 urban footprints considering different climate scenarios with implications for urban mitigation. The new
34 analysis presents a comparison of ways urban emissions can evolve given different scenario contexts
35 (see Section 8.3.4.2). Additionally, new research has quantified trends in urban CO₂ emissions and their
36 key drivers across 91 global cities from 2000 to 2018 (Luqman et al. 2021).

37 Figures 8.8 and 8.9 present key urban emission metrics and trends for six regions (based on the WGIII
38 AR6 regional breakdown)—the first for the year 2015, and the latter for both 2000 and 2015.

39 The key trends are as follows. First, the urban share of global GHG emissions (including CO₂ and CH₄)
40 is substantive and continues to increase (see Figure 8.9). Total urban CO₂-eq emissions based on
41 consumption-based accounting were estimated to be 24.5 GtCO₂-eq, or 62% of the global total in 2015,
42 and increased to an estimated 28.5 ± 0.1 GtCO₂-eq in 2020, representing about 67-72% of global
43 emissions, excluding aviation, shipping, and biogenic sources. About 100 of the highest-emitting urban
44 areas account for approximately 18% of the global carbon footprint (Moran et al. 2018). Globally, the
45 urban share of national CO₂-eq emissions increased 6 percentage points, from 56% in 2000 to 62% in
46 2015.

1

7 **urban population for a given region, based on 2015 values for both axes. Provided within the bars are the**
8 **percentage shares of the urban population by region as a share of the total urban population.**

9
10 Source: Adapted from UN DESA (2019) and Gurney et al. (2021a)

11
12 Second, while urban CO₂ emissions were increasing in all urban areas, the dominant drivers were
13 dependent upon development level. Emissions growth in urban areas other than in Developed
14 Countries was driven by increases in area and per capita emissions. Across all cities, higher
15 population densities are correlated with lower per capita GHG emissions (Luqman et al. 2021).

16 Third, the urban share of regional GHG emissions increased between 2000 and 2015, with much inter-
17 region variation in the magnitude of the increase (*high confidence*) (see Figure 8.9). Between 2000 to
18 2015, the urban emissions share across WGIII AR6 regions (6-region aggregation) increased from 28%
19 to 38% in Africa, from 46% to 54% in Asia and Developing Pacific, from 62% to 72% in Developed
20 Countries, from 57% to 62% in Eastern Europe and West-Central Asia, from 55% to 66% in Latin
21 America and Caribbean, and from 68% to 69% in the Middle East.

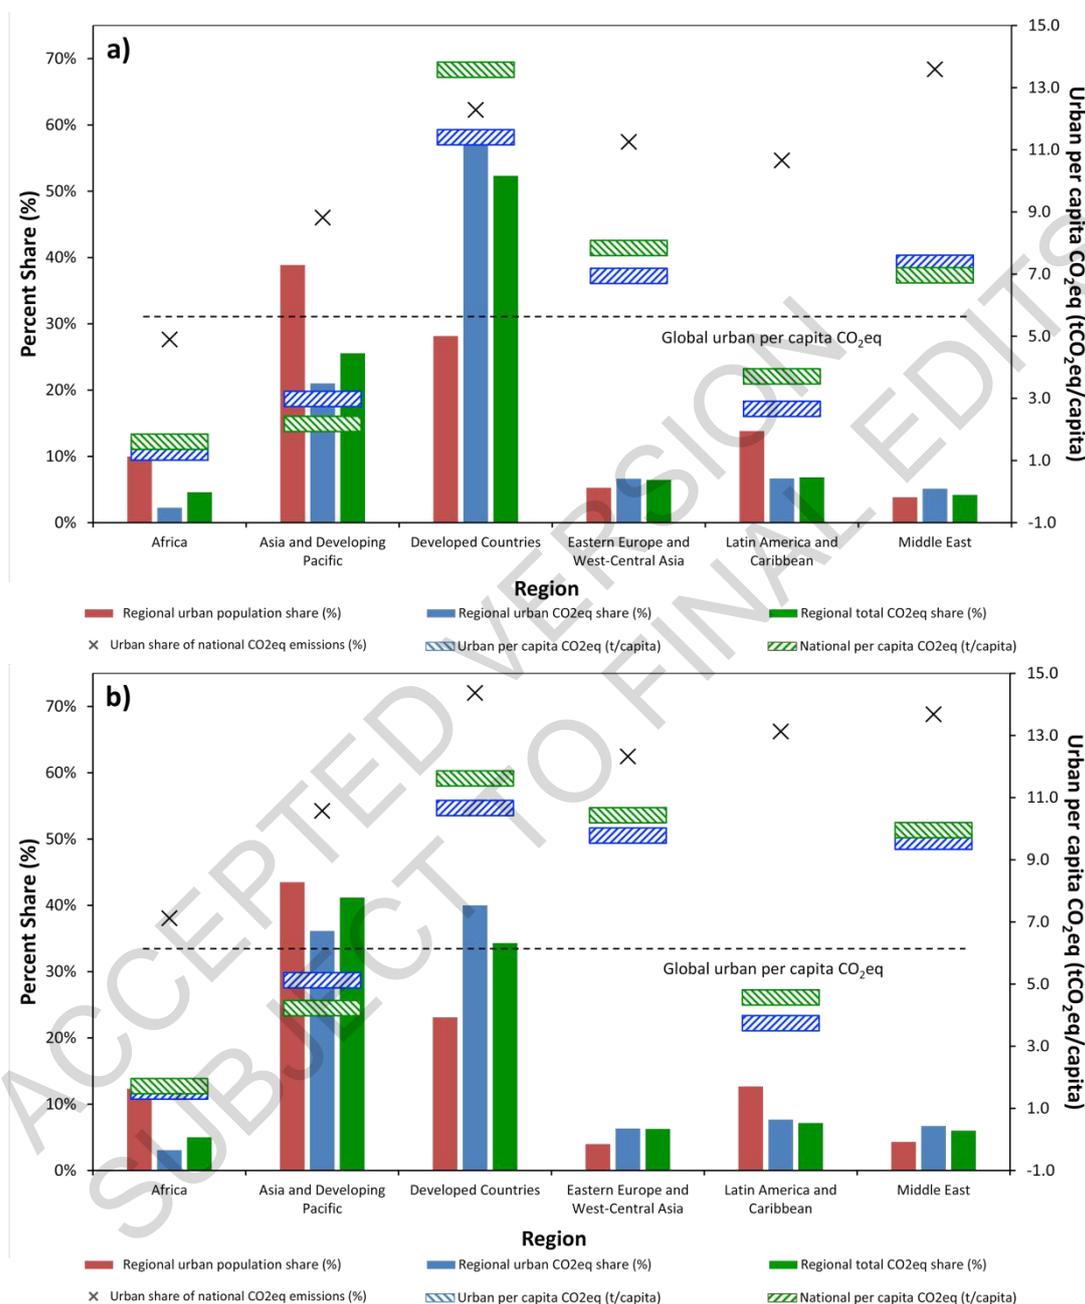

22 Between 2000 and 2015, urban population, urban CO₂-eq emissions, and national CO₂-eq emissions
23 increased as a share of the global total in the Asia and Developing Pacific region while the share
24 declined for Developed Countries. The urban share of total regional CO₂-eq emissions decreased in
25 Developed Countries from 58.2% (2000) to 40.0% (2015). Urban per capita CO₂-eq and national per
26 capita CO₂-eq also increased in all regions except for the urban per capita CO₂-eq value in the
27 Developed Countries region which declined slightly.

28 Fourth, the global average per capita urban GHG emissions increased between 2000 and 2015, with
29 cities in the Developed Countries region producing nearly seven times more per capita than the lowest
30 emitting region (*medium confidence*). From 2000 to 2015, the global urban GHG emissions per capita
31 increased from 5.5 to 6.2 tCO₂-eq per person (an increase of 11.8%), with increases across five of the
32 six regions: Africa increased from 1.3 to 1.5 tCO₂-eq per person (22.6%); Asia and Developing Pacific
33 increased from 3.0 to 5.1 tCO₂-eq per person (71.7%); Eastern Europe and West-Central Asia increased
34 from 6.9 to 9.8 tCO₂-eq per person (40.9%); Latin America and the Caribbean increased from 2.7 to 3.7
35 tCO₂-eq per person (40.4%); and the Middle East increased from 7.4 to 9.6 tCO₂-eq per person (30.1%).
36 Albeit starting from the highest level, Developed Countries had a decline of 11.4 to 10.7 tCO₂-eq per
37 person (-6.5%).

38 In 2015, regional urban per capita consumption-based CO₂-eq emissions were lower than regional
39 consumption-based national per capita CO₂-eq emissions in five of the six regions. These regions in
40 order of the difference are Developed Countries (lower by 1.0 tCO₂-eq per capita), Latin America and

1 Caribbean (lower by 0.8 tCO₂-eq per capita), Eastern Europe and West-Central Asia (lower by 0.7 tCO₂-
 2 eq per capita), Middle East (lower by 0.4 tCO₂-eq per capita), and Africa (lower by 0.2 tCO₂-eq per
 3 capita), while higher only in the Asia and Developing Pacific region (higher by 0.9 tCO₂-eq per capita).
 4 All regions show convergence of the urban and national per capita CO₂-eq, as the urban share of national
 5 emissions increases and dominates the regional total.

6

7

8 **Figure 8.9** Changes in six metrics associated with urban and national-scale CO₂ and CH₄ emissions
 9 represented in the WGIII AR6 6-region aggregation, with (a) 2000 and (b) 2015

10

11 The trends in Luqman et al. (2021) were combined with the work of Moran et al. (2018) to estimate the
 12 regional urban CO₂-eq share of global urban emissions, the urban share of national CO₂-eq emissions,
 13 and the urban per capita CO₂-eq emissions by region. The total values exclude aviation, shipping, and
 14 biogenic sources. The dashed grey line represents the global average urban per capita CO₂-eq emissions.

2 **CO₂-eq emissions by region are given for comparison.**

3
4 Source: Adapted from Gurney et al. (2021)

5
6 **START BOX 8.1 HERE**

7
8 **Box 8.1 Does urbanization drive emissions?**

9
10 Urbanization can drive emissions if the process is accompanied by an income increase and higher levels
11 of consumption (Sudmant et al. 2018). This is typically observed in countries with a large urban-rural
12 disparity in income and basic services, and where urbanization is accompanied by economic growth
13 that is coupled to emissions. In addition, the outward expansion of urban land areas often results in the
14 conversion and loss of agricultural land (Pandey et al. 2018; Liu et al. 2019), forests (Austin et al. 2019),
15 and other vegetated areas, thereby reducing carbon uptake and storage (Quesada et al. 2018) (see
16 Section 8.3.1). Furthermore, the build-up and use of urban infrastructure (e.g., buildings, power,
17 sanitation) requires large amounts of embodied energy and carbon (see Figures 8.17 and 8.22). Building
18 new and upgrading existing urban infrastructure could produce a cumulative emissions of 226 GtCO₂
19 by 2050 (Bai et al. 2018).

20 However, for the same level of consumption and basic services, an average urban dweller often requires
21 less energy than their rural counterparts, due to higher population densities that enable sharing of
22 infrastructure and services, and economies of scale. Whether and to what extent such emission reduction
23 potentials can be realized depends on how cities are designed and laid out (i.e., urban form – see Section
24 8.4.2) as well as how urban infrastructure is built and powered, such as the energy intensity of the city’s
25 transportation system, type and level of urban services, the share of renewable energy, as well as the
26 broader national and international economic and energy structure that supports the function of the cities
27 (see Sections 8.4.3 and 8.6).

28 Although population-dense cities can be more efficient than rural areas in terms of per capita energy
29 use, and cities contribute less GHG emissions per person than low-density suburbs (Jones and Kammen
30 2014), there is some, albeit *limited*, evidence that larger cities are not more efficient than smaller ones
31 (Fragkias et al. 2013; Ribeiro et al. 2019). A number of studies comparing urban and rural residents in
32 the same country have shown that urban residents have higher per capita energy consumption and CO₂
33 emissions (Chen et al. 2019a; Hachaichi and Baouni 2021). There is some evidence that the benefits of
34 higher urban densities on reducing per capita urban GHG emissions may be offset by higher incomes,
35 smaller household sizes, and, most importantly, higher consumption levels, thus creating a counter-
36 effect that could increase GHG emissions with urbanization (Gill and Moeller 2018).

37 Many studies have shown that the relationship between urbanization and GHG emissions is dependent
38 on the level and stage of urban development, and follows an inverted U-shaped relationship of the
39 environmental Kuznets curve (Wang et al. 2016, 2022; Zhang et al. 2017; Xu et al. 2018a; Zhou et al.
40 2019) (see Sections 8.3.1 and 8.6, and Figure 8.20). Considering existing trends, earlier phases of
41 urbanization accompanied by rapid industrialization, development of secondary industries, and high
42 levels of economic growth, are correlated with higher levels of energy consumption and GHG
43 emissions. However, more mature phases of urbanization, with higher levels of economic development
44 and establishment of the service sector, are correlated with lower levels of energy consumption and
45 GHG emissions (Khan and Su 2021).

46 **END BOX 8.1 HERE**

47

1 **8.3.4 Scenarios of future urbanization and GHG emissions**

2 This section assesses scenarios of future urban land expansion and urban GHG emissions. These
3 scenarios have implications for the urban climate change mitigation strategies discussed in Sections 8.4
4 and 8.6—in particular, in the context of the potential mitigation and development pathways for urban
5 areas under certain scenarios.

6 **8.3.4.1 Urban land expansion and GHG emissions**

7 The uncertainties across urban land expansion forecasts, and associated SSPs, highlight an opportunity
8 to pursue compact, low- or net zero GHG emissions development that minimizes land-use competition,
9 avoids carbon lock-in, and preserves carbon-sequestering areas like forests and grasslands (see Sections
10 8.4. and 8.6, and Figure 8.21). Among the forecasts available are six global-scale spatially explicit
11 studies of urban land expansion that have been published since AR5; four of the six, which present
12 forecasts for each of the five SSPs, are considered in Table 8.1 and Figure 8.10 (Huang et al. 2019; Li
13 et al. 2019b; Chen et al. 2020a; Gao and O’Neill 2020). All four have forecasts to 2050 but only three
14 to 2100. One of the two not included here (van Vliet et al. 2017) also forecasts land displacement due
15 to urban land expansion.

16 Four overarching findings can be gleaned from these studies.

17 First, urban land areas will expand significantly by 2050—by as much as 211% (see SSP5 forecast in
18 Huang et al. 2019), but likely within a large potential range of about 43–106% over the 2015 extent by
19 2050—to accommodate the growing urban population (see Table 8.1). Globally, there are large
20 uncertainties and variations among the studies—and between the SSPs—about the rates and extent of
21 future urban expansion, owing to uncertainties about economic development and population growth
22 (ranges of estimates are provided in Table 8.1). Overall, the largest urban extents are forecasted under
23 SSP5 (fossil fuel-intensive development) for both 2050 and 2100, whereas the smallest forecasted urban
24 extents are under SSP3 (‘regional rivalry’). Forecasted global urban extents could reach between 1 and
25 2.2 million km² (median of 1.4 million km², a 106% increase) in 2050 under SSP5, and between 0.85
26 and 1.5 million km² (median of 1 million km², a 43% increase) in 2050 under SSP3. Under SSP1, which
27 is characterized by a focus on sustainability with more compact, low-emissions development, urban
28 extents could reach 1 million km² (range of 0.9 to 2 million km²), a 49% increase, in 2050. By 2100,
29 the forecasted urban extents reach between 1.4 and 3.6 million km² (median 2.5 million km²) under
30 SSP5 and between 1 and 1.5 million km² (median 1.3 million km²) under SSP3. Across the studies,
31 substantially larger amounts of urban land expansion are expected after 2050 under SSP5 compared to
32 other SSPs.

33 Second, there is a wide variation in estimates of urban land expansion across regions (using the WGIII
34 AR6 6-region aggregation). Across all four sets of forecasts, current urban land (circa 2015) is the
35 largest in Developed Countries and in the Asia and Developing Pacific region, with approximately two-
36 thirds of the current urban extent occurring in those two regions (see Table 8.1 and Figure 8.10). The
37 largest increases in urban land by 2050 are expected in the Asia and Developing Pacific and Developed
38 Countries regions, across all the SSPs. However, the rate of increase in urban land in Eastern Europe
39 and West-Central Asia, Latin America and the Caribbean, and the Middle East is significant and urban
40 land could more than double by 2050. One-third of the studies conclude that the United States, China,
41 and India will experience continued urban land expansion at least until 2050 (Huang et al. 2019; Li et
42 al. 2019b). However, Li et al. (2019) report that, after 2050, China could experience a decrease in the
43 rate of urban land expansion, while growth will continue for India. This is not surprising since India’s
44 urban demographic transition will only get underway after the middle of the century, when the urban
45 population is expected to exceed the rural population. In contrast, China’s urban demographic transition
46 could be nearly complete by 2050.

1 Third, in spite of these general trends, there are differences in forecasted urban expansion in each region
2 across the SSPs and studies, with Huang et al. (2019) forecasting the most future urban land expansion
3 between 2015 and 2050. The range across studies is significant. Under SSP1, urban land areas could
4 increase by between 69,000 and 459,000 km² in Developed Countries, 77,000–417,000 km² in Asia and
5 Developing Pacific, and 28,000–216,000 km² in Africa. Under SSP3, where urban land expansion is
6 forecasted to be the lowest, urban land areas could increase by between 23,000 and 291,000 km² in
7 Developed Countries, 57,000–168,000 km² in Asia and Developing Pacific, and 16,000–149,000 km²
8 in Africa. Under SSP5, where urban land expansion is forecasted to be the highest, urban land area
9 could increase by 129,000 to 573,000 km² in Developed Countries, 83,000–472,000 km² in Asia and
10 Developing Pacific, and 40,000–222,000 km² in Africa (Huang et al. 2019; Li et al. 2019b; Chen et al.
11 2020a; Gao and O’Neill 2020). By 2100, however, the Developed Countries region is expected to have
12 the most urban expansion only in SSP5. In SSP2 and SSP4, the Developed Countries and Asia and
13 Developing Pacific regions have about equal amounts of new urban land; in SSP3, Asia and Developing
14 Pacific has more new urban land forecasted.

15 Fourth, both the range of estimates and their implications on land-use competition and urban life point
16 to an opportunity for urban areas to consider their urban form when developing. Under the current
17 urbanization trajectory, 50–63% of newly expanded urban areas are expected to occur on current
18 croplands (Chen et al. 2020a). However, there is significant regional variation; between 2000 and 2040,
19 12.5% of cropland in China and 7.5% of cropland in the Middle East and North Africa could be
20 displaced due to urban expansion, compared to the world average of 3.7% (van Vliet et al. 2017). As
21 urban clusters increase in size and green space is converted, future urban land expansion is expected to
22 intensify UHIs and exacerbate night-time extreme temperatures. An urban footprint increase of 78–
23 171% by 2050 over the urban footprint in 2015 is expected to result in average summer daytime and
24 night-time warming in air temperature of 0.5°C–0.7°C, even up to about 3°C in certain locations (Huang
25 et al. 2019). Furthermore, this urban expansion-induced warming is on average about half—and in
26 certain locations nearly twice—as strong as warming that will be caused by GHG emissions based on
27 the multi-model ensemble average forecasts in RCP4.5. In short, future urban expansion will amplify
28 the background warming caused by GHG emissions, with extreme warming most pronounced during
29 night-time (*very high confidence*) (Huang et al. 2019). These findings corroborate those in the Technical
30 Summary of AR6 WGI (Arias et al. 2021).

31 The forecasted amounts and patterns of urban expansion presented here bear significant uncertainty due
32 to underlying factors beyond mere methodological differences between the studies. These factors
33 include potential changes in the social, economic, and institutional dynamics that drive urban land
34 development across the world (Güneralp and Seto 2013). Some of these changes may come in the form
35 of sudden shocks such as another global economic crisis or pandemic. The forecasts presented here do
36 not take such factors into account.

2 **Figure 8.10** Forecasts of urban land expansion in 2050 and 2100 according to each SSP and WGIII AR6
3 6-region aggregation, by study, where A: Gao and O’Neill (2020), B: Chen et al. (2020a), C: Li et al.
4 (2019), D: Huang et al. (2019), E: Mean across studies, and F: Median across all studies.

5 Three studies (Li et al. 2019b; Chen et al. 2020a; Gao and O’Neill 2020) report forecasts of urban land
6 expansion to both 2050 and 2100. One study (Huang et al. 2019) reports the forecast only to 2050. Global
7 current urban extents and the respective initial years vary slightly among the four studies. Years for
8 values of current urban extent range from 2010 to 2020. See Table 8.1 for the range of data across the
9 four studies and across SSPs.

1 **8.3.4.2 Scenarios of future urban GHG emissions**

2 There remains little globally comprehensive literature on projections of future baseline GHG emissions
3 from urban areas or scenarios deploying urban mitigation actions on the part of city or regional
4 governments. This dearth of research rests on limited urban emissions data that are consistent and
5 comparable across the globe, making review and synthesis challenging (Creutzig et al. 2016b). Some
6 research has presented urban emissions forecasts and related projections, including estimated urban
7 energy use in 2050 (Creutzig et al. 2015), energy savings for low-carbon development (Creutzig et al.
8 2016b), emission savings from existing and new infrastructure (Creutzig et al. 2016a) (see Figure 8.12),
9 and urban emissions from buildings, transport, industry, and agriculture (IEA 2016a).

10 In its study of about 700 urban areas with a population of at least 750,000, the Coalition for Urban
11 Transitions (2019), attempts to quantify the urban portion of global GHG emissions, including the
12 residential and commercial building, transport, waste, and material production (focusing on cement,
13 aluminium, and steel) sectors, along with mitigation wedges aimed at staying below a 2°C level of
14 atmospheric warming (Figure 8.11). Starting in 2015 with a global urban emissions total of almost 14
15 GtCO₂-eq, the study projects an increase to 17.3 GtCO₂-eq by 2050—but this reduces to 1.8 GtCO₂-eq
16 by 2050 with the inclusion of mitigation wedges: 58% from buildings, 21% from transport, 15%
17 materials efficiency, and 5% waste, with decarbonization of electricity supply as a cross-cutting strategy
18 across the wedges.

19 Similar analysis by the urban networks C40 and GCoM examine current and future GHG emissions on
20 smaller subsets of global cities, offering further insight on the potential emissions impacts of urban
21 mitigation options. However, this analysis is limited to just a sample of the global urban landscape and
22 primarily focused on cities in the Global North (GCoM 2018, 2019; C40 Cities et al. 2019) with methods
23 to project avoided emissions in development (Kovac et al. 2020). Different scopes of analysis between
24 sectors, as well as limited knowledge of the impact of existing and new urban infrastructure, limit the
25 possibility of direct comparisons in emissions. Still, the shares of urban mitigation potential ranges
26 between 77.7% and 78.9% for combined strategies that involve decarbonized buildings and transport
27 in urban infrastructure, and the wedges approach the remaining emissions reductions also considering
28 construction materials and waste. This data supports urban areas pursuing a package of multiple,
29 integrated mitigation strategies in planning for decarbonization (see Sections 8.4 and 8.6, and Figure
30 8.21).

31

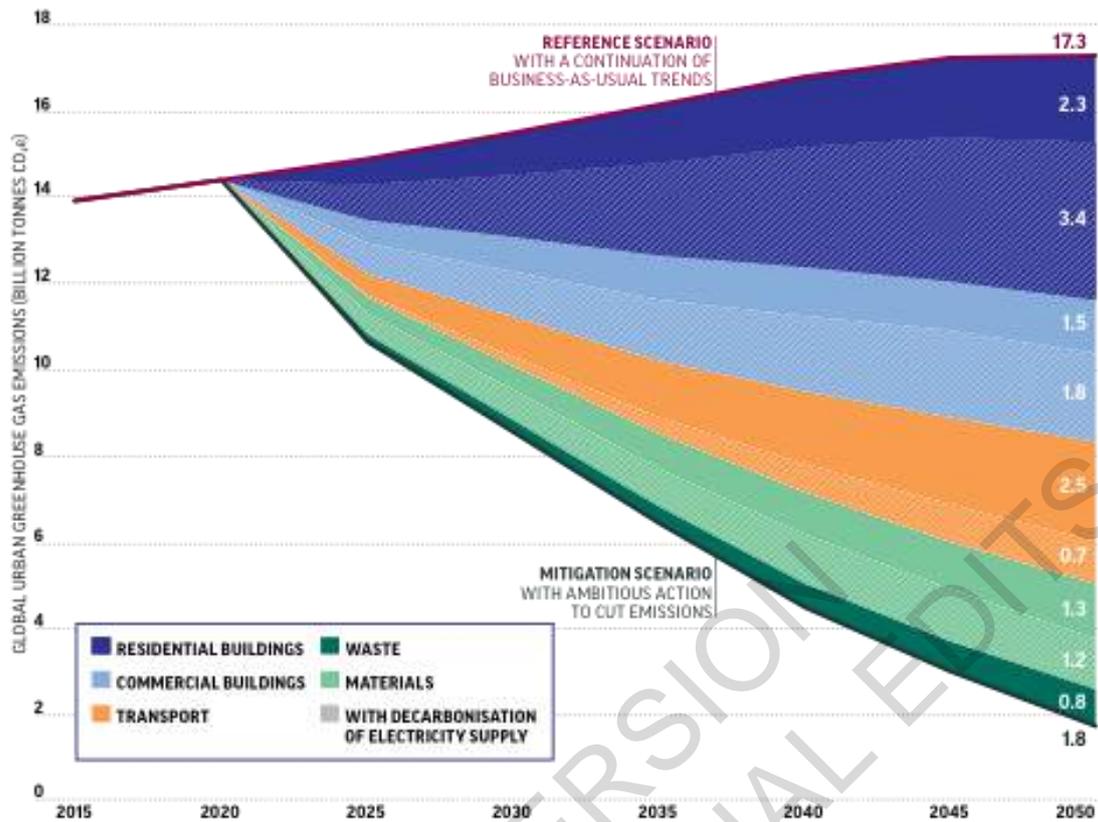

Figure 8.11 Reference scenario and mitigation potential for global urban areas in the residential and commercial building, transport, waste, and material production sectors

The top red line indicates the reference scenario where no further emissions reduction efforts are taken, while the bottom dark line indicates the combined potential of reducing emissions across the sectors displayed. Wedges are provided for potential emissions savings associated with decarbonizing residential buildings, commercial buildings, transport, waste, and materials as indicated in the legend. The shaded areas that take place among the wedges with lines indicate contributions from decarbonization of electricity supply.

1
2 **Figure 8.13 CO₂-eq emissions from global urban areas in seven SSP-RCP variations spanning the 1990 to**
3 **2100 time period**

4 Urban areas are aggregated to six regional domains based on the WGIII AR6 6-region aggregation.
5 Global total CO₂-eq emissions (CO₂ and CH₄) are also shown as marked by the dashed line. Future urban
6 emissions in the context of SSP-RCP-SPA variations correspond to (a) SSP1-RCP1.9-SPA1, (b) SSP1-
7 RCP2.6-SPA1, (c) SSP4-RCP3.4-SPA4, (d) SSP2-RCP4.5-SPA2, (e) SSP4-RCP6.0-SPA4, (f) SSP3-
8 RCP7.0-SPA0 and (g) SSP5-RCP8.5 based on the marker scenario implementations. The first three
9 scenarios (a-c) with more stringent reduction pathways represent contexts where urban per capita
10 emissions decline rapidly against various increases in urban population and are oriented to reach net zero
11 emissions within this century at different radiative forcing levels. SSP1 scenarios (a-b) represent contexts
12 where urbanization takes place rapidly while providing resource efficiency based on compact urban form
13 (Jiang and O'Neill 2017), with high levels of electrification (van Vuuren et al. 2017b; Rogelj et al. 2018).
14 The scenario context of SSP1-RCP1.9 represents a pathway in which there can be a transformative shift
15 towards sustainability. Note that the scale of the panels (f) and (g) are different from the other panels.²

16 See Table 8.2 detailing the SSP-RCPs.

17
18 Source: Adapted from Gurney et al. (2021)

19
20
²FOOTNOTE: The SSP1-RCP1.9 scenario is aligned with the same SSP-RCP context as the Illustrative Mitigation Pathways (IMP) for IMP-LD, IMP-Ren and IMP-SP. Implications are provided in Table 8.3.

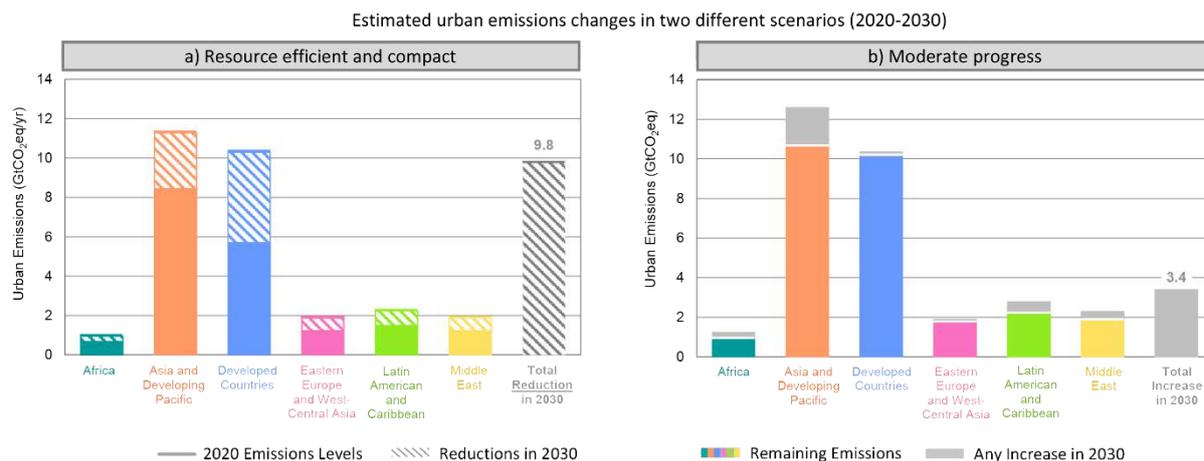

Figure 8.14 Comparison of urban emissions under different urbanization scenarios (GtCO₂-eq yr⁻¹) for the WGIII AR6 6-region aggregation

The panels represent the estimated urban emissions change in two different scenarios for the time period 2020-2030. Panel (a) represents resource efficient and compact urbanization while panel (b) represents urbanization with moderate progress. The two scenarios are consistent with estimated urban emissions under the SSP1-RCP1.9-SPA1 and SSP2-RCP4.5-SPA2 scenarios, respectively (see Figure 8.13). In both panels, urban emissions estimates for the year 2020 are marked by the lines for each region. In the resource efficient and compact scenario, various reductions in urban emissions that take place by 2030 are represented by the dashed areas within the bars. The remaining solid shaded areas represent the remaining urban emissions in 2030 for each region on the path towards net zero emissions. The total reductions in urban emissions worldwide that are given by the last dashed grey bar in panel (a) is estimated to be 9.8 GtCO₂-eq yr⁻¹ between 2020 and 2030 in this scenario. In the scenario with moderate progress, there are no regions with reductions in urban emissions. Above the white lines that represent urban emissions in 2020, the grey shaded areas are the estimated increases for each region so that the total urban emissions would increase by 3.4 GtCO₂-eq yr⁻¹ from 2020 levels in 2030 under this scenario. The values are based on urban scenario analyses as given in Gurney et al. (2021).

Source: Adapted from Gurney et al. (2021)

Table 8.2 Synthesis of the urbanization and scenario contexts of the urban emissions scenarios. Descriptions for urbanization are adapted based on Jiang and O'Neill (2017) while high-, medium-, low-, or mixed-levels in the scenario context are drawn from the marker model implementations of SSP1-SSP5 for IMAGE (van Vuuren et al. 2017b; Rogelj et al. 2018), MESSAGE-GLOBIOM (Fricko et al. 2017), AIM/CGE (Fujimori et al. 2017), GCAM (Calvin et al. 2017), and REMIND-MAGPIE (Kriegler et al. 2017). The letters in parentheses refer to the panels in Figure 8.13. Energy and material efficiency relate to energy efficiency improvement and decrease in the intermediate input of materials, including steel, and cement. Dietary responses include less meat-intensive diets. Implications for urban areas relate to the mitigation options in Section 8.4.

Source: Adapted from Gurney et al. (2021).

SSP/RCP Frame-work	Urbanization Context	Scenario Context					
		Electrification	Energy and material efficiency	Technology development/ innovation	Renewable energy preferences	Behavioural, lifestyle and dietary responses	Afforestation and re-forestation
	Resource efficient,	High	High	High	High	High	High

SSP1 RCP1.9 (a) RCP2.6 (b)	walkable and sustainable rapid urbanization	Implications for urban climate mitigation include: → Electrification across the urban energy system while supporting flexibility in end-use → Resource efficiency from a consumption-based perspective with cross-sector integration → Knowledge and financial resources to promote urban experimentation and innovation → Empowerment of urban inhabitants for reinforcing positive lock-in for decarbonisation → Integration of sectors, strategies and innovations across different typologies and regions					
SSP2 RCP4.5 (d)	Moderate progress	Medium	Medium	Medium	Medium	Medium	Medium
SSP3 RCP7.0 (f)	Slow urbanization, inadequate urban planning	Medium	Low	Low	Medium	Low	Low
SSP4 RCP 3.4 (c) RCP6.0 (e)	Pace of urbanization differs with inequalities	Mixed	Mixed	Mixed	Mixed	Mixed	Mixed
SSP5 RCP8.5 (g)	Rapid urbanization with carbon lock-in	High	Low	High	Low	Low	-

1

2

3 Among the 500 urban areas with the highest consumption-based urban emissions footprint in 2015
4 (Moran et al. 2018), urban level emission scenarios under SSP1 conditions are constructed for 420 urban
5 areas located across all regions of the world (Kılıkış 2021a). These scenarios are based on urban level
6 population projections by SSP (Kii 2021), trends in relevant CMIP6 scenarios (Gidden et al. 2019), and
7 a 100% renewable energy scenario (Bogdanov et al. 2021). In the year 2020, the 420 urban areas are
8 responsible for about 10.7 ± 0.32 GtCO₂-eq, or 27% of the global total CO₂ and CH₄ emissions of about
9 40 GtCO₂-eq, excluding aviation, shipping, and biogenic sources. Under three SSP1-based scenarios,
10 the urban emissions of the 420 urban areas in 2030 is projected to be about 7.0 GtCO₂-eq in SSP1-
11 RCP1.9, 10.5 GtCO₂-eq in SSP1-RCP2.6, and 5.2 GtCO₂-eq in the SSP1 renewable energy scenario.

12 The Illustrative Mitigation Pathways (IMPs) represent different strategies for maintaining temperature
13 goals that are compliant with the Paris Agreement, as well as their comparison with the continuation of
14 current policies (see Table 8.3 and Sections 1.5 and 3.2.5). The key characteristics that define the IMPs
15 involve aspects of energy, land use, lifestyle, policy, and innovation. Urban areas provide cross-cutting
16 contexts where each of these key characteristics can be enabled and have a particularly important role
17 in the transformation pathways for renewable energy (IMP-Ren), low demand (IMP-LD), and shifting
18 to sustainability (IMP-SP). Pathways that are compliant with the Paris Agreement include such urban
19 implications as a reversal of decreasing land-use efficiency in urban areas to lower energy demand
20 based on spatial planning for compact urban form (see Section 8.4.2), changes in urban infrastructure
21 for supporting demand flexibility to handle variable energy supply (see Section 8.4.3), as well as
22 policies and governance that are conducive to innovation in urban areas (see Section 8.5). Spatial
23 planning for compact urban form can enable reduced energy demand and changes in service
24 provisioning, including through walkable neighbourhoods and mixed land use, providing venues for
25 socio-behavioural change towards active transport (see Section 8.4.5). Electrification and sector
26 coupling in urban infrastructure can, for instance, be an important enabler of supporting higher
27 penetrations of renewable energy in the energy system.

28

29

1 **Table 8.3 Cross-cutting implications of the reference scenarios and Illustrative Mitigation Pathways (IMPs) for urban areas. The IMPs illustrate key themes of**
 2 **mitigation strategies throughout the WGIII report (Section 3.2.5). The implications of the key themes of the 6 IMPs (in addition to 2 Pathways illustrative of higher**
 3 **emissions) for mitigation in urban areas are represented based on the main storyline elements that involve energy, land use, food biodiversity and lifestyle, as well**
 4 **as policy and innovation. The cross-cutting implications of these elements for urban areas where multiple elements interact are summarized for each reference**
 5 **scenario and the IMPs. IMP-Ren, IMP-LD and IMP-SP represent pathways in the context of SSP1-1.9.**

6 Source: Adapted from the key themes of the IMPs for urban areas.

Reference Scenarios and IMPs	Cross-Cutting Implications for Urban Areas
Current Policies (CurPol scenario)	<ul style="list-style-type: none"> → Urban mitigation is challenged by overcoming lock-in to fossil fuel consumption also with car-based and low-density urban growth prevailing → Consumption patterns has land impacts, supply chains remain the same, urban inhabitants have limited participation in mitigation options → Progress in low-carbon urban development takes place at a relatively slower pace and there is limited policy learning within climate networks
Moderate Action (ModAct scenarios)	<ul style="list-style-type: none"> → Renewable energy continues to increase its share that is supported by urban areas to a more limited extent with ongoing lock-in effects → Changes in land use, consumption patterns, and lifestyles mostly continue as before with negligible changes taking place—if any → The fragmented policy landscape also prevails at the urban level with different levels of ambitions and without integration across the urban system
Gradual Strengthening (IMP-GS)	<ul style="list-style-type: none"> → Urban areas depend upon energy supply from distant power plants or those in rural areas without rapid progress in urban electrification → Afforestation/reforestation is supported with some delay while lower incentives for limiting growth in urban extent provide inconsistencies → The mobilization of urban actors for GHG emission reductions is strengthened more gradually with stronger coordination taking place after 2030
Net Negative Emissions (IMP-Neg)	<ul style="list-style-type: none"> → Urban areas depend upon energy supply from distant power plants or those in rural areas with more limited electrification in urban energy systems → Afforestation/reforestation is supported to a certain extent while lower incentives for limiting growth in urban extent provide inconsistencies → Urban areas are less prominent in policy and innovation given emphasis on CCS options. Rural areas are more prominent considering BECCS
Renewable Electricity (IMP-Ren)	<ul style="list-style-type: none"> → Urban areas support renewable energy penetration with electrification of urban infrastructure and sector coupling for increasing system flexibility → Consumption patterns and urban planning are able to reduce pressures on land use, demand response is increased to support renewables → Urban climate governance is enabling rapid deployment of renewable energy while fostering innovation for sustainable urban planning
Low Demand (IMP-LD)	<ul style="list-style-type: none"> → Walkable urban form is increased, active and public transport modes are encouraged, low energy buildings and green-blue infrastructure is integrated → Changes in consumption patterns and urban planning reduce pressures on land use to lower levels while service provisioning is improved → Urban policy making is used to accelerate solutions that foster innovation and increased efficiencies across all sectors, including material use
Shifting Pathways (IMP-SP)	<ul style="list-style-type: none"> → Urban areas are transformed to be resource efficient, low demand, and renewable energy supportive with an integrated approach in urban planning → Reinforcing measures enable GHG emission reductions from consumption patterns while also avoiding resource impacts across systems → Urban climate mitigation is best aligned with the SDGs to accelerate GHG emission reductions, increasing both scalability and acceptance

7

1 **8.4 Urban mitigation options**

2 Urban mitigation options can be categorized into three broad strategies: (1) reducing urban energy
3 consumption across all sectors, including through spatial planning and infrastructure; (2) electrification
4 and switching to net zero emissions resources; and (3) enhancing carbon stocks and uptake through
5 urban green and blue infrastructure, which can also offer multiple co-benefits. A fourth, socio-
6 behavioural aspects, can shift energy demand and emerge as the result of implementing the strategies.
7 Urban mitigation options covered in this section are organized around these three strategies and can
8 facilitate deep decarbonization through systemic transformation (see Section 8.6 and Figure 8.21 for
9 prioritizing mitigation options based on urban form and urban growth typologies).

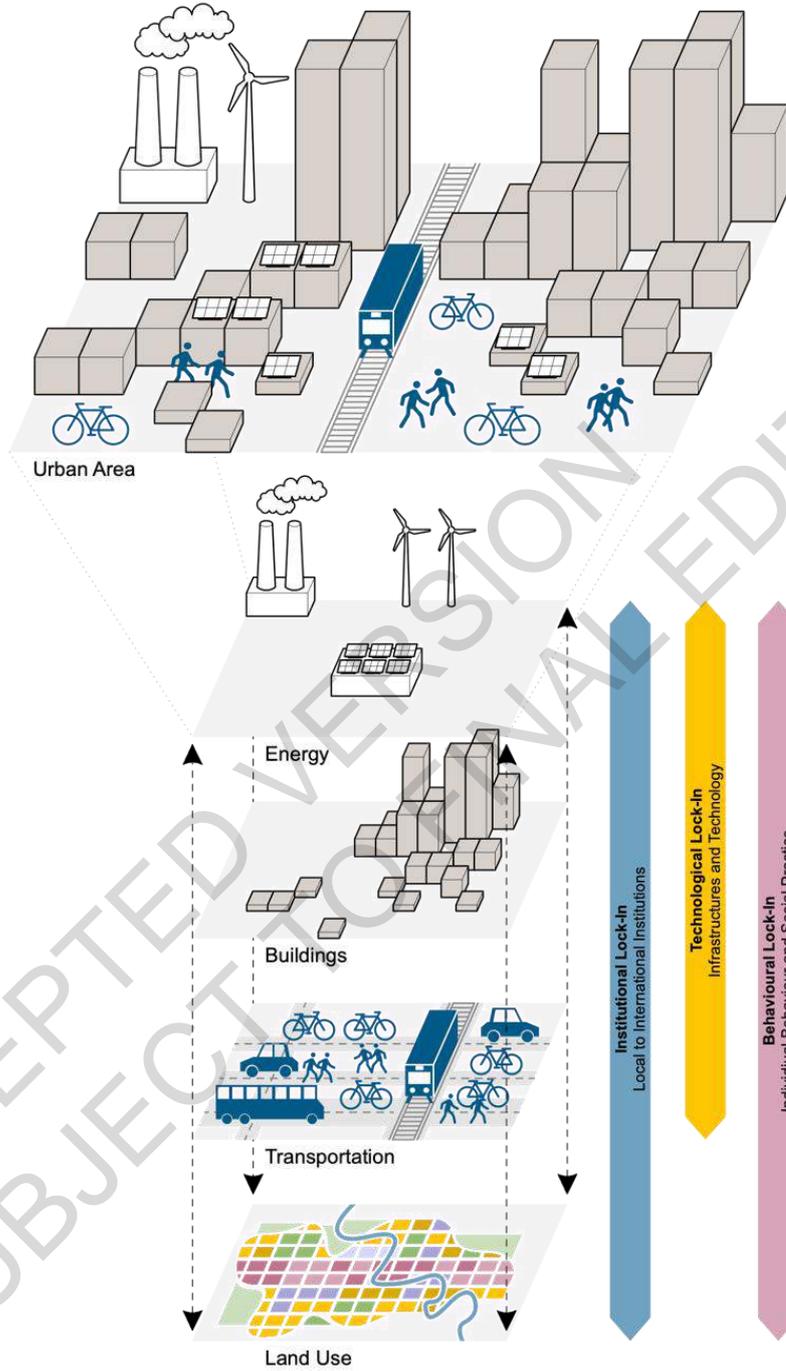

10 Urban areas are systems where multiple mitigation options—especially when integrated—have
11 cascading effects across transport, energy, buildings, land use, and behaviour. These cascading effects
12 take place both within and across urban systems (see Figure 8.15). Mitigation actions also occur at
13 multiple urban scales, from households and blocks to districts and city regions, and can be implemented
14 as standalone sectoral strategies, such as increasing energy efficiency for appliances, and also as system-
15 wide actions. In reducing emissions locally, urban areas can help lower emissions outside of their
16 administrative boundaries through their use of materials and resources, and by increasing the efficiency
17 of infrastructure and energy use beyond what is possible with individual sectoral strategies. Urban
18 mitigation policies that implement multiple integrated interventions will provide more emissions
19 savings than the sum of individual interventions (Sethi et al. 2020).

20 Integrated action also has a key role in providing benefits for human well-being. Urban mitigation
21 options and strategies that are effective, efficient, and fair can also support broader sustainability goals
22 (Güneralp et al. 2017; Kona et al. 2018; Pasimeni et al. 2019). Due to the complex and intensive
23 interactions in urban systems and the interlinked nature among the SDGs, cities can be important
24 intervention points to harness synergies and co-benefits for achieving emissions reductions along with
25 other SDGs (Nilsson et al. 2016; Corbett and Mellouli 2017) (see Section 8.2 and Figure 8.4).

Figure 8.15 Urban systems, lock-in, and cascading effects of mitigation strategies.

Cities are systems of inter-connected sectors, activities, and governance structures. Urban-scale mitigation action can have cascading effects across multiple sectors, as shown in panel (a), as well as regional, national, and global impacts through supply chains, resource flows, and institutions, as shown in panel (b). Mitigation efforts implemented at larger scales of governance or in sectors that transcend urban boundaries, like energy and transportation, can also facilitate and amplify mitigation at the urban scale, as shown by the arrows extending in both directions across layers (a). Because urban areas are connected locally and globally, urban mitigation efforts can also impact other cities and surrounding areas (AFOLU). Cities are prone to carbon lock-in due to the numerous reinforcing interactions among urban infrastructures and technologies, institutions, and individual and collective behaviours; see the side arrows extending across the layers in panel (a): the yellow arrow represents the infrastructure and technological lock-in involving user technologies and supporting infrastructure, the blue arrow indicates lock-in of local to international institutions, and the pink arrow represents behavioural lock-in for individuals and society. Urban carbon lock-in is strongly determined by urban form, in particular the layout of streets and land-use mix. The different coloured spatial patterns represent varying levels of co-location of housing and jobs, and mobility options (also see Figure 8.16). Efforts to break urban carbon lock-in require meta-transformations to break inertia in and among infrastructures, institutions, and behaviours.

Source: Adapted in part from Seto et al. (2016)

1 **8.4.1 Avoiding carbon lock-in**

2 Carbon lock-in occurs as the result of interactions between different geographic and administrative
3 scales (institutional lock-in) and across sectors (infrastructural and technological lock-in), which create
4 the conditions for behavioural lock-in covering both individual and social structural behaviours (Seto
5 et al. 2016) (see Glossary for a broader definition of ‘lock-in’). The way that urban areas are designed,
6 laid out, and built affects and is affected by the interactions across the different forms of carbon lock-
7 in (see Figures 8.15 and 8.16). Cities are especially prone to carbon lock-in because of the multiple
8 interactions of technological, institutional, and behavioural systems, which create inertia and path
9 dependency that are difficult to break. For example, the lock-in of gasoline cars is reinforced by
10 highway and energy infrastructures that are further locked-in by social and cultural preferences for
11 individual mobility options. The dominance of cars and their supporting infrastructures in auto-centric
12 urban forms is further reinforced by zoning and urban development patterns, such as dispersed and low-
13 density housing distantly located from jobs, that create obstacles to create alternative mobility options
14 (Seto et al. 2016) (see Figure 8.16 on urban form). (Linton et al. 2021)

15 Urban infrastructures and the built environment are long-lived assets, embodying triple carbon lock-ins
16 in terms of their construction, operations, and demolition (Creutzig et al. 2016b; Seto et al. 2016; Ürgel-
17 Vorsatz et al. 2018). There is much focus in the climate change literature on the operational lifetimes
18 of the energy sector, especially power plants and the electricity grid, which are between 30 and 60 years
19 (Rode et al. 2017). Yet, in reality, the lifespans of urban infrastructures, especially the basic layout of
20 roadways, are often much longer (Reyna and Chester 2015). A number of detailed case studies on the
21 evolution of urban road networks for cities around the world reveal that the current layout of streets
22 grew out of street networks that were established hundreds of years ago (Strano et al. 2012; Masucci et
23 al. 2013; Mohajeri and Gudmundsson 2014). Furthermore, there is evidence that urban street layout,
24 population growth, urban development, and automobile ownership co-evolve (Li et al. 2019a).

25 For cities to break out of mutually reinforcing carbon lock-in, it will require systematic transformation
26 and systems-based planning that integrates mitigation strategies across sectors and geo-political scales.
27 Urban energy demand patterns are locked-in whenever incremental urban design and planning
28 decisions, coupled with investments in long-lasting infrastructure, such as roads and buildings, take
29 place (Seto et al. 2016). The fundamental building blocks of cities are based on the layout of the street
30 network, the size of city blocks, and the density of street intersections. If not significantly altered, these
31 three factors will continue to shape and lock-in energy demand for decades after their initial
32 construction, influencing the mitigation potential of urban areas (see Section 8.4.2 and Figure 8.22).

33 Avoiding carbon lock-in inherently involves decisions that extend beyond the administrative boundaries
34 of cities. This includes pricing of low-emissions technology or materials, such as electric battery or
35 hydrogen vehicles and buses, although cities can support their development and deployment (see Cross-
36 Chapter Box 12 in Chapter 16 on Transition Dynamics). In contrast, urban governments in most parts
37 of the world do have powers to set building codes that regulate materials and construction standards for
38 buildings, including heating and cooling technologies, and major appliances. Other examples include
39 zoning that determines the location of buildings, land uses, standards for densities, and the inclusion of
40 energy planning in their building standards and public works, including streets, parks, and open spaces
41 (Blanco et al. 2011; Raven et al. 2018).

42

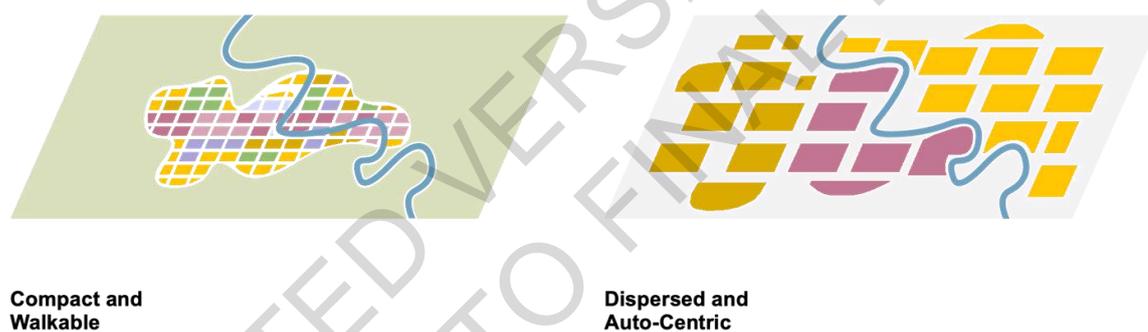

43 **8.4.2 Spatial planning, urban form, and infrastructure**

44 Urban form is the resultant pattern and spatial layout of land use, transportation networks, and urban
45 design elements, including the physical urban extent, configuration of streets and building orientation,
46 and the spatial figuration within and throughout cities and towns (Lynch 1981; Handy 1996).
47 Infrastructure describes the physical structures, social and ecological systems, and corresponding

1 institutional arrangements that provide services and enable urban activity (Dawson et al. 2018; Chester
2 2019) and comprises services and built-up structures that support urban functioning, including
3 transportation infrastructure, water and wastewater systems, solid waste systems, telecommunications,
4 and power generation and distribution (Seto et al. 2014).

5 *Urban Form*

6 AR5 concluded that infrastructure and four dimensions of urban form are especially important for
7 driving urban energy use: density, land use mix, connectivity, and accessibility. Specifically, low-
8 carbon cities have the following characteristics: (1) co-located medium to high densities of housing,
9 jobs, and commerce; (2) high mix of land uses; (3) high connectivity of streets; and (4) high levels of
10 accessibility, distinguished by relatively low travel distances and travel times that are enabled by
11 multiple modes of transportation. Urban areas with these features tend to have smaller dwelling units,
12 smaller parcel sizes, walking opportunities, high density of intersections, and are highly accessible to
13 shopping. For brevity, we will refer to these characteristics collectively as ‘compact and walkable urban
14 form’ (see Figure 8.16). Compact and walkable urban form has many co-benefits, including mental and
15 physical health, lower resource demand, and saving land for AFOLU. In contrast, dispersed and auto-
16 centric urban form is correlated with higher GHG emissions, and characterized by separated land uses,
17 low population and job densities, large block size, and low intersection density.

18
19

Figure 8.16 Urban form and implications for GHG emissions

20 **Compact and walkable urban form is strongly correlated with low GHG emissions and characterized by**
21 **co-located medium to high densities of housing and jobs, high street density, small block size, and mixed**
22 **land use (Seto et al. 2014). Higher population densities at places of origin (e. g., home) and destination (e.**
23 **g., employment, shopping) concentrate demand and are necessary for achieving the ASI approach for**
24 **sustainable mobility (see Chapters 5 and 10). Dispersed and auto-centric urban form is strongly**
25 **correlated with high GHG emissions, and characterized by separated land uses, especially of housing and**
26 **jobs, low street density, large block sizes, and low urban densities. Separated and low densities of**
27 **employment, retail, and housing increase average travel distances for both work and leisure, and make**
28 **active transport and modal shift a challenge. Since cities are systems, urban form has interacting**
29 **implications across energy, buildings, transport, land use, and individual behaviour. Compact and**
30 **walkable urban form enables effective mitigation while dispersed and auto-centric urban form locks-in**
31 **higher levels of energy use. The colours represent different land uses and indicate varying levels of co-**
32 **location and mobility options.**

33 Since AR5, a range of studies have been published on the relationships between urban spatial structures,
34 urban form, and GHG emissions. Multiple lines of evidence reaffirm the key findings from AR5,

1 especially regarding the mitigation benefits associated with reducing vehicle miles or kilometres
2 travelled (VMT/VKT) through spatial planning. There are important cascading effects not only for
3 transport but also other key sectors and consumption patterns, such as in buildings, households, and
4 energy. However, these benefits can be attained only when the existing spatial structure of an urban
5 area does not limit locational and mobility options, thereby avoiding carbon lock-in through the
6 interaction of infrastructure and the resulting socio-behavioural aspects.

7 Modifying the layout of emerging urbanization to be more compact, walkable, and co-located can
8 reduce future urban energy use by 20–25% in 2050 while providing a corresponding mitigation potential
9 of 23–26% (Creutzig et al. 2015, 2016b; Sethi et al. 2020), forming the basis for other urban mitigation
10 options. Cross-Chapter Box 7 in Chapter 10 provides perspectives on simultaneously reducing urban
11 transport emissions, avoiding infrastructure lock-in, and providing accessible services (see Chapter 10).
12 The systemic nature of compact urban form and integrated spatial planning influences ‘Avoid-Shift-
13 Improve’ (ASI, see Glossary) options across several sectors simultaneously, including for mobility and
14 shelter (for an in-depth discussion on the integration of service provision solutions within the ASI
15 framework, see Section 5.3).

16 **8.4.2.1 Co-located housing and jobs, mixed land use, and high street connectivity**

17 Integrated spatial planning, co-location of higher residential and job densities, and systemic approaches
18 are widely identified with development that is characterized by the 5Ds of TOD based on density,
19 diversity (mixed land uses), design (street connectivity), destination accessibility, and distance to
20 transit. Spatial strategies that integrate the 5Ds are shown to reduce VMT/VKT, and thereby transport-
21 related GHG emissions through energy savings. The effect of urban form and built environment
22 strategies on VMT per capita varies by a number of factors (Ewing and Cervero 2010; Stevens 2017;
23 Blanco and Wikstrom 2018). Density and destination accessibility have the highest elasticities, followed
24 by design (Stevens 2017). Population-weighted densities for 121 metropolitan areas have further found
25 that the concentration of population and jobs along mass transit corridors decreases VMT/VKT
26 significantly when compared to more dispersed metropolitan areas. In this sample, elasticity rates were
27 twice as high for dense metropolitan areas located along mass transit lines (Lee and Lee 2020).

28 Meta-analyses of the reduction in VMT and the resulting GHG emissions consider the existing and still
29 dominant use of emitting transportation technology, transportation fleets, and urban form
30 characteristics. Varied historical legacies of transportation and the built environment, which can be
31 utilized to develop more sustainable cities (Newman et al. 2016, 2017), are often not taken into account
32 directly. Metropolitan policies and spatial planning, as evident in Copenhagen’s Finger Plan, as well as
33 strategic spatial planning in Stockholm and Seoul, have been major tools to restructure urban regions
34 and energy patterns (Sung and Choi 2017). Road prices and congestion charges can provide the
35 conditions for urban inhabitants to shift mobility demands and reduce vehicle use (see Section 5.6.2).
36 Surprisingly, even cities with higher population densities and a greater range of land uses can show
37 declines in these important attributes, which can lead to emissions increases, such as found in a study
38 of 323 East and South East Asian cities (Chen et al. 2020c). Conversely, the annual CO₂ emissions
39 reduction of passenger cars in compact versus dispersed urban form scenarios can include at least a
40 10% reduction by 2030 (Matsuhashi and Ariga 2016). When combined with advances in transport
41 technology, this share increases to 64–70% in 2050 based on compact urban form scenarios for 1,727
42 municipalities (Kii 2020).

43 As a reaffirmation of AR5, population density reduces emissions per capita in the transport, building,
44 and energy sectors (Baur et al. 2015; Gudipudi et al. 2016; Wang et al. 2017; Yi et al. 2017) (see also
45 Sections 8.3.1 and 8.3.4 on past trends and forecasts of urban population density and land expansion).
46 Urban compactness tends to reduce emissions per capita in the transport sector, especially for
47 commuting (Matsuhashi and Ariga 2016; Lee and Lim 2018; Lee and Lee 2020). The relative
48 accessibility of neighbourhoods to the rest of the region, in addition to the density of individual

1 neighbourhoods, is important (Ewing et al. 2018). Creating higher residential and employment
2 densities, developing smaller block sizes, and increasing housing opportunities in an employment area
3 can significantly reduce household car ownership and car driving, and increase the share of transit,
4 walk, and bicycle commuting (Ding et al. 2018). In addition to population density, land-use mix, rail
5 transit accessibility, and street design reduce emissions from transport (Dou et al. 2016; Cao and Yang
6 2017; Choi 2018). The impact of population density and urban compactness on emissions per capita in
7 the household or energy sector is also associated with socioeconomic characteristics or lifestyle
8 preferences (Baiocchi et al. 2015; Miao 2017). Changes in the attributes of urban form and spatial
9 structure have influences on overall energy demand across spatial scales, particularly street, block,
10 neighbourhood, and city scales, as well as across the building (housing) and transport (mobility) sectors
11 (Silva et al. 2017). Understanding the existing trade-offs (or synergetic links) between urban form
12 variables across major emissions source sectors, and how they impact the size of energy flows within
13 the urban system, is key to prioritizing action for energy-efficient spatial planning strategies, which are
14 likely to vary across urban areas.

16 **8.4.2.2 Urban form, growth, and sustainable development**

17 Spatial planning for compact urban form is a system-wide intervention (Sethi et al. 2020) and has
18 potential to be combined with sustainable development objectives while pursuing climate mitigation
19 for urban systems (Große et al. 2016; Cheshmehzangi and Butters 2017; Facchini et al. 2017; Lwasa
20 2017; Stokes and Seto 2019). Compact urban form can enable positive impacts on employment and
21 green growth given that the local economy is decoupled from GHG emissions and related parameters
22 while the concentration of people and activity can increase productivity based on both proximity and
23 efficiency (Lee and Erickson 2017; Salat et al. 2017; Gao and Newman 2018; Han et al. 2018; Li and
24 Liu 2018; Lall et al. 2021)

25 Public acceptance can have a positive impact on integrated spatial planning especially when there is a
26 process of co-design (Grandin et al. 2018; Webb et al. 2018). The quality of spatial planning can also
27 increase co-benefits for health and well-being, including decisions to balance urban green areas with
28 density (Li et al. 2016; Sorkin 2018; Pierer and Creutzig 2019). The distributional effects of spatial
29 planning can depend on the policy tools that shape the influence of urban densification on affordable
30 housing while evidence for transit-induced gentrification is found to be partial and inconclusive (Chava
31 and Newman 2016; Jagarnath and Thambiran 2018; Padeiro et al. 2019; Debrunner and Hartmann 2020)
32 (see Sections 8.2 and 8.4.4).

33 Reducing GHG emissions across different urban growth typologies (see Figure 8.20) depends in part
34 on the ability to integrate opportunities for climate mitigation with co-benefits for health and well-being
35 (Grandin et al. 2018). At the same time, requirements for institutional capacity and governance for
36 cross-sector coordination for integrated urban planning is high given the complex relations between
37 urban mobility, buildings, energy systems, water systems, ecosystem services, other urban sectors, and
38 climate adaptation (Große et al. 2016; Castán Broto 2017a; Endo et al. 2017; Geneletti et al. 2017). The
39 capacity for implementing land-use zoning and regulations in a way that is consistent with supporting
40 spatial planning for compact urban form is not equal across urban areas and depends on different
41 contexts as well as institutional capacities (Bakır et al. 2018; Deng et al. 2018; Shen et al. 2019).

42 Currently, integrating spatial planning, urban form, and infrastructure in urban mitigation strategies
43 remains limited in mainstream practices, including in urban areas targeting an emissions reduction of
44 36–80% in the next decades (Asarpota and Nadin 2020). Capacity building for integrated spatial
45 planning for urban mitigation includes increasing collaboration among city departments and with civil
46 society to develop robust mitigation strategies, bringing together civil engineers, architects, urban

1 designers, public policy and spatial planners, and enhancing the education of urban professionals
2 (Asarpota and Nadin 2020) (see Section 8.5).

3 Spatial planning for compact urban form is a prerequisite for efficient urban infrastructure, including
4 district heating and/or cooling networks (Swilling et al. 2018; Möller et al. 2019; Persson et al. 2019;
5 UNEP and IRP 2020). District heating and cooling networks benefit from urban design parameters,
6 including density, block area, and elongation that represent the influence of urban density on energy
7 density (Fonseca and Schlueter 2015; Shi et al. 2020). Heat-demand density is a function of both
8 population density and heat demand per capita and can be equally present in urban areas with high
9 population density or high heat demand per capita (Möller et al. 2019; Persson et al. 2019). Low-
10 temperature networks that utilize waste heat or renewable energy can provide an option to avoid carbon
11 lock-in to fossil fuels while layout and eco-design principles can further optimize such networks (Gang
12 et al. 2016; Buffa et al. 2019; Dominković and Krajačić 2019). Replacing gas-based heating and cooling
13 with electrified district heating and cooling networks, for instance, provide 65% emissions reductions
14 also involving carbon-aware scheduling for grid power (De Chalendar et al. 2019). The environmental
15 and ecological benefits increase through the interaction of urban energy and spatial planning (Tuomisto
16 et al. 2015; Bartolozzi et al. 2017; Dénarié et al. 2018; Zhai et al. 2020). These interactions include
17 support for demand-side flexibility, spatial planning using geographic information systems, and access
18 to renewable and urban waste heat sources (Möller et al. 2018; REN21 2020; Sorknæs et al. 2020;
19 Dorotić et al. 2019) (see Table SM8.2 for other references).

20

21 **8.4.3 Electrification and switching to net zero emissions resources**

22 Pursuing the electrification mobility, heating, and cooling systems, while decarbonizing electricity and
23 energy carriers, and switching to net zero materials and supply chains, represent important strategies
24 for urban mitigation. Electrification of energy end uses in cities and efficient energy demand for heating,
25 transport, and cooking through multiple options and urban infrastructure, has an estimated mitigation
26 potential of at least 6.9 GtCO₂-eq by 2030 and 15.3 GtCO₂-eq by 2050 (Coalition for Urban Transitions
27 2019). Energy efficiency measures in urban areas can be enabled by urban form, building codes,
28 retrofitting and renovation, modal shifts, and other options. Decarbonizing electricity supply raises the
29 mitigation potential of efficient buildings and transport in urban areas to about 75% of the total estimate
30 (Coalition for Urban Transitions 2019). In addition, relatively higher-density urban areas enable more
31 cost-effective infrastructure investments, including electric public transport and large-scale heat pumps
32 in districts that support electrification. Urban policymakers can play a key role in supporting carbon-
33 neutral energy systems by acting as target setters and planners, demand aggregators, regulators,
34 operators, conveners, and facilitators for coordinated planning and implementation across sectors, urban
35 form, and demand (IEA 2021a; IRENA 2021).

36

37 **8.4.3.1 Electrification and decarbonization of the urban energy system**

38 Urban energy infrastructures often operate as part of larger energy systems that can be electrified,
39 decarbonized, and become enablers of urban system flexibility through demand-side options. With
40 multiple end-use sectors (e.g., transport, buildings) and their interactions with land use drawing on the
41 same urban energy system(s), increasing electrification is essential for rapid decarbonization, renewable
42 energy penetration, and demand flexibility (Kammen and Sunter 2016) (see IMPs in Sections 3.2.5 and
43 8.3.4). The mitigation potential of electrification is ultimately dependent on the carbon intensity of the
44 electricity grid (Kennedy 2015; Hofmann et al. 2016; Peng et al. 2018; Zhang and Fujimori 2020) and
45 starts providing lifecycle emission savings for carbon intensities below a threshold of 600 tCO₂-eq
46 GWh⁻¹ (Kennedy et al. 2019). Integrated systems of roof-top photovoltaics (PVs) and all-electric
47 vehicles (EVs) alone could supply affordable carbon-free electricity to cities and reduce CO₂ emissions

1 by 54%–95% (Brenna et al. 2014; Kobashi et al. 2021). Furthermore, electrification and
2 decarbonization of the urban energy system holds widespread importance for climate change mitigation
3 across different urban growth typologies and urban form (see Section 8.6 and Figure 8.21) and leads to
4 a multitude of public health co-benefits (see Section 8.2).

5 Strategies that can bring together electrification with reduced energy demand based on walkable and
6 compact urban form can accelerate and amplify decarbonization. Taking these considerations—across
7 the energy system, sectors, and land use—contributes to avoiding, or breaking out of, carbon lock-in
8 and allows continued emission savings as the energy supply is decarbonized (Kennedy et al. 2018;
9 Teske et al. 2018; Seto et al. 2021). Indeed, electrification is already transforming urban areas and
10 settlements and has the potential to continue transforming urban areas into net-negative electric cities
11 that may sequester more carbon than emitted (Kennedy et al. 2018; Seto et al. 2021).

12 In its simplest form, electrification involves the process of replacing fossil fuel-based technologies with
13 electrified innovations such as electric vehicles, buses, streetcars, and trains (see Sections 10.4.1 and
14 10.4.2), heat pumps, PVs (see Section 6.4.2.1), electric cook-stoves (see Section 9.8.2.1), and other
15 technologies (Stewart et al. 2018). Cost-effective decarbonisation of energy use can be supported by
16 electrification in urban areas if there is also demand-side flexibility for power, heat, mobility, and water
17 with sector coupling (Guelpa et al. 2019; Pfeifer et al. 2021). Overall, demand-side flexibility across
18 sectors in urban areas is supported by smart charging, electric mobility, electrified urban rail, power-
19 to-heat, demand side response, and water desalination (Lund et al. 2015; Calvillo et al. 2016; Salpakari
20 et al. 2016; Newman 2017; Meschede 2019).

21 As an enabler, electrification supports integrating net zero energy sources in urban infrastructure across
22 sectors, especially when there is more flexible energy demand in mobility, heating, and cooling to
23 absorb greater shares of variable renewable energy. In the transport sector, smart charging can reduce
24 electric vehicle impacts on peak demand by 60% (IEA 2021a). Urban areas that connect efficient
25 building clusters with the operation of smart thermal grids in district heating and cooling networks with
26 large-scale heat pumps can support higher penetrations of variable renewable energy in smart energy
27 systems (Lund et al. 2014, 2017). Higher urban densities provide the advantage of increasing the
28 penetration of renewable power for deep decarbonization, including mixed-use neighbourhoods for grid
29 balancing and electric public transport (Hsieh et al. 2017; Tong et al. 2017; Fichera et al. 2018; Kobashi
30 et al. 2020). Based on these opportunities, urban areas that provide low-cost options to energy storage
31 for integrating the power sector with multiple demands reduce investment needs in grid electricity
32 storage capacities (Mathiesen et al. 2015; Lund et al. 2018).

33 Electrification at the urban scale encompasses strategies to aggregate energy loads for demand response
34 in the urban built environment to reduce the curtailment of variable renewable energy and shifting time-
35 of-use based on smart charging for redistributing energy demands (O'Dwyer et al. 2019). Peak shaving
36 or shifting takes place among frequent interventions at the urban level (Sethi et al. 2020). Business
37 models and utility participation, including municipal level demonstrations, can allow for upscaling
38 (Gjorgievski et al. 2020; Meha et al. 2020). The urban system can support increasing demand-side
39 flexibility in energy systems, including in contexts of 100% renewable energy systems (Drysdale et al.
40 2019; Thellufsen et al. 2020).

41 *Smart grids in the urban system*

42 Smart electricity grids enable peak demand reductions, energy conservation, and renewable energy
43 penetration, and are a subset of smart energy systems. GHG emission reductions from smart grids range
44 from 10 to 180 gCO₂ kWh⁻¹ (grams of CO₂ per kilowatt-hour) with a median value of 89 gCO₂ kWh⁻¹,
45 depending on the electricity mix, penetration of renewable energy, and the system boundary (Moretti
46 et al. 2017). Smart electricity grids are characterized by bi-directional flows of electricity and
47 information between generators and consumers, although some actors can be both as ‘prosumer’ (see

1 Glossary). Two-way power flows can be used to establish peer-to-peer trading (P2P) (Hansen et al.
2 2020). Business models based on local citizen utilities (Green and Newman 2017; Green et al. 2020;
3 Syed et al. 2020) and community batteries (Mey and Hicks 2019; Green et al. 2020) can support the
4 realization of distributed energy and solar energy cities (Galloway and Newman 2014; Byrne and
5 Taminiou 2016; Stewart et al. 2018; Allan 2020).

6 Currently, despite power outages that are costly to local economies, the adoption of smart electricity
7 grids or smart energy systems have been slow in many developing regions, including in Sub-Saharan
8 Africa (Westphal et al. 2017; Kennedy et al. 2019). This is due to a number of different factors, such as
9 unreliable existing infrastructure, fractured fiscal authority, lack of electricity access in urban areas,
10 upfront cost, financial barriers, inefficient pricing of electricity, and low consumer education and
11 engagement (Venkatachary et al. 2018; Acakpovi et al. 2019; Cirolia 2020).

12 *Pathways and trade-offs of electrification in urban systems*

13 Urbanization and population density are one of the key drivers for enabling access to electricity across
14 the world with benefits for sustainable development (Aklin et al. 2018). Grid-connected PV systems for
15 urban locations that currently lack electricity access can allow urban areas to leapfrog based on green
16 electrification (Abid et al. 2021). In the Global South, the conversion of public transport to electric
17 transport, especially municipal buses (e.g., Bengaluru, India; Jakarta, Indonesia; Medellín, Colombia;
18 Rio de Janeiro, Brazil; Quito, Ecuador) and micro-mobility (e.g., e-trikes in Manila, Philippines) have
19 been quantified based on reductions in GHG and PM_{2.5} emissions, avoided premature deaths, and
20 increases in life expectancies (IEA 2014; C40 Cities 2018, 2020b,c,d,e). In 22 Latin American cities,
21 converting 100% of buses and taxis in 2030 to electric were estimated to result in a reduction of 300
22 MtCO₂-eq compared to 2017 (ONU Medio Ambiente 2017). Yet the scaling up of electric vehicles in
23 cities can be examined within a larger set of possible social objectives, such as reducing congestion and
24 the prioritization of other forms of mobility.

25 Electrification requires a layering of policies at the national, state, and local levels. Cities have roles as
26 policy architects, including transit planning (e.g., EV targets and low-emissions zones, restrictions on
27 the types of energy use in new buildings, etc.), implementers (e.g., building codes and compliance
28 checking, financial incentives to encourage consumer uptake of EV's and heat pumps, etc.), and
29 complementary partners to national and state policymaking (e.g., permitting or installation of charging
30 infrastructure) (Broekhoff et al. 2015). The number of cities that have instituted e-mobility targets that
31 aim for a certain percentage of EV's sold, in circulation or registered, is increasing (REN21 2021).
32 Realizing the mitigation potential of electrification will require fiscal and regulatory policies and public
33 investment (Hall et al. 2017a; Deason and Borgeson 2019; Wappelhorst et al. 2020) (see Section 8.5).

34 EVs are most rapidly deployed when there has been a suite of policies, including deployment targets,
35 regulations and use incentives (e.g., zero-emission zone mandates, fuel economy standards, building
36 codes), financial incentives (e.g., vehicles, chargers), industrial policies (e.g., subsidies), and fleet
37 procurement (IEA 2016b, 2017, 2018, 2020a; Cazzola et al. 2019). The policy mix has included
38 mandates for bus deployment, purchase subsidies, or split ownership of buses and chargers (IEA 2021b)
39 (see Chapter 10). Subsidies are often critical to address the often-higher upfront costs of electric devices.
40 In other instances, the uptake of electric induction stoves was increased through government credit and
41 allotment of free electricity (Martínez et al. 2017; Gould et al. 2018).

42 Bringing multiple stakeholders together in local decision-making for smart energy systems requires
43 effort beyond usual levels while multi-actor settings can be increased to enable institutional conditions
44 (Lammers and Hoppe 2019). Public participation and community involvement in the planning, design
45 and operation of urban energy projects can be an enabler of decarbonizing local energy demands
46 (Corsini et al. 2019). Cooperation across institutions is important for municipalities that are engaged in
47 strategic energy planning and implementation for smart energy systems (Krog 2019) (see Section 8.5).

1 Electrification technologies can present potential trade-offs that can be minimized through governance
2 strategies, smart grid technologies, circular economy practices, and international cooperation. One
3 consideration is the increase in electricity demand (see 5.3.1.1). Across 23 megacities in the world
4 (population greater than 10 million people), electrification of the entire gasoline vehicle fleet could
5 increase electricity demand on average by 18% (Kennedy et al. 2018). How grid capacity will be
6 impacted is dependent on the match between daily electricity loads and supply (Tarroja et al. 2018).
7 Materials recycling of electrification technologies are also key to minimising potential environmental
8 and social costs (Church and Crawford 2018; Gaustad et al. 2018; Sovacool et al. 2020) and can ensure
9 electrification reaches its complete mitigation potential. Circular economy strategies are particularly
10 valuable to this goal by creating closed-loop supply chains through recycling, material recovery, repair,
11 and reuse. For instance, the PV Cycle program in Europe prevented more than 30,000 metric tonnes of
12 renewable technology from reaching the waste stream (Sovacool et al. 2020) (see Box 10.7 as well as
13 ‘circular economy’ in Glossary).

14 **8.4.3.2 Switching to net zero emissions materials and supply chains**

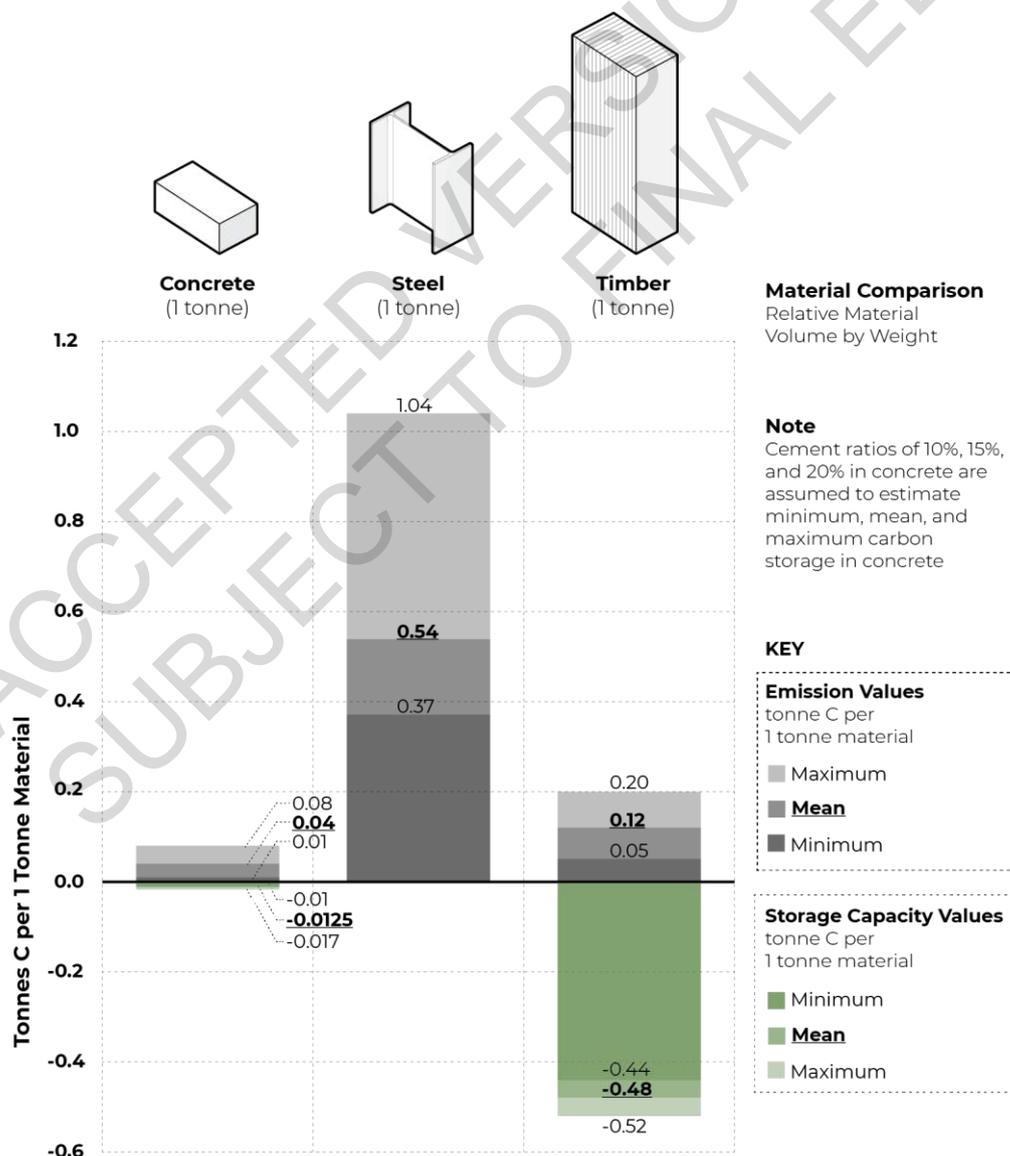

15 For the carbon embodied in supply chains to become net zero, all key infrastructure and provisioning
16 systems will need to be decarbonized, including electricity, mobility, food, water supply, and
17 construction (Seto et al. 2021). The growth of global urban populations that is anticipated over the next
18 several decades will create significant demand for buildings and infrastructure. As cities expand in size
19 and density, there is an increase in the production of mineral-based structural materials and enclosure
20 systems that are conventionally associated with mid- and high-rise urban construction morphologies,
21 including concrete, steel, aluminium, and glass. This will create a significant spike in GHG emissions
22 and discharge of CO₂ at the beginning of each building lifecycle, necessitating alternatives (Churkina
23 et al. 2020).

24 The initial carbon debt incurred in the production stage, even in sustainable buildings, can take decades
25 to offset through operational stage energy efficiencies alone. Increased reduction in the energy demands
26 and GHG emissions associated with the manufacture of mineral-based construction materials will be
27 challenging, as these industries have already optimized their production processes. Among the category
28 of primary structural materials, it is estimated that final energy demand for steel production can be
29 reduced by nearly 30% compared to 2010 levels, with 12% efficiency improvement for cement
30 (Lechtenböhmer et al. 2016). Even when industries are decarbonized, residual CO₂ emissions will
31 remain from associated chemical reactions that take place in calcination and use of coke from coking
32 coal to reduce iron oxide (Davis et al. 2018). Additionally, carbon sequestration by cement occurs over
33 the course of the building lifecycle in quantities that would offset only a fraction of their production
34 stage carbon spike (Xi et al. 2016; Davis et al. 2018). Moreover, there are collateral effects on the carbon
35 cycle related to modern construction and associated resource extraction. The production of cement,
36 asphalt, and glass requires large amounts of sand extracted from beaches, rivers, and seafloors,
37 disturbing aquatic ecosystems and reducing their capacity to absorb atmospheric carbon. The mining of
38 ore can lead to extensive local deforestation and soil degradation (Sonter et al. 2017). Deforestation
39 significantly weakens the converted land as a carbon sink and in severe cases may even create a net
40 emissions source.

41 A broad-based substitution of monolithic engineered timber systems for steel and concrete in mid-rise
42 urban buildings offers the opportunity to transform cityscapes from their current status as net sources
43 of GHG emissions into large-scale, human-made carbon sinks. The storage of photosynthetic forest
44 carbon through the substitution of biomass-based structural materials for emissions-intensive steel and
45 concrete is an opportunity for urban infrastructure. The construction of timber buildings for 2.3 billion
46 new urban dwellers from 2020 to 2050 could store between 0.01 and 0.68 GtCO₂ per year depending
47 on the scenario and the average floor area per capita. Over thirty years, wood-based construction can

1 accumulate between 0.25 and 20 GtCO₂ and reduce cumulative emissions from 4 GtCO₂ (range of 7–
 2 20 GtCO₂) to 2 GtCO₂ (range of 0.3–10 GtCO₂) (*high confidence*) (Churkina et al. 2020).

3 Figure 8.17 indicates that new and emerging structural assemblies in engineered timber rival the
 4 structural capacity of steel and reinforced concrete while offering the benefit of storing significant
 5 quantities of atmospheric carbon (see also Figure 8.22). Mass timber refers to engineered wood products
 6 that are laminated from smaller boards or lamella into larger structural components such as glue-
 7 laminated (glulam) beams or cross-laminated timber (CLT) panels. Methods of mass-timber production
 8 that include finger-jointing, longitudinal and transverse lamination with both liquid adhesive and
 9 mechanical fasteners have allowed for the re-formulation of large structural timbers. The parallel-to-
 10 grain strength of mass (engineered) timber is similar to that of reinforced concrete (Ramage et al. 2017).
 11 As much as half the weight of a given volume of wood is carbon, sequestered during forest growth as a
 12 by-product of photosynthesis (Martin et al. 2018). Mass timber is inflammable, but in large sections
 13 forms a self-protective charring layer when exposed to fire that will protect the remaining ‘cold wood’
 14 core. This property, formed as massive structural sections, is recognized in the fire safety regulations
 15 of building codes in several countries, which allow mid- and high-rise buildings in timber. Ongoing
 16 studies have addressed associated concerns about the vulnerability of wood to decay and the capacity
 17 of structural timber systems to withstand seismic and storm related stresses.

18

1 **Figure 8.17 Relative volume of a given weight, its carbon emissions, and carbon storage capacity of**
2 **primary structural materials comparing one tonne of concrete, steel, and timber**

3
4 **Concrete and steel have substantial embodied carbon emissions with minimal carbon storage capacities,**
5 **while timber stores a considerable quantity of carbon with a relatively small ratio of carbon emissions-to-**
6 **material volume. The displayed carbon storage of concrete is the theoretical maximum value, which may**
7 **be achieved after hundreds of years. Cement ratios of 10%, 15%, and 20% are assumed to estimate**
8 **minimum, mean, and maximum carbon storage in concrete. Carbon storage of steel is not displayed as it**
9 **is negligible (0.004 tonne C per tonne of steel). The middle-stacked bars represent the mean carbon**
10 **emission or mean carbon storage values displayed in bold font and underlined. The darker and lighter**
11 **coloured stacked bars depict the minimum and maximum values. Grey tones represent carbon emissions**
12 **and green tones are given for storage capacity values. Construction materials have radically different**
13 **volume-to-weight ratios, as well as material intensity (see representation by a structural column in the**
14 **upper panel. These differences should be accounted for in the estimations of their carbon storage and**
15 **emissions (see also Figure 8.22).**

16
17 Source: Adapted from Churkina et al. (2020)

18
19 Transitioning to biomass-based building materials, implemented through the adoption of engineered
20 structural timber products and assemblies, will succeed as a mitigation strategy only if working forests
21 are managed and harvested sustainably (Churkina et al. 2020). Since future urban growth and the
22 construction of timber cities may lead to increased timber demand in regions with low forest cover, it
23 is necessary to systematically analyse timber demand, supply, trade, and potential competition for
24 agricultural land in different regions (Pomponi et al. 2020). The widespread adoption of biomass-based
25 urban construction materials and techniques will demand more robust forest and urban land governance
26 and management policies, as well as internationally standardized carbon accounting methods to
27 properly value and incentivize forest restoration, afforestation, and sustainable silviculture.

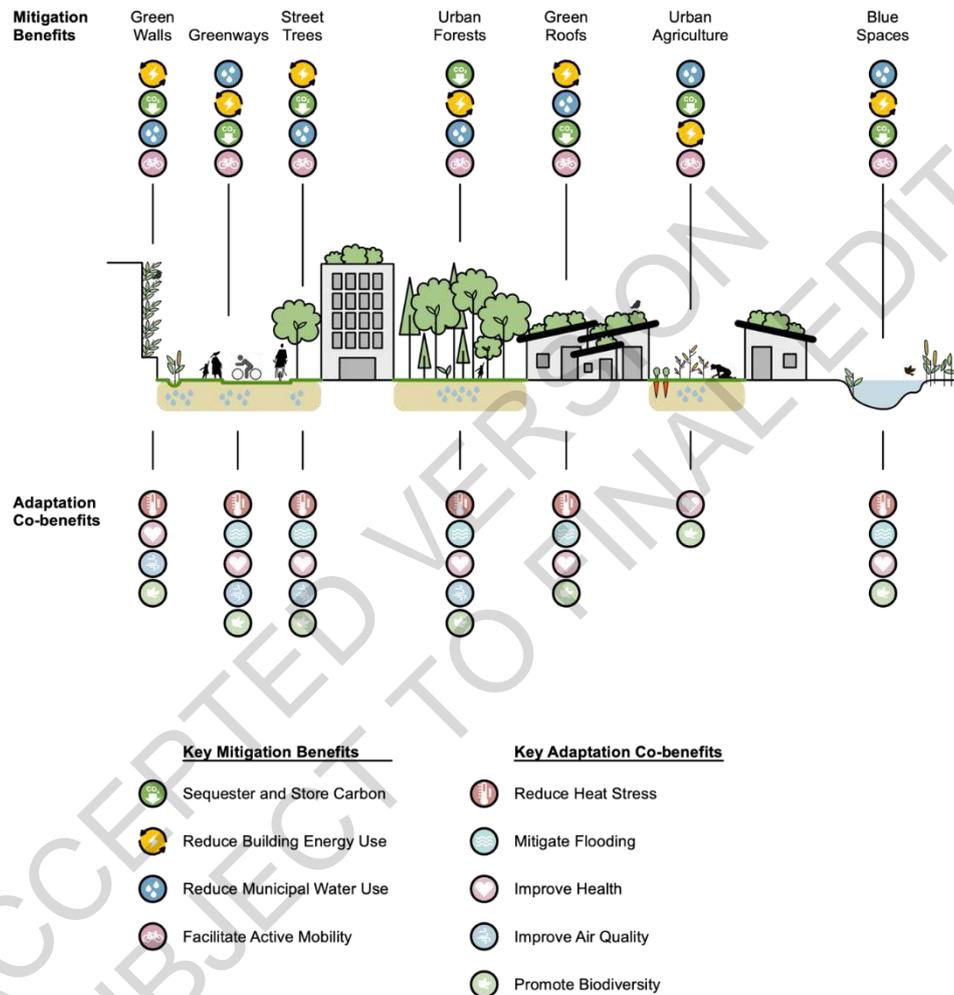

28
29 Expansion of agroforestry practices may help to reduce land-use conflicts between forestry and
30 agriculture. Harvesting pressures on forests can be reduced through the reuse and recycling of wooden
31 components from dismantled timber buildings. Potential synergies between the carbon sequestration
32 capacity of forests and the associated carbon storage capacity of dense mid-rise cities built from
33 engineered timber offer the opportunity to construct carbon sinks deployed at the scale of landscapes,
34 sinks that are at least as durable as other buildings (Churkina et al. 2020). Policies and practices
35 promoting design for disassembly and material reuse will increase their durability.

36 37 **8.4.4 Urban green and blue infrastructure**

38 The findings of AR6 WGI and WGII have underscored the importance of urban green and blue
39 infrastructure for reducing the total warming in urban areas due to its local cooling effect on temperature
40 and its benefits for climate adaptation (IPCC 2021; Cross-Working Group Box 2 in this chapter). Urban
41 green and blue infrastructure in the context of NBS involves the protection, sustainable management,
42 and restoration of natural or modified ecosystems while simultaneously providing benefits for human
43 well-being and biodiversity (IUCN 2021) (see Glossary for additional definitions). As an umbrella
44 concept, urban NBS integrates established ecosystem-based approaches that provide multiple
45 ecosystem services and are important in the context of societal challenges related to urbanization,
46 climate change, and reducing GHG emissions through the conservation and expansion of carbon sinks
47 (Naumann et al. 2014; Raymond et al. 2017) (see Section 8.1.6.1).

48 Urban green and blue infrastructure includes a wide variety of options, from street trees, parks, and
49 sustainable urban drainage systems (Davis and Naumann 2017), to building-related green roofs or green
50 facades, including green walls and vertical forests (Enzi et al. 2017). Figure 8.18 synthesizes urban
51 green and blue infrastructure based on urban forests, street trees, green roofs, green walls, blue spaces,

1 greenways, and urban agriculture. Key mitigation benefits, adaptation co-benefits, and SDG linkages
 2 are represented by types of green and blue infrastructure. Local implementations of urban green and
 3 blue infrastructure can pursue these linkages while progressing toward inclusive sustainable urban
 4 planning (SDG 11.3) and the provision of safe, inclusive and accessible green and public spaces for all
 5 (SDG 11.7) (Butcher-Gollach 2018; Pathak and Mahadevia 2018; Rigolon et al. 2018; Anguelovski et
 6 al. 2019; Buyana et al. 2019; Azunre et al. 2021) (see Section 8.2).

Figure 8.18 Key mitigation benefits, adaptation co-benefits, and SDG linkages of urban green and blue infrastructure

4

5 Panel (a) illustrates the potential integration of various green and blue infrastructure strategies within an
 6 urban system. Panel (b) evaluates those strategies in the context of their mitigation benefits, adaptation
 7 co-benefits, and linkages to the SDGs. Urban forests and street trees provide the greatest mitigation
 8 benefit because of their ability to sequester and store carbon while simultaneously reducing building

1 energy demand. Moreover, they provide multiple adaptation co-benefits and synergies based on the
2 linkages to the SDGs (see Figure 8.4). The assessments of mitigation benefits are dependent on context,
3 scale, and spatial arrangement of each green and blue infrastructure type and their proximity to
4 buildings. Mitigation benefits due to reducing municipal water use are based on reducing wastewater
5 loads that reduce energy use in wastewater treatment plants. The sizes in the bars are illustrative and
6 their relative size is based on the authors' best understanding and assessment of the literature.

8 8.4.4.1 The mitigation potential of urban trees and associated co-benefits

9 Due to their potential to store relatively high amounts of carbon compared to other types of urban
10 vegetation, as well as their ability to provide many climate mitigation co-benefits (*medium agreement,*
11 *limited evidence*), natural area protection and natural forest management in urban areas is an important
12 priority for cities looking to mitigate climate change. Globally, urban tree cover averages 26.5%, but
13 varies from an average of 12% in deserts to 30.4% in forested regions (Nowak and Greenfield 2020).

14 Global urban tree carbon storage is approximately 7.4 billion tonnes (GtC) given 363 million hectares
15 of urban land, 26.5% tree cover, and an average carbon storage density of urban tree cover of 7.69
16 kgC/m² (kilograms carbon per square metre) (Nowak et al. 2013; World Bank et al. 2013). Estimated
17 global annual carbon sequestration by urban trees is approximately 217 million tonnes (MtC) given an
18 average carbon sequestration density per unit urban tree cover of 0.226 kgC/m² (Nowak et al. 2013).
19 With an average plantable (non-tree and non-impervious) space of 48% globally (Nowak and
20 Greenfield 2020), the carbon storage value could nearly triple if all this space is converted to tree cover.
21 In Europe alone, if 35% of the urban surfaces (26450 km²) were transformed into green surfaces, the
22 mitigation potential based on carbon sequestration would be an estimated 25.9 MtCO₂ year⁻¹ with the
23 total mitigation benefit being 55.8 MtCO₂ year⁻¹, including an energy saving of about 92 TWh year⁻¹
24 (Quaranta et al. 2021). Other co-benefits include reducing urban runoff by about 17.5% and reducing
25 summer temperatures by 2.5°C–6°C (Quaranta et al. 2021).

26 Urban tree carbon storage is highly dependent on biome. For example, carbon sequestered by vegetation
27 in Amazonian forests is two- to five-times higher compared to boreal and temperate forests (Blais et al.
28 2005). At the regional level, the estimated carbon storage density rates of tree cover include a range of
29 3.14–14.1 kgC/m² in the United States, 3.85–5.58 kgC/m² in South Korea, 1.53–9.67 kgC/m² in
30 Barcelona, 28.1–28.9 kgC/m² in Leicester, England, and an estimated 6.82 kgC/m² in Leipzig, Germany
31 and 4.28 kgC/m² in Hangzhou, China (Nowak et al. 2013). At the local scale, above- and below-ground
32 tree carbon densities can vary substantially, as with carbon in soils and dead woody materials. The
33 conservation of natural mangroves have been shown to provide urban mitigation benefits through
34 carbon sequestration, as demonstrated in the Philippines (Abino et al. 2014). Research on urban carbon
35 densities from the Southern hemisphere will contribute to better estimates.

36 On a per-tree basis, urban trees offer the most potential to mitigate climate change through both carbon
37 sequestration and GHG emissions reduction from reduced energy use in buildings (Nowak et al. 2017).
38 Maximum possible street tree planting among 245 world cities could reduce residential electricity use
39 by about 0.9–4.8% annually (McDonald et al. 2016). Urban forests in the United States reduce building
40 energy use by 7.2%, equating to an emissions reduction of 43.8 MtCO₂ annually (Nowak et al. 2017).

41 Urban trees can also mitigate some of the impacts of climate change by reducing the UHI effect and
42 heat stress, reducing stormwater runoff, improving air quality, and supporting health and well-being in
43 areas where the majority of the world's population resides (Nowak and Dwyer 2007). Urban forest
44 planning and management can maximize these benefits for present and future generations by sustaining
45 optimal tree cover and health (also see SDG linkages in Figure 8.4). Urban and peri-urban (see
46 Glossary) agriculture can also have economic benefits from fruit, ornamental, and medicinal trees
47 (Gopal and Nagendra 2014; Lwasa 2017; Lwasa et al. 2018).

4

Box 8.2 Urban carbon storage: An example from New York City

5 The structure, composition, extent, and growing conditions of vegetation in cities has an influence on
6 their potential for mitigating climate change (Pregitzer et al. 2021). Urban natural areas, particularly
7 forested natural areas, grow in patches and contain many of the same components as non-urban forests,
8 such as high tree density, down woody material, and regenerating trees (see Figure 1).

9 Urban forested natural areas have unique benefits as they can provide habitat for native plants and
10 animals, protecting local biodiversity in a fragmented landscape (Di Giulio et al. 2009). Forests can
11 have a greater cooling effect on cities than designed greenspaces, and the bigger the forest the greater
12 the effect (Jaganmohan et al. 2016). In New York City, urban forested natural areas have been found to
13 account for the majority of trees estimated in the city (69%), but are a minority of the total tree canopy
14 (25%, or 5.5% of the total city land area) (Pregitzer et al. 2019a). In New York City, natural areas are
15 estimated to store a mean of 263.5 Mg C ha⁻¹ (megagram carbon per hectare), adding up to 1.86 TgC
16 (teragram carbon) across the city, with the majority of carbon (86%) being stored in the trees and soils
17 (Pregitzer et al. 2021). These estimates are similar to per-hectare estimates of carbon storage across
18 different pools in non-urban forest types (see Table 1), and 1.5-times greater than estimates for carbon
19 stored in just trees across the entire city (Pregitzer et al. 2021).

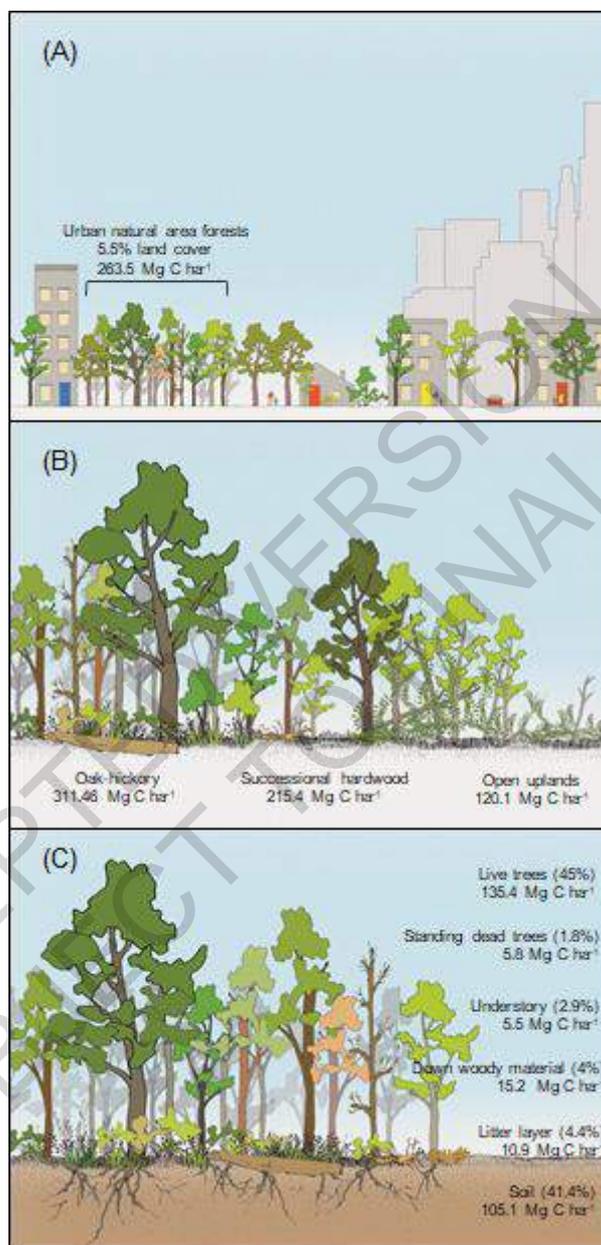

20 Within urban natural areas, the amount of carbon stored varies widely based on vegetation type, tree
21 density, and the species composition (see Figure 1). The oak-hardwood forest type is one of the most
22 abundant in New York City's natural areas and is characterized by large and long-lived native hardwood
23 tree species, with relatively dense wood. These forests store an estimated 311.5 Mg C ha⁻¹. However,
24 non-native exotic invasive species can be prevalent in the understory vegetation layer (<1m height),
25 and account for about 50% of cover in New York City (Pregitzer et al. 2019b).

26 This could lead to a trajectory where exotic understory species, which are often herbaceous, out-
27 compete regenerating trees in the understory layer, alter the soil (Ward et al. 2020), and alter the forest
28 canopy (Matthews et al. 2016). A change in New York City's vegetation structure and composition to
29 a more open vegetation type could reduce the carbon storage by over half (open grassland 120.1 Mg C
30 ha⁻¹).

31 When compared to estimates of carbon storage presented in other studies, the components (pools) of
32 the natural area forests in New York City store carbon in similar proportions to other non-urban forests
33 (see Table 1). This might suggest that in other geographies, similar adjacent non-urban forest types may
34 store similar carbon stocks per unit area (*medium confidence*). However, despite similarities to non-
35 urban forests, the urban context can lead to altered forest function and carbon cycling that should be
36 considered. For example, trees growing in urban areas have been observed to grow at much higher rates
37 due to higher access to light, nutrients, and increased temperatures (Gregg et al. 2003; Reinmann et al.
38 2020).

39 Higher growth rates coupled with the UHI effect have also been suggested to yield greater evaporative
40 cooling by urban canopies relative to rural forests (Winbourne et al. 2020). Based on estimates in New
41 York City, it is likely that the majority of tree biomass, and carbon in trees in cities, could be found in
42 urban natural area forest patches (*medium agreement, limited evidence*). More research is needed to
43 map urban natural areas, assess vegetation, and differentiate tree canopy types (natural vs. non-natural)
44 at fine scales within many cities and geographies. Accurate maps, as well as greater understanding of
45 definitions of urban canopies and vegetation, could lead to better accounts for carbon stocks and the
46 many other unique benefits they provide (Raciti et al. 2012; Pregitzer et al. 2019a).

1 Despite this potential, natural areas are inherently a minority land use type in cities and should be
 2 viewed along with other types of urban tree canopy that occur in more designed environments that
 3 might out-perform natural areas in other ecosystem services. The mosaic of vegetation characteristics
 4 and growing conditions will yield different ecosystem services across cities (Pataki et al. 2011) and
 5 should be an important consideration in planning, management, and policy in the future.

Box 8.2, Figure 1 Estimates for carbon storage in natural area forests in New York City

(a) Mean estimated carbon stock per hectare in natural area forests (Pregitzer et al. 2019a, 2021); (b) estimates for carbon stocks vary based on vegetation types; and (c) estimates of the amount of carbon stock in different forest pools per hectare. The proportion of the total estimated carbon stock per pool is out of the total estimated for the entire city (1.86 TgC).

Source: Figure from Pregitzer et al. (2021)

Box 8.2, Table 1 A selection of benchmark reference estimates of different carbon pools sampled and the related urban considerations to contextualize the results from New York City (NYC), United States (US) natural area carbon stocks. The benchmark estimates are intended to provide a point of reference to help contextualize the calculations for carbon pools in NYC's forests. Forest carbon is highly variable and dependent on microclimatic conditions such as moisture, microbial communities, and nutrient availability, all of which can be impacted by human activity in urban or altered environments. Standard errors and 95% confidence intervals can be found in Pregitzer et al. (2021). DBH: diameter at breast height; DWM: down woody material; and FWM: fine woody material.

Source: Pregitzer et al. (2021).

Pool considered in NYC Natural Area	Published Estimates of Carbon Stock (Mg C ha ⁻¹)	NYC Estimated Carbon Stock (Mg C ha ⁻¹)	Urban Considerations
Live Trees: All trees (>2 cm DBH) including above and below ground	87.1 - North-eastern US (Smith et al. 2013) 73.3 - NYC assuming 100% cover (Nowak et al. 2013)	135.4	Lower ozone levels, higher CO ₂ , warmer temperatures, and higher nutrient deposition could lead to increase growth rates and annual carbon sequestration. However, pollutants in soil (e.g., heavy metals), increased pests, and GHGs in the atmosphere (e.g., NO _x and SO ₂) could decrease annual tree growth and carbon sequestration (Gregg et al. 2003)
Groundcover: All vegetation growing <1 m height	1.8 - North-eastern US (Smith et al. 2013)	5.5	Anthropogenic disturbance creates canopy gaps that accelerate herbaceous growth; invasive vines are prevalent in urban forests that can alter tree survival and growth and soils (Matthews et al. 2016; Ward et al. 2020)
Standing Dead Trees	5.1 - North-eastern US (Smith et al. 2013) 2.59 - Massachusetts (Liu et al. 2006)	5.8	Removal may occur due to safety considerations
DWM: Coarse (>10 cm) and FWM (>0.1 cm)	9.18 - Coarse woody material – New York state 2.52 - Coarse woody material- Massachusetts (Liu et al. 2006) 6.37 - Fine woody material- New York (Woodall et al. 2013) 3.67 - Fine woody material Northern hardwood; 0 to 227.94 - Northern US (Domke et al. 2016)	15.25 (added together DWM and FWM)	Removal may occur due to safety considerations
Litter and Duff: Depth measured	12 - NYC (Pouyat et al. 2002) 9.36 - Northern hardwood; 0.04 to 86.1, Northern US (Domke et al. 2016)	10.95	Decomposition increases with temperature (Hanson et al. 2003); decreased ozone levels facilitate litter decay (Carreiro et al. 2009)
Mineral Soil (Organic 30 cm)	104 - to 30 cm depth, NYC (Cambou et al. 2018) 50 - to 10 cm depth, NYC (Pouyat et al. 2002)	105.11(30 cm) and 77.78 (10 cm)	UHI and pollution alter the litter chemistry, decomposer organisms, conditions, and resources, which all influence respiration rates (Carreiro et al. 2009); earthworms, prevalent in urban areas, accelerate decay, but some carbon is sequestered in passive pools (Pouyat et al. 2002). Soil could be compacted.

END BOX 8.2 HERE

1

2 **8.4.4.2 Benefits of green roofs, green walls, and greenways**

3 Green roofs and green walls have potential to mitigate air and surface temperature, improve thermal
4 comfort, and mitigate UHI effects (Jamei et al. 2021; Wong et al. 2021), while lowering the energy
5 demand of buildings (Susca 2019) (see Figure 8.18). Green roofs have the highest median cooling effect
6 in dry climates (3°C) and the lowest cooling effect in hot, humid climates (1°C) (Jamei et al. 2021).
7 These mitigation potentials depend on numerous factors and the scale of implementation. The
8 temperature reduction potential for green roofs when compared to conventional roofs can be about 4°C
9 in winter and about 12°C during summer conditions (Bevilacqua et al. 2016). Green roofs can reduce
10 building heating demands by about 10–30% compared to conventional roofs (Besir and Cuce 2018),
11 60–70% compared to black roofs, and 45–60% compared to white roofs (Silva et al. 2016). Green walls
12 or facades can provide a temperature difference between air temperature outside and behind a green
13 wall of up to 10°C, with an average difference of 5°C in Mediterranean contexts in Europe (Perini et
14 al. 2017). The potential of saving energy for air conditioning by green facades can be around 26% in
15 summer months. Considerations of the spatial context are essential given their dependence on climatic
16 conditions (Susca 2019). Cities are diverse and emissions savings potentials depend on several factors,
17 while the implementation of green roofs or facades may be prevented in heritage structures.

18 Green roofs have been shown to have beneficial effects in stormwater reduction (Andrés-Doménech et
19 al. 2018). A global meta-analysis of 75 international studies on the potential of green roofs to mitigate
20 runoff indicate that the runoff retention rate was on average 62% but with a wide range (0–100%)
21 depending on a number of interdependent factors (Zheng et al. 2021). These factors relate to the
22 characteristics of the rainfall event (e.g., intensity) and characteristics of the green roof (e.g., substrate,
23 vegetation type, and size), and of the climate and season type. A hydrologic modelling approach applied
24 to an Italian case demonstrated that implementing green roofs may reduce peak runoff rates and water
25 volumes by up to 35% in a 100% green roof conversion scenario (Masseroni and Cislighi 2016).

26 Greenways support stormwater management to mitigate water runoff and urban floods by reducing the
27 water volume (e.g., through infiltration) and by an attenuation or temporal shift of water discharge (Fiori
28 and Volpi 2020; Pour et al. 2020). Using green infrastructure delays the time to runoff and reduces
29 water volume but depends on the magnitude of floods (Qin et al. 2013). Measures are most effective
30 for flood mitigation at a local scale; however, as the size of the catchment increases, the effectiveness
31 of reducing peak discharge decreases (Fiori and Volpi 2020). Reduction of water volume through
32 infiltration can be more effective with rainfall events on a lower return rate. Overall, the required
33 capacity for piped engineered systems for water runoff attenuation and mitigation can be reduced while
34 lowering flow rates, controlling pollution transport, and increasing the capacity to store stormwater
35 (Srishantha and Rathnayake 2017). Benefits for flood mitigation require a careful consideration of the
36 spatial context of the urban area, the heterogeneity of the rainfall events, and characteristics of
37 implementation (Qiu et al. 2021). Maintenance costs and stakeholder coordination are other aspects
38 requiring attention (Mguni et al. 2016).

39 Providing a connected system of greenspace throughout the urban area may promote active
40 transportation (Nieuwenhuijsen and Khreis 2016), thereby reducing GHG emissions. Soft solutions for
41 improving green infrastructure connectivity for cycling is an urban NBS mitigation measure, although
42 there is *low evidence* for emissions reductions. In the city of Lisbon, Portugal, improvements in cycling
43 infrastructure and bike-sharing system resulted in 3.5-times more cyclists within two years (Félix et al.
44 2020). In Copenhagen, the cost of cycling (Euro 0.08/km) is declining and is about six times lower than
45 car driving (Euro 0.50/km) (Vedel et al. 2017). In addition, participants were willing to cycle 1.84 km
46 longer if the route has a designated cycle track and 0.8 km more if there are also green surroundings.
47 Changes in urban landscapes, including through the integration of green infrastructure in sustainable

1 urban and transport planning, can support the transition from private motorized transportation to public
2 and physically active transportation in carbon-neutral, more liveable and healthier cities
3 (Nieuwenhuijsen and Khreis 2016; Nieuwenhuijsen 2020). Car infrastructure can be also transferred
4 into public open and green space, such as in the Superblock model in Barcelona’s neighbourhoods
5 (Rueda 2019). Health impact assessment models estimated that 681 premature deaths may be prevented
6 annually with this implementation (Mueller et al. 2020) and the creation of greenways in Maanshan,
7 China has stimulated interests in walking or cycling (Zhang et al. 2020).

8 9 **8.4.5 Socio-behavioural aspects**

10 Urban systems shape the behaviour and social structures of their residents through urban form, energy
11 systems, and infrastructure—all of which provide a range of options for consumers to make choices
12 about residential location, mobility, energy sources, and the consumption of materials, food, and other
13 resources. The relative availability of options across these sectors has implications on urban emissions
14 through individual behaviour. In turn, urban GHG emissions, as well as emissions from the supply
15 chains of cities, are driven by the behaviour and consumption patterns of residents, with households
16 accounting for over 60% of carbon emissions globally (Ivanova et al. 2016). The exclusion of
17 consumption-based emissions and emissions that occur outside of city boundaries as a result of urban
18 activities will lead to significant undercounting to the effect of undercounting 41% of territorial
19 emissions and 4% of global emissions annually, respectively (Wiedmann et al. 2021).

20 Changes in behaviour across all areas (e.g., transport, buildings, food, etc.) could reduce an individual’s
21 emissions by 5.6–16.2% relative to the accumulated GHG emissions from 2011 to 2050 in a baseline
22 scenario modelled with the Global Change Assessment Model (van de Ven et al. 2018). In other models,
23 behaviour change in transport and residential energy use could reduce emissions by 2 GtCO₂-eq in 2030
24 compared to 2019 (IEA 2020b) (see Chapter 5). Voluntary behaviour change can support emissions
25 reduction, but behaviours that are not convenient to change are unlikely to shift without changes to
26 policy (Sköld et al. 2018). Cities can increase the capability of citizens to make sustainable choices by
27 making these choices less onerous, through avenues such as changing urban form to increase locational
28 and mobility options and providing feedback mechanisms to support socio-behavioural change.

29 Transport emissions can be reduced by options including telecommuting (0.3%), taking closer holidays
30 (0.5%), avoiding short flights (0.5%), using public transit (0.7%), cycling (0.6%), car sharing (1.1%),
31 and carpool commuting (1.2%); all reduction estimates reflect cumulative per capita emission savings
32 relative to baseline emissions for the period 2011–2050, and assume immediate adoption of behavioural
33 changes (van de Ven et al. 2018). Cities can support voluntary shift to walking, cycling, and transit
34 instead of car use through changes to urban form, such as TOD (Kamruzzaman et al. 2015), increased
35 density of form with co-location of activities (Ma et al. 2015; Ding et al. 2017; Duranton and Turner
36 2018; Masoumi 2019), and greater intersection density and street integration (Koohsari et al. 2016).
37 Mechanisms such as providing financial incentives or disincentives for car use can also be effective in
38 reducing emissions (Wynes et al. 2018) (see Section 8.4.2).

39 Adopting energy efficient practices in buildings could decrease global building energy demand in 2050
40 by 33–44% compared to a business-as-usual scenario (Levesque et al. 2019). Reductions in home
41 energy use can be achieved by reducing floor area (0.5–3.0%), utilising more efficient appliances and
42 lighting (2.7–5.0%), optimising thermostat settings (8.3–11%), using efficient heating and cooling
43 technologies (6.7–10%), improving building insulation (2.9–4.0%), optimising clothes washing (5.0–
44 5.7%), and optimising dishwashing (1–1.1%) (Levesque et al. 2019). Building standards and mandates
45 could work towards making these options required or more readily available and accessible. Residential
46 appliance use, water heating, and thermostat settings can be influenced by feedback on energy use,
47 particularly when paired with real-time feedback and/or instructions on how to reduce energy use

1 (Kastner and Stern 2015; Stern et al. 2016; Wynes et al. 2018; Tiefenbeck et al. 2019). The energy-
2 saving potentials of changing occupant behaviour can range between 10% and 25% for residential
3 buildings, and between 5% and 30% for commercial buildings (Zhang et al. 2018). Households are
4 more likely to invest in energy-related home technologies if they believe it financially benefits (rather
5 than disadvantages) them, increases comfort, or will benefit the natural environment (Kastner and Stern
6 2015). Social influences and availability of funding for household energy measures also support
7 behaviour change (Kastner and Stern 2015).

8 9 **8.4.5.1 Increasing locational and mobility options**

10 Spatial planning, urban form, and infrastructure can be utilized to deliberately increase both locational
11 and mobility options for socio-behavioural change in support of urban mitigation. The mitigation
12 impacts of active travel can include a reduction of mobility-related lifecycle CO₂ emissions by about
13 0.5 tonnes over a year when an average person cycles one trip per day more, and drives one trip per day
14 less, for 200 days a year (Brand et al. 2021). Urban areas that develop and implement effective 15/20-
15 minute city programs are very likely to reduce urban energy use and multiply emission reductions,
16 representing an important cascading effect.

17 Accessibility as a criterion widens the focus beyond work trips and VMTs, paying attention to a broader
18 set of destinations beyond workplaces, as well as walking and biking trips or active travel. It holds
19 promise for targeting and obtaining greater reductions in GHG emissions in household travel by
20 providing access through walking, biking, and public transit. Accessibility as a criterion for urban form
21 has been embedded in neighbourhood form models since at least the last century and in more recent
22 decades in the urban village concept of the New Urbanism (Duany and Plater-Zyberck 1991) and TODs
23 (Calthorpe 1993). However, accessibility did not gain much traction in urban planning and
24 transportation until the last decade. The experience of cities and metropolitan areas with the COVID-
25 19 pandemic has led to a further resurgence in interest and importance (Handy 2020; Hu et al. 2020),
26 and is becoming a criterion at the core of the concept of the 15/20-minute city (Moreno et al. 2021;
27 Pozoukidou and Chatziyiannaki 2021). Initially, neighbourhoods have been designed to provide quality,
28 reliable services within 15 or 20 minutes of active transport (i.e., walking or cycling), as well as a variety
29 of housing options and open space (Portland Bureau of Planning and Sustainability 2012; Pozoukidou
30 and Chatziyiannaki 2021; State Government of Victoria 2021). Community life circles strategy for
31 urban areas have also emphasized walking access and health (Weng et al. 2019; Wu et al. 2021). The
32 growing popularity of the 15/20-minute city movement has significant potential for reducing
33 VMT/VKT and associated GHG emissions.

34 35 **8.4.5.2 Avoiding, minimizing, and recycling waste**

36 The waste sector is a significant source of GHG emissions, particularly CH₄ (Gonzalez-Valencia et al.
37 2016; Nisbet et al. 2019). Currently, the sector remains the largest contributor to urban emissions after
38 the energy sector, even in low-carbon cities (Lu and Li 2019). Since waste management systems are
39 usually under the control of municipal authorities, they are a prime target for city-level mitigation efforts
40 with co-benefits (EC 2015, 2020; Gharfalkar et al. 2015; Herrero and Vilella 2018; Zaman and Ahsan
41 2019). Despite general agreement on mitigation impacts, quantification remains challenging due to
42 differing assumptions for system boundaries and challenges related to measuring avoided waste (Zaman
43 and Lehmann 2013; Bernstad Saraiva Schott and Cánovas 2015; Matsuda et al. 2018).

44 The implementation of the waste hierarchy from waste prevention onward, as well as the effectiveness
45 of waste separation at source, involves socio-behavioural options in the context of urban infrastructure
46 (Sun et al. 2018a; Hunter et al. 2019). Managing and treating waste as close to the point of generation
47 as possible, including distributed waste treatment facilities, can minimize transport-related emissions,

1 congestion, and air pollution. Home composting and compact urban form can also reduce waste
2 transport emissions (Oliveira et al. 2017). Decentralized waste management can reinforce source-
3 separation behaviour since the resulting benefits can be more visible (Eisted et al. 2009; Hoornweg and
4 Bhada-Tata 2012; Linzner and Lange 2013). Public acceptance for waste management is greatest when
5 system costs for citizens are reduced, there is greater awareness of primary waste separation at source,
6 and there are positive behavioural spill-over across environmental policies (Milutinović et al. 2016;
7 Boyer and Ramaswami 2017; Díaz-Villavicencio et al. 2017; Slorach et al. 2020). In addition to the
8 choice of technology, the costs of waste management options depends on the awareness of system users
9 that can represent time-dependent costs (Khan et al. 2016; Chifari et al. 2017; Ranieri et al. 2018; Tomić
10 and Schneider 2020). Waste management systems and the inclusion of materials from multiple urban
11 sectors for alternative by-products can increase scalability (Eriksson et al. 2015; Boyer and Ramaswami
12 2017; D’Adamo et al. 2021). As a broader concept, circular economy approaches can contribute to
13 managing waste (see Box 12.2) with varying emissions impacts (see Section 5.3.4).

14 The generation and composition of waste varies considerably from region to region and city to city. So
15 do the levels of institutional management, infrastructure, and (informal) work in waste disposal
16 activities. Depending on context, policy priorities are directed towards reducing waste generation and
17 transforming waste to energy or other products in a circular economy (Diaz 2017; Ezeudu and Ezeudu
18 2019; Joshi et al. 2019; Calderón Márquez and Rutkowski 2020; Fatimah et al. 2020). Similarly, waste
19 generation, waste collection coverage, recycling, and composting rates, as well as the means of waste
20 disposal and treatment, differ widely, including the logistics of urban waste management systems.
21 Multiple factors influence waste generation, and regions with similar urbanization rates can generate
22 different levels of waste per capita (Kaza et al. 2018).

23 Under conventional practices, municipal solid waste is projected to increase by about 1.4 Gt between
24 2016 and 2050, reaching 3.4 Gt in 2050 (Kaza et al. 2018). Integrated policymaking can increase the
25 energy, material, and emissions benefits in the waste management sector (Hjalmarsson 2015; Fang et
26 al. 2017; Jiang et al. 2017). Organisational structure and program administration poses demands for
27 institutional capacity, governance, and cross-sectoral coordination for obtaining the maximum benefit
28 (Hjalmarsson 2015; Kalmykova et al. 2016; Conke 2018; Marino et al. 2018; Yang et al. 2018).

29 The informal sector plays a critical role in waste management, particularly but not exclusively in
30 developing countries (Linzner and Lange 2013; Dias 2016). Sharing of costs and benefits, and
31 transforming informality of waste recycling activities into programs, can support distributional effects
32 (Conke 2018; Grové et al. 2018). Balancing centralized and decentralized waste management options
33 along low-carbon objectives can address potential challenges in transforming informality (de Bercegol
34 and Gowda 2019). Overall, the positive impacts of waste management on employment and economic
35 growth can be increased when informality is transformed to stimulate employment opportunities for
36 value-added products with an estimated 45 million jobs in the waste management sector by 2030
37 (Alzate-Arias et al. 2018; Coalition for Urban Transitions 2020; Soukiazis and Proença 2020).

38

39 **8.4.6 Urban-rural linkages**

40 Urban-rural linkages, especially through waste, food, and water, are prominent elements of the urban
41 system, given that cities are open systems that depend on their hinterlands for imports and exports
42 (Pichler et al. 2017), and include resources, products for industrial production or final use (see Section
43 8.1.6). As supply chains are becoming increasingly global in nature, so are the resource flows with the
44 hinterlands of cities. In addition to measures within the jurisdictional boundaries of cities, cities can
45 influence large upstream emissions through their supply chains, as well as through activities that rely
46 on resources outside city limits. The dual strategy of implementing local actions and taking
47 responsibility for the entire supply chains of imported and exported goods can reduce GHG emissions
48 outside of a city’s administrative boundaries (see Figure 8.15).

1 Waste prevention, minimisation, and management provides the potential of alleviating resource usage
2 and upstream emissions from urban settlements (Swilling et al. 2018; Chen et al. 2020a; Harris et al.
3 2020). Integrated waste management and zero-waste targets can allow urban areas to maximize the
4 mitigation potential while reducing pressures on land use and the environment. This mitigation option
5 reduces emissions due to (1) avoided emissions upstream in the supply chain of materials based on
6 measures for recycling and the reuse of materials, (2) avoided emissions due to land use changes as well
7 as emissions that are released into the atmosphere from waste disposal, and (3) avoided primary energy
8 (see Glossary) spending and emissions. Socio-behavioural change that reduces waste generation
9 combined with technology and infrastructure according to the waste hierarchy can be especially
10 effective. The mitigation potential of waste-to-energy depends on the technological choices that are
11 undertaken (e.g., anaerobic digestion of the organic fraction), the emissions factor of the energy mix
12 that it replaces, and its broader role within integrated municipal solid management practices (Eriksson
13 et al. 2015; Potdar et al. 2016; Yu and Zhang 2016; Soares and Martins 2017; Alzate-Arias et al. 2018;
14 Islam 2018). The climate mitigation potential of anaerobic digestion plants can increase when power,
15 heat and/or cold is co-produced (Thanopoulos et al. 2020).

16 Urban food systems, as well as city-regional production and distribution of food, factors into supply
17 chains. Reducing food demand from urban hinterlands can have a positive impact on energy and water
18 demand for food production (Eigenbrod and Gruda 2015) (see ‘food system’ in Glossary). Managing
19 food waste in urban areas through recycling or reduction of food waste at source of consumption would
20 require behavioural change (Gu et al. 2019). Urban governments could also support shifts towards more
21 climate-friendly diets, including through procurement policies. These strategies have created economic
22 opportunities or have enhanced food security while reducing the emissions that are associated with
23 waste and the transportation of food. Strategies for managing food demand in urban areas would depend
24 on the integration of food systems in urban planning.

25 Urban and peri-urban agriculture and forestry is pursued by both developing and some developed
26 country cities. There is increasing evidence for economically feasible, socially acceptable, and
27 environmentally supportive urban and peri-urban agricultural enterprises although these differ between
28 cities (Brown 2015; Eigenbrod and Gruda 2015; Blay-Palmer et al. 2019; De la Sota et al. 2019). The
29 pathways include integrated crop-livestock systems, urban agroforestry systems, aquaculture-livestock-
30 crop systems, and crop systems (Lwasa et al. 2015), while the mitigation potential of urban and peri-
31 urban agriculture has *medium agreement and low evidence*. Strategies for urban food production in
32 cities have also relied on recycling nutrients from urban waste and utilisation of harvested rainwater or
33 wastewater.

34 Systems for water reallocation between rural areas and urban areas will require change by leveraging
35 technological innovations for water capture, water purification, and reducing water wastage either by
36 plugging leakages or changing behaviour in regard to water use (Eigenbrod and Gruda 2015; Prior et
37 al. 2018). Reducing energy use for urban water systems involves reducing energy requirements for
38 water supply, purification, distribution, and drainage (Ahmad et al. 2020). Various levels of rainwater
39 harvesting in urban settings for supplying end-use water demands or supporting urban food production
40 can reduce municipal water demands, including by up to 20% or more in Cape Town (Fisher-Jeffes et
41 al. 2017).

42

43 **8.4.7 Cross-sectoral integration**

44 There are two broad categories of urban mitigation strategies. One is from the perspective of key sectors,
45 including clean energy, sustainable transport, and construction (Rocha et al. 2017; Álvarez Fernández
46 2018; Magueta et al. 2018; Seo et al. 2018; Waheed et al. 2018); the coupling of these sectors can be
47 enabled through electrification (see Section 8.4.3.1). The other looks at the needs for emissions through
48 a more systematic or fundamental understanding of urban design, urban form, and urban spatial

1 planning (Wang et al. 2017; Privitera et al. 2018), and proposes synergistic scenarios for their
2 integration for carbon neutrality (Ravetz et al. 2020).

3 Single-sector analysis in low-carbon urban planning examines solutions in supply, demand, operations,
4 and assets management either from technological efficiency or from a system approach. For example,
5 the deployment of renewable energy technologies for urban mitigation can be evaluated in detail and
6 the transition to zero-carbon energy in energy systems and EVs in the transport sector can bring about
7 a broad picture for harvesting substantial low-carbon potentials through urban planning (Álvarez
8 Fernández 2018; Tarigan and Sagala 2018) (*high agreement, robust evidence*).

9 The effect of urban carbon lock-in on land use, energy demand, and emissions vary depending on
10 national circumstances (Wang et al. 2017; Pan 2020). Systematic consideration of urban spatial
11 planning and urban forms, such as polycentric urban regions and rational urban population density, is
12 essential not only for liveability but also for achieving net zero GHG emissions as it aims to shorten
13 commuting distances and is able to make use of NBS for energy and resilience (*high agreement, medium
14 evidence*). However, crucial knowledge gaps remain in this field. There is a shortage of consistent and
15 comparable GHG emissions data at the city level and a lack of in-depth understanding of how urban
16 renewal and design can contribute to carbon neutrality (Mi et al. 2019).

17 An assessment of opportunities suggests that strategies for material efficiency that cross-cut sectors will
18 have greater impact than those that focus one dimensionally on a single sector (UNEP and IRP 2020).
19 In the urban context, this implies using less material by the design of physical infrastructure based on
20 light-weighting and down-sizing, material substitution, prolonged use, as well as enhanced recycling,
21 recovery, remanufacturing, and reuse of materials and related components. For example, light-weight
22 design in residential buildings and passenger vehicles can enable about 20% reductions in lifecycle
23 material-related GHG emissions (UNEP and IRP 2020).

24 The context of urban areas as the nexus of both sectors (i.e., energy, and urban form and planning)
25 underlines the role of urban planning and policies in contributing to reductions in material-related GHG
26 emissions while enabling housing and mobility services for the benefit of inhabitants. In addition,
27 combining resource efficiency measures with strategic densification can increase the GHG reduction
28 potential and lower resource impacts. While resource efficiency measures are estimated to reduce GHG
29 emissions, land use, water consumption, and metal use impacts from a lifecycle assessment perspective
30 by 24–47% over a baseline, combining resource efficiency with strategic densification can increase this
31 range to about 36–54% over the baseline for a sample of 84 urban settlements worldwide (Swilling et
32 al. 2018).

33 Evidence from a systematic scoping of urban solutions further indicates that the GHG abatement
34 potential of integrating measures across urban sectors is greater than the net sum of individual
35 interventions due to the potential of realizing synergies when realized in tandem, such as urban energy
36 infrastructure and renewable energy (Sethi et al. 2020). Similarly, system-wide interventions, such as
37 sustainable urban form, are important for increasing the GHG abatement potential of interventions
38 based on individual sectoral projects (Sethi et al. 2020). Overall, the pursuit of inter-linkages among
39 urban interventions are important for accelerating GHG reductions in urban areas (Sethi et al. 2020);
40 this is also important for reducing reliance on carbon capture and storage technologies (CCS) at the
41 global scale (Figures 8.15 and 8.21).

42 Currently, cross-sectoral integration is one of the main thematic areas of climate policy strategies among
43 the actions that are adopted by signatories to an urban climate and energy network (Hsu et al. 2020c).
44 Although not as prevalent as those for efficiency, municipal administration, and urban planning
45 measures (Hsu et al. 2020c), strategies that are cross-cutting in nature across sectors can provide
46 important emission saving opportunities for accelerating the pace of climate mitigation in urban areas.
47 Cross-sectoral integration also involves mobilizing urban actors to increase innovation in energy

1 services and markets beyond individual energy efficiency actions (Hsu et al. 2020c). Indeed, single-
2 sector versus cross-sector strategies for 637 cities from a developing country can enable an additional
3 15–36% contribution to the national climate mitigation reduction potential (Ramaswami et al. 2017a).
4 The strategies at the urban level involved those for energy cascading and exchange of materials that
5 connected waste, heat, and electricity strategies (Section 8.5 and Box 8.4).

6 The feasibility of upscaling multiple response options depends on the urban context as well as the stage
7 of urban development with certain stages providing additional opportunities over others (Dienst et al.
8 2015; Maier 2016; Affolderbach and Schulz 2017; Roldán-Fontana et al. 2017; Zhao et al. 2017a; Beygo
9 and Yüzer 2017; Lwasa 2017; Pacheco-Torres et al. 2017; Alhamwi et al. 2018; Kang and Cho 2018;
10 Lin et al. 2018; Collaço et al. 2019) (see Figures 8.19 and 8.21, and SM8.2).

12 **8.5 Governance, institutions, and finance**

13 Governance and other institutions act as core components to urban systems by facilitating and managing
14 linkages between different sectors, geographic regions, and stakeholders. This position renders
15 subnational governments and institutions key enablers of climate change mitigation (Seto et al. 2016,
16 2021; Hsu et al. 2018, 2020c; ; Vedeld et al. 2021) (see Section 8.4.1). Indeed, since AR5 more research
17 has emerged identifying these actors as vehicles through which to accelerate local-to-global efforts to
18 decarbonize (IPCC 2018a; Hsu et al. 2020b; Salvia et al. 2021; Seto et al. 2021) (see also Chapter 13,
19 and Sections 4.2.3, 14.5.5, 15.6.5 and 16.4.7, and ‘subnational actors’ in Glossary). The current extent
20 (Section 8.3.3) and projected rise (Section 8.3.4.2) in the urban share of global emissions underscores
21 the transformative global impact of supporting urban climate governance and institutions (see also
22 Section 8.5.2). Further, the multisector approach to mitigation emphasized in this chapter (see Sections
23 8.4 and 8.6, and Figure 8.21) highlights the need for facilitation across sectors (Hsu et al. 2020c) (see
24 also Figure 8.19).

26 **8.5.1 Multi-level governance**

27 SR1.5 identified multilevel governance (see Glossary for full definition) as an enabling condition that
28 facilitates systemic transformation consistent with keeping global temperatures below 1.5°C (IPCC
29 2018a, 18–19). The involvement of governance at multiple levels is necessary to enable cities to plan
30 and implement emissions reductions targets (*high confidence*) (Seto et al. 2021) (see Boxes 8.3 and
31 8.4). Further, regional, national, and international climate goals are most impactful when local
32 governments are involved alongside higher levels, rendering urban areas key foci of climate governance
33 more broadly (*high confidence*) (Fuhr et al. 2018; Kern 2019; Hsu et al. 2020b).

34 Since AR5, multilevel governance has grown in influence within the literature and has been defined as
35 a framework to understanding the complex interaction of the many players involved in GHG generation
36 and mitigation across geographic scales—the ‘vertical’ levels of governance from neighbourhoods to
37 the national and international levels, and those ‘horizontal’ networks of non-state and subnational actors
38 at various scales (Corfee-Morlot et al. 2009; Seto et al. 2014; Castán Broto 2017b; Fuhr et al. 2018;
39 Peng and Bai 2018; Kern 2019), and well as the complex linkages between them (Vedeld et al. 2021).
40 This more inclusive understanding of climate governance provides multiple pathways through which
41 urban actors can engage in climate policy to reduce emissions.

42 *Multilevel, multi-player climate governance in practice*

43 A multilevel, multi-player framework highlights both the opportunities and constraints on local
44 autonomy to engage in urban mitigation efforts (Castán Broto 2017b; Fuhr et al. 2018; Vedeld et al.
45 2021). When multiple actors—national, regional, and urban policymakers, as well as nonstate actors

1 and civil society—work together to exploit the opportunities, it leads to the most impactful mitigation
2 gains (Melica et al. 2018). This framework also highlights the multiple paths and potential synergies
3 available to actors who wish to pursue mitigation policies despite not having a full slate of enabling
4 conditions (Castán Broto 2017b; Keller 2017; Fuhr et al. 2018; Hsu et al. 2020b,a; Seto et al. 2021).

5 For example, Section 8.4.3. and 8.4.5 highlight how instigating the electrification of urban energy
6 systems requires a ‘layered’ approach to policy implementation across different levels of governance
7 (see Section 8.4.3.1 for specific policy mechanisms associated with electrification), with cities playing
8 a key role in setting standards, particularly through mechanisms like building codes (Hsu et al. 2020c;
9 Salvia et al. 2021), as well as through facilitation between stakeholders (e.g., consumers, government,
10 utilities, etc.) to advocate for zero-emissions targets (Linton et al. 2021; Seto et al. 2021). Local
11 governments can minimize trade-offs associated with electrification technologies by enabling circular
12 economy practices and opportunities (Pan et al. 2015; Gaustad et al. 2018; Sovacool et al. 2020). These
13 include public-private partnerships between consumers and producers, financial and institutional
14 support, and networking for stakeholders like entrepreneurs, so as to increase accessibility and
15 efficiency of recycling for consumers by providing a clear path from consumer waste back to the
16 producers (Pan et al. 2015; Prendeville et al. 2018; Fratini et al. 2019). Box 8.3 discusses the mitigation
17 benefits of coordination between local and central government in the context of Shanghai’s GHG
18 emissions reductions goals.

19 Still, there are constraints on urban autonomy that might limit urban mitigation influence. The capacity
20 of subnational governments to autonomously pursue emissions reductions on their own depends on
21 different political systems and other aspects of multilevel governance, such as innovation, legitimacy,
22 and institutional fit, as well as the resources, capacity, and knowledge available to subnational
23 technicians and other officials (Widerberg and Pattberg 2015; Valente de Macedo et al. 2016; Green
24 2017; Roger et al. 2017). Financing is considered one of the most crucial facets of urban climate change
25 mitigation. It is also considered one of the biggest barriers given the limited financial capacities of local
26 and regional governments (see Section 8.5.4 and 8.5.5).

27 When sufficient local autonomy is present, local policies have the ability to upscale to higher levels of
28 authority imparting influence at higher geographic scales. Established urban climate leaders with large
29 institutional capacity can influence small and mid-sized cities, or other urban areas with less
30 institutional capacity, to enact effective climate policies, by engaging with those cities through
31 transnational networks and by adopting a public presence of climate leadership (Chan et al. 2015; Kern
32 2019; Seto et al. 2021) (see Section 8.5.3). Increasingly, subnational actors are also influencing their
33 national and international governments through lobbying efforts that call on them to adopt more
34 ambitious climate goals and provide more support for subnational GHG mitigation effort. These
35 dynamics underscore the importance of relative local autonomy in urban GHG mitigation policy. They
36 also highlight the growing recognition of subnational authorities’ role in climate change mitigation by
37 national and international authorities.

38 The confluence of political will and policy action at the local level, and growing resources offered
39 through municipal and regional networks and agreements, have provided a platform for urban actors to
40 engage in international climate policy (see Section 8.5.3). This phenomena is recognized in the Paris
41 Agreement, which, for the first time in a multilateral climate treaty, referenced the crucial role
42 subnational and nonstate actors like local communities have in meeting the goals set forth in the
43 agreement (UNFCCC 2015). The Durban Platform for Enhanced Action (Widerberg and Pattberg 2015)
44 as well as UN Habitat’s NUA and the 2030 Development Agenda are other examples of the international
45 sphere elevating the local level to global influence (Fuhr et al. 2018). Another facet of local-to-global
46 action is the emergence of International Cooperative Initiatives (ICIs) (Widerberg and Pattberg 2015).
47 One such ICI, the City Hall Declaration, was signed alongside the Paris Agreement during the first
48 Climate Summit for Local Leaders. Signatories included hundreds of local government leaders, private

1 sector representatives, and NGOs, who pledged to enact the goals of the Paris Agreement through their
2 own spheres of influence (Cities for Climate 2015). A similar Summit has been held at each subsequent
3 UNFCCC COP. Like transnational climate networks, these platforms provide key opportunities to local
4 governments to further their own mitigation goals, engage in knowledge transfer with other cities and
5 regions, and shape policies at higher levels of authority (Cities for Climate 2015; Castán Broto 2017b).

7 **START BOX 8.3 HERE**

8 **Box 8.3 Coordination of fragmented policymaking for low-carbon urban development: example** 9 **from Shanghai**

10 As a growing megacity in the Global South, Shanghai represents the challenge of becoming low carbon
11 despite its economic growth and population size (Chen et al. 2017). Shanghai was designated as one of
12 the pilot low-carbon cities by the central government. The city utilized a coordination mechanism for
13 joining fragmented policymaking across the city's economy, energy, and environment. The
14 coordination mechanism was supported by a direct fund that enabled implementation of cross-sector
15 policies beyond a single-sector focus across multiple institutions while increasing capacity for enabling
16 a low carbon transition for urban sustainability (Peng and Bai 2020).

17 *Implementation and governance process*

18 In Shanghai, coordination between the central and local governments had an instrumental role for
19 encouraging low-carbon policy experimentation. Using a nested governance framework, the central
20 government provided target setting and performance evaluation while the local government initiated
21 pilot projects for low-carbon development. The policy practices in Shanghai surpassed the top-down
22 targets and annual reporting of GHG emissions, including carbon labelling standards at the local level,
23 pilot programs for transitioning sub-urban areas, and the engagement of public utilities (Peng and Bai
24 2018).

25 *Towards low-carbon urban development*

26 New policy measures in Shanghai were built upon a series of related policies from earlier, ranging from
27 general energy saving measures to air pollution reduction. This provided a continuum of policy learning
28 for implementing low-carbon policy measures. An earlier policy was a green electricity scheme based
29 on the Jade Electricity Program while the need for greater public awareness was one aspect requiring
30 further attention in policy design (Baeumler et al. 2012), supporting policy-learning for policies later
31 on. The key point here is that low-carbon policies were built on and learned from earlier policies with
32 similar goals.

33 *Outcomes and impacts of the policy mix*

34 Trends during 1998 and 2015 indicate that energy intensity decreased from about 130 ton per million
35 RMB to about 45 ton per million RMB and carbon intensity decreased from about 0.35 Mt per billion
36 RMB to 0.10 Mt per billion RMB (Peng and Bai 2018). These impacts on energy and carbon intensities
37 represent progress while challenges remain. Among the challenges are the need for investment in low
38 carbon technology and increases in urban carbon sinks (Yang and Li 2018) while cross-sector
39 interaction and complexity are increasing.

40 **END BOX 8.3 HERE**

42 **8.5.2 Mitigation potential of urban subnational actors**

43 A significant research question that has been paid more attention in both the scientific and policy
44 communities is related to subnational actors' role in and contribution to global climate mitigation. The

1 2018 UN Environment Programme's (UNEP) annual Emissions Gap report in 2018 included for the
2 first time a special chapter on subnational and non-state (i.e., businesses and private actors) and assessed
3 the landscape of studies aiming to quantify their contributions to global climate mitigation. Non-state
4 action on net zero GHG or CO₂ emissions continues to be emphasized (UNEP 2021) (see Box 8.4).
5 There has been an increase in the number of studies aiming to quantify the overall aggregate mitigation
6 impact of subnational climate action globally. Estimates for the significance of their impact vary widely,
7 from up to 30 MtCO₂-eq from 25 cities in the United States in 2030 (Roelfsema 2017), to a 2.3 GtCO₂-
8 eq reduction in 2030 compared to a current policy scenario from over 10,239 cities participating in
9 GCoM (Hsu et al. 2018; GCoM 2019). For regional governments, the Under 2 Coalition, which includes
10 260 governments pledging goals to keep global temperature rise below 2°C, is estimated to reduce
11 emissions by 4.2 GtCO₂-eq in 2030, compared to a current policy scenario (Kuramochi et al. 2020).

12 Some studies suggest that subnational mitigation actions (Roelfsema 2017; Kuramochi et al. 2020) are
13 in addition to national government mitigation efforts and can therefore reduce emissions even beyond
14 current national policies, helping to 'bridge the gap' between emissions trajectories consistent with
15 least-cost scenarios for limiting temperature rise below 1.5°C or 2°C (Blok et al. 2012). In some
16 countries, such as the United States, where national climate policies have been curtailed, the potential
17 for cities and regions' emissions reduction pledges to make up the country's Paris NDC is assessed to
18 be significant (Kuramochi et al. 2020).

19 These estimates are also often contingent on assumptions that subnational actors fulfil their pledges and
20 that these actions do not result in rollbacks in climate action (i.e., weakening of national climate
21 legislation) from other actors or rebound in emissions growth elsewhere, but data tracking or
22 quantifying the likelihood of their implementation remains rare (Chan et al. 2018; Hsu et al. 2019; Hale
23 et al. 2020; Kuramochi et al. 2020). Reporting networks may attract high-performing cities, suggesting
24 an artificially high level of cities interested in taking climate action or piloting solutions that may not
25 be effective elsewhere (van der Heijden 2018). These studies could also present a conservative view of
26 potential mitigation impact because they draw upon publicly reported mitigation actions and inventory
27 data, excluding subnational actors that may be taking actions but not reporting them (Kuramochi et al.
28 2020). The nuances of likelihood, and the drivers and obstacles of climate action across different
29 contexts is a key source of uncertainty around subnational actors' mitigation impacts.

30

31 **8.5.3 Urban climate networks and transnational governance**

32 As of 2019, more than 10,000 cities and regions (Hsu et al. 2020a) have recorded participation in a
33 transnational or cooperative climate action network, which are voluntary membership networks of a
34 range of subnational governments such as cities, as well as regional governments like states and
35 provinces (Hsu et al. 2020a). These organizations, often operating across and between national
36 boundaries, entail some type of action on climate change. Among the most prominent climate networks
37 are GCoM, ICLEI, and C40, all of which ask its members to adopt emission reduction commitments,
38 develop climate action plans, and regularly report on emissions inventories.

39 Municipal and regional networks and agreements have provided a platform for urban actors to engage
40 in international climate policy (Fraundorfer 2017; Keller 2017; Fuhr et al. 2018; Hsu et al. 2018, 2020b;
41 Westman and Broto 2018; Kern 2019; Seto et al. 2021). Their impact comes through (1) providing
42 resources for cities and regions to reduce their GHG emissions and improve environmental quality more
43 generally, independent of national policy; (2) encouraging knowledge transfer between member cities
44 and regions; and (3) as platforms of national and international policy influence (Castán Broto 2017b;
45 Fuhr et al. 2018).

46 Subnational governments that participate in transnational climate networks, however, are primarily
47 located in developed countries, particularly Europe and North America, with far less representation in

1 developing countries. In one of the largest studies of subnational climate mitigation action, more than
2 93% of just over 6,000 quantifiable subnational climate commitments come from cities and regions
3 based in the European Union (NewClimate Institute et al. 2019). Such gaps in geographic coverage
4 have been attributed to factors such as the dominating role of Global North actors in the convening and
5 diffusion of ‘best practices’ related to climate action (Bouteligier 2013), or the more limited autonomy
6 or ability of subnational or non-state actors in Global South countries to define boundaries and interests
7 separately from national governments, particularly those that exercise top-down decision-making or
8 have vertically-integrated governance structures (Bulkeley et al. 2012). Many of the participating
9 subnational actors from under-represented regions are large mega-cities (of 10 million people or more)
10 that will play a pivotal role in shaping emissions trajectories (Data Driven Yale et al. 2018; NewClimate
11 Institute et al. 2019).

12 While these networks have proven to be an important resource in local-level mitigation, their long-term
13 effects and impact at larger scales is less certain (Valente de Macedo et al. 2016; Fuhr et al. 2018). Their
14 influence is most effective when multiple levels of governance are aligned in mitigation policy.
15 Nevertheless, these groups have become essential resources to cities and regions with limited
16 institutional capacity and support (Kern 2019) (for more on transnational climate networks and
17 transnational governance more broadly, see Sections 13.5 and 14.5).

18

19 **START BOX 8.4 HERE**

20

Box 8.4 Net zero targets and urban settlements

21 Around the world, net zero emissions targets, whether economy-wide or targeting a specific sector (e.g.,
22 transport, buildings) or emissions scope (e.g., direct scope 1, or both scope 1 and 2), have been adopted
23 by at least 826 cities and 103 regions that represent 11% of the global population with 846 million
24 people across 6 continents (NewClimate Institute and Data-Driven EnviroLab 2020). In some countries,
25 the share of such cities and regions have reached a critical mass by representing more than 70% of their
26 total populations with or without net zero emissions targets at the national level.

27 In some cases, the scope of these targets extends beyond net zero emissions from any given sector based
28 on direct emissions (see Glossary) and encompass downstream emissions from a consumption-based
29 perspective with 195 targets that are found to represent economy-wide targets. These commitments
30 range from ‘carbon neutrality’ (see Glossary) or net zero GHG emissions targets, which entail near
31 elimination of city’s own direct or electricity-based emissions but could involve some type of carbon
32 offsetting, to more stringent net zero emissions goals (Data-Driven EnviroLab and NewClimate
33 Institute 2020) (for related definitions, such as ‘carbon neutral,’ ‘net zero CO₂ emissions,’ ‘net zero
34 GHG emissions’ and ‘offset,’ see Glossary).

35 Currently, 43% of the urban areas with net zero emissions targets have also put into place related action
36 plans while about 24% have integrated net zero emissions targets into formal policies and legislation
37 (Data-Driven EnviroLab and NewClimate Institute 2020). Moreover, thousands of urban areas have
38 adopted renewable energy-specific targets for power, heating/cooling and transport and about 600 cities
39 are pursuing 100% renewable energy targets (REN21 2019, 2021) with some cities already achieving
40 it.

41 The extent of realising and implementing these targets with the collective contribution of urban areas
42 to net zero emissions scenarios with sufficient timing and pace of emission reductions will require a
43 coordinated integration of sectors, strategies, and innovations (Swilling et al. 2018; Hsu et al. 2020c;
44 Sethi et al. 2020; UNEP and IRP 2020). In turn, the transformation of urban systems can significantly
45 impact net zero emissions trajectories within mitigation pathways. Institutional capacity, governance,

1 financing, and cross-sector coordination is crucial for enabling and accelerating urban actions for rapid
2 decarbonization.

3 **END BOX 8.4 HERE**

4

5 **8.5.4 Financing urban mitigation**

6 Meeting the goals of the Paris Agreement will require fundamental changes that will be most successful
7 when cities work together with provincial and national leadership and legislation, third-sector
8 leadership, transformative action, and supportive financing. Urban governments often obtain their
9 powers from provincial, state and/or national governments, and are subjected to laws and regulations to
10 regulate development and implement infrastructure. In addition, the sources of revenue are often set at
11 these levels so that many urban governments rely on state/provincial and national government funds for
12 improving infrastructure, especially transit infrastructure. The increasing financialisation of urban
13 infrastructures is another factor that can make it more difficult for local governments to determine
14 infrastructure choices (O'Brien et al. 2019). Urban transit system operations, in particular, are heavily
15 subsidized in many countries, both locally and by higher levels of government. As a result of this
16 interplay of policy and legal powers among various levels of government, the lock-in nature of urban
17 infrastructures and built environments will require multi-level governance response to ensure meeting
18 decarbonization targets. The reliance on state and national policy and/or funding can accelerate or
19 impede the decarbonization of urban environments (McCarney et al. 2011; McCarney 2019).

20 The world's infrastructure spending is expected to more than double from 2015 to 2030 under a low-
21 carbon and climate resilient scenario. More than 70% of the infrastructure will concentrate in urban
22 areas by requiring USD 4.5-5.4 trillion per year (CCFLA 2015). However, today's climate finance
23 flows for cities or 'urban climate finance,' estimated at USD 384 billion annually on average in 2017/18,
24 are insufficient to meet the USD 4.5 trillion to USD 5.4 trillion-dollar annual investment needs for urban
25 mitigation actions across key sectors (CCFLA 2015; CPI and World Bank 2021; Negreiros et al. 2021).
26 Low-carbon urban form (e.g., compact, high-density, and mixed-use characteristics) is likely to
27 economize spending in infrastructure along with the application of new technologies and renewable
28 energies that would be able to recover the increasing upfront cost of low-carbon infrastructure from
29 more efficient operating and energy savings (Global Commission on the Economy and Climate 2014;
30 Foxon et al. 2015; Bhattacharya et al. 2016; Floater et al. 2017; Colenbrander et al. 2018b) (*medium*
31 *evidence, high agreement*).

32 Governments have traditionally financed a large proportion of infrastructure investment. When budget
33 powers remain largely centralized, intergovernmental transfers will be needed to fund low-carbon
34 infrastructure in cities. During the COVID-19 pandemic, cities tend to rely more on intergovernmental
35 transfers in the form of stimulus packages for economic recovery. Nonetheless, the risk of high carbon
36 lock-ins is likely to increase in rapidly growing cities if long-term urban mitigation strategies are not
37 incorporated into short-term economic recovery actions (Granoff et al. 2016; Floater et al. 2017;
38 Colenbrander et al. 2018b; CPI and World Bank 2021; Negreiros et al. 2021). Indeed, large and complex
39 infrastructure projects for urban mitigation are often beyond the capacity of both national government
40 and local municipality budgets. Additionally, the COVID-19 pandemic necessitates large government
41 expenditures for public health programs and decimates municipal revenue sources for urban
42 infrastructure projects in cities.

43 To meet the multi-trillion-dollar annual investment needs in urban areas, cities in partnership with
44 international institutions, national governments, and local stakeholders increasingly play a pivotal role
45 in mobilizing global climate finance resources for a range of low-carbon infrastructure projects and
46 related urban land use and spatial planning programs across key sectors (*high confidence*). In particular,

1 national governments are expected to set up enabling conditions for the mobilization of urban climate
2 finance resource by articulating various goals and strategies, improving pricing, regulation and
3 standards, and developing investment vehicles and risk sharing instruments (Qureshi 2015; Bielenberg
4 et al. 2016; Granoff et al. 2016; Floater et al. 2017; Sudmant et al. 2017; Colenbrander et al. 2018b;
5 Zhan and de Jong 2018; Hadfield and Cook 2019; CPI and World Bank 2021; Negreiros et al. 2021).

6 Indeed, 75% of the global climate finance for both mitigation and adaptation in 2017 and 2018 took the
7 form of commercial financing (e.g., balance sheets, commercial-rate loans, and equity), while 25%
8 came from the form of concessionary financing (e.g., grants, below-market-rate loans, etc.). However,
9 cities in developing countries are facing difficulty making use of commercial financing and gaining
10 access to international credit markets. Cities without international creditworthiness currently rely on
11 local sources, including domestic commercial banks (Global Commission on the Economy and Climate
12 2014; CCFLA 2015; Floater et al. 2017; Buchner et al. 2019) (*medium evidence, high agreement*).

13 Cities with creditworthiness have rapidly become issuers of ‘green bonds’ eligible for renewable
14 energy, energy efficiency, low-carbon transport, sustainable water, waste, and pollution, and other
15 various climate mitigation projects across the global regions since 2013. The world’s green bond market
16 reached USD 1 trillion in cumulative issuance, with issuance of USD 280 billion in 2020, during the
17 COVID-19 pandemic. While green municipal bonds still account for a small share of the whole green
18 bond market in 2020, scale is predicted to grow further in emerging markets over the coming years.
19 Green municipal bonds have great potential for cities to expand and diversify their investor base. In
20 addition, the process of issuing green municipal bonds is expected to promote cross-sector cooperation
21 within a city by bringing together various agencies responsible for finance, climate change,
22 infrastructure, planning and design, and operation. Indeed, the demand for green bonds presently
23 outstrips supply as being constantly over-subscribed (Global Commission on the Economy and Climate
24 2014; Saha and D’Almeida 2017; Amundi and IFC 2021) (*robust evidence, high agreement*).

25 On the other hand, cities without creditworthiness face difficulty making use of commercial financing
26 and getting access to international credit markets (Global Commission on the Economy and Climate
27 2014; CCFLA 2015; Floater et al. 2017). The lack of creditworthiness is one of the main problems
28 preventing cities from issuing green municipal bonds in developing countries. As a prerequisite for the
29 application of municipal debt-financing, it is an essential condition for cities to ensure sufficient own
30 revenues from low-carbon urbanization, or the default risk becomes too high for potential investors.
31 Indeed, many cities in developed countries and emerging economies have already accumulated
32 substantial amounts of debts through bond insurances, and on-going debt payments prevent new
33 investments in low-carbon infrastructure projects.

34 National governments and multilateral development banks might be able to provide support for debt
35 financing by developing municipal creditworthiness programs and issuing sovereign bonds or providing
36 national guarantees for investors (Floater et al. 2017). Another problem with green municipal bonds is
37 the lack of aggregation mechanisms to support various small-scale projects in cities. Asset-backed
38 securities are likely to reduce the default risk for investors through portfolio diversification and create
39 robust pipelines for a bundle of small-scale projects (Granoff et al. 2016; Floater et al. 2017; Saha and
40 D’Almeida 2017).

41 In principle, the upfront capital costs of various low-carbon infrastructure projects, including the costs
42 of urban climate finance (dividend and interest payments), are eventually transferred to users and other
43 stakeholders in the forms of taxes, charges, fees, and other revenue sources. Nevertheless, small cities
44 in developing countries are likely to have a small revenue base, most of which is committed to recurring
45 operating costs, associated with weak revenue collection and management systems. In recent years,
46 there has been scope to apply not only user-based but also land-based funding instruments for the
47 recovery of upfront capital costs (Braun and Hazelroth 2015; Kościelniak and Górka 2016; Floater et
48 al. 2017; Colenbrander et al. 2018b; Zhan and de Jong 2018; Zhan et al. 2018a).

1 In practice, however, the application of land-based or ‘land value capture’ funding requires cities to
2 arrange various instruments, including property (both land and building taxes), betterment levies/special
3 assessments, impact fees (exactions), tax increment financing, land readjustment/land pooling, sales of
4 public land/development rights, recurring lease payments, and transfer taxes/stamp duties, across
5 sectors in different urban contexts (Suzuki et al. 2015; Chapman 2017; Walters and Gaunter 2017;
6 Berrisford et al. 2018). Land value capture is expected not only for cities to generate additional revenue
7 streams but also to prevent low-density urban expansion around city-fringe locations. Inversely, land
8 value capture is supposed to perform well when accompanied by low-carbon urban form and private
9 real estate investments along with the application of green building technologies (Suzuki et al. 2015;
10 Floater et al. 2017; Colenbrander et al. 2018b) (*robust evidence, high agreement*).

11 For the implementation of land-based funding, property rights are essential. However, weak urban-rural
12 governance leads to corruption in land occupancy and administration, especially in developing countries
13 with no land information system or less reliable paper-based land records under a centralized
14 registration system. The lack of adequate property rights seriously discourages low-carbon
15 infrastructure and real estate investments in growing cities.

16 The emerging application of blockchain technology for land registry and real estate investment is
17 expected to change the governance framework, administrative feasibility, allocative efficiency, public
18 accountability, and political acceptability of land-based funding in cities across developed countries,
19 emerging economies, and developing countries (Graglia and Mellon 2018; Kshetri and Voas 2018).
20 Particularly, the concept of a transparent, decentralized public ledger is adapted to facilitate value-added
21 property transactions on a P2P basis without centralized intermediate parties and produce land-based
22 funding opportunities for low-carbon infrastructure and real estate development district-wide and city-
23 wide in unconventional ways (Veuger 2017; Nasarre-Aznar 2018).

24 The consolidation of local transaction records into national or supranational registries is likely to
25 support large-scale land formalisation, but most pilot programs are not yet at the scale (Graglia and
26 Mellon 2018). Moreover, the potential application of blockchain for land-based funding instruments is
27 possibly associated with urban form attributes, such as density, compactness, and land use mixture, to
28 disincentivize urban expansion and emissions growth around city-fringe locations (*medium confidence*)
29 (Allam and Jones 2019).

30

31 **8.5.5 Barriers and enablers for implementation**

32 Irrespective of geography or development level, many cities face similar climate governance challenges
33 such as lacking institutional, financial, and technical capacities (Gouldson et al. 2015; Hickmann and
34 Stehle 2017; Sharifi et al. 2017; Fuhr et al. 2018). Large-scale system transformations are also deeply
35 influenced by factors outside governance and institutions such as private interests and power dynamics
36 (Jaglin 2014; Tyfield 2014). In some cases, these private interests are tied up with international flows
37 of capital. At the local level, a lack of empowerment, high upfront costs, inadequate and uncertain
38 funding for mitigation, diverse and conflicting policy objectives, multiple agencies and actors with
39 diverse interests, high levels of informality, and a siloed approach to climate action are constraining
40 factors to mainstreaming climate action (Beermann et al. 2016; Gouldson et al. 2016; Pathak and
41 Mahadevia 2018; Khosla and Bhardwaj 2019).

42 Yet urban mitigation options that can be implemented to transform urban systems involve the interplay
43 of multiple enablers and barriers. Based on a framework for assessing feasibility from a multi-
44 dimensional perspective, feasibility is malleable and various enablers can be brought into play to
45 increase the implementation of mitigation options. The scope of this assessment enables an approach
46 for considering multiple aspects that have an impact on feasibility as a tool for policy support (Singh et
47 al. 2020). In Figure 8.19, the assessment framework that is based on geophysical, environmental-

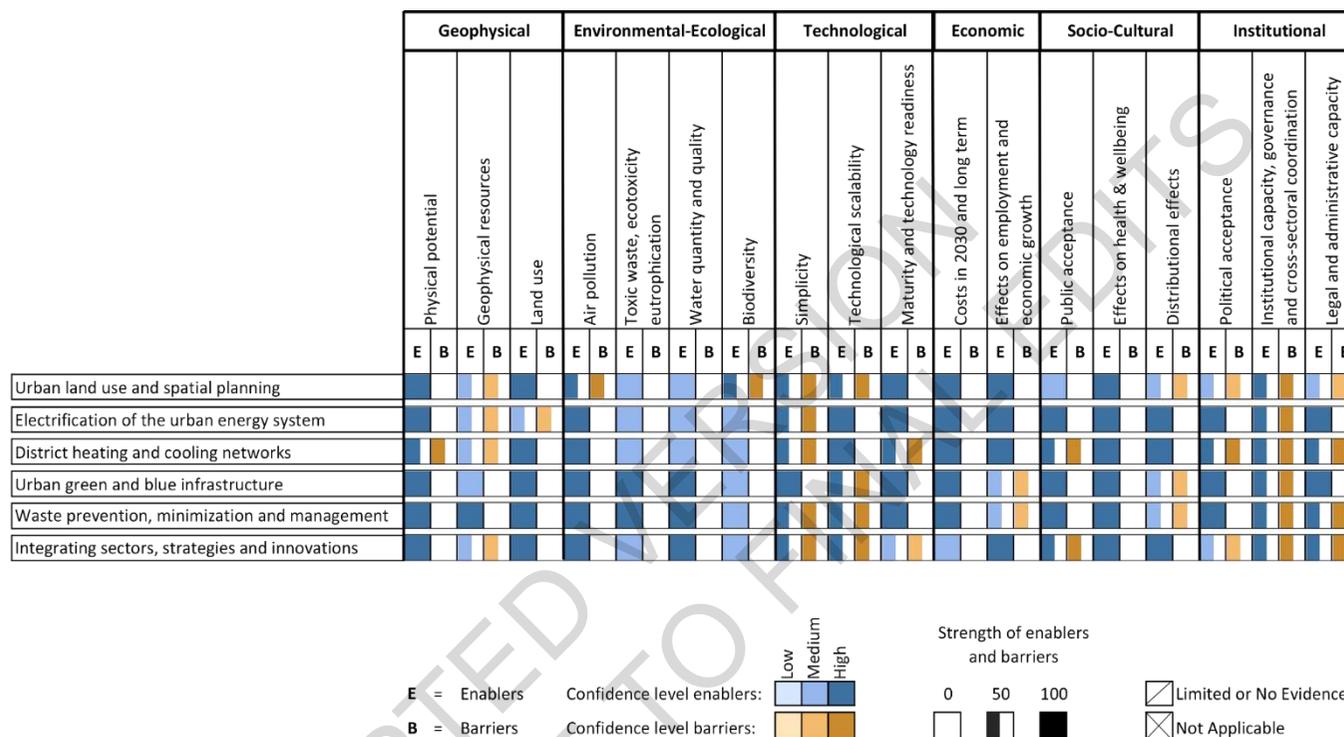

1 ecological, technological, economic, socio-cultural, and institutional dimensions is applied to identify
2 the enablers and/or barriers in implementing mitigation options in urban systems. The feasibility of
3 options may differ across context, time, and scale (see Supplementary Material 8.2). The line of sight
4 upon which the assessment is based includes urban case studies (Lamb et al. 2019) and assessments of
5 land use and spatial planning in IPCC SR1.5 (IPCC 2018a).

6 Across the enablers and barriers of different mitigation options, urban land use and spatial planning for
7 increasing co-located densities in urban areas has positive impacts in multiple indicators, particularly
8 reducing land use and preserving carbon sinks when the growth in urban extent is reduced and avoided,
9 which if brought into interplay in decision-making, can support the enablers for its implementation.
10 Improvements in air quality are possible when higher urban densities are combined with modes of active
11 transport, electrified mobility as well as urban green and blue infrastructure (see Sections 8.3.4, 8.4 and
12 8.6). The demands on geophysical resources, including materials for urban development, will depend
13 on whether additional strategies are in place with largely negative impacts under conventional practices.
14 The technological scalability of multiple urban mitigation options is favourable while varying according
15 to the level of existing urban development and scale of implementation (see Tables SM8.3 - SM8.4 in
16 Supplementary Material 8.2).

17 Similarly, multiple mitigation options have positive impacts on employment and economic growth,
18 especially when urban densities enable productivity. Possible distributional effects, including
19 availability of affordable accommodation and access to greenspace, are best addressed when urban
20 policy packages combine more than one policy objective. Such an approach can provide greater support
21 to urban mitigation efforts with progress towards shifting urban development to sustainability. The
22 electrification of the urban energy system involves multiple enablers that support the feasibility of this
23 mitigation option, including positive impacts on health and well-being. In addition, increases in urban
24 densities can support the planning of district heating and cooling networks that can decarbonize the
25 built environment at scale with technology readiness levels increasing for lower temperature supply
26 options. Preventing, minimizing, and managing waste as an urban mitigation option can be enabled
27 when informality in the sector is transformed to secure employment effects and value addition based on
28 the more circular use of resources (see Tables SM8.3 and SM8.4 in Supplementary Material 8.2, and
29 Sections 8.4.3 and 8.4.5).

30 As a combined evaluation, integrating multiple mitigation options in urban systems involves the greatest
31 requirement for strengthening institutional capacity and governance through cross-sectoral coordination
32 (see Section 8.4 and 8.6, and Figure 8.21). Notably, integrated action requires significant effort to
33 coordinate sectors and strategies across urban growth typologies (see Section 8.6). Institutional
34 capacity, if not strengthened to a suitable level to handle this process—especially to break out of carbon
35 lock-in—can fall short of the efforts this entails. These conditions can pose barriers for realizing cross-
36 sectoral coordination while the formation of partnerships and stakeholder engagement take place as
37 important enablers. Overcoming institutional challenges for cross-sectoral coordination can support
38 realizing synergies among the benefits that each mitigation option can offer within and across urban
39 systems, including for the SDGs. These include those that can be involved in co-located and walkable
40 urban form together with decarbonizing and electrifying the urban energy system as well as urban green
41 and blue infrastructure, providing the basis for more liveable, resource efficient and compact urban
42 development with benefits for urban inhabitants (see Section 8.2).

3 **Figure 8.19 Feasibility assessment based on the enablers and barriers of implementing mitigation options for urban systems across multiple dimensions.**
 4 **The figure summarizes the extent to which different factors would enable or inhibit the deployment of mitigation options in urban systems. These factors are**
 5 **assessed systematically based on 18 indicators in 6 dimensions (geophysical, environmental-ecological, technological, economic, socio-cultural, and institutional**
 6 **dimensions). Blue bars indicate the extent to which the indicator enables the implementation of the option (E) and orange bars indicate the extent to which an**
 7 **indicator is a barrier (B) to the deployment of the option, relative to the maximum possible barriers and enablers assessed. The shading indicates the level of**
 8 **confidence, with darker shading signifying higher levels of confidence. Supplementary Material SM8.2 provides an overview of the extent to which the feasibility of**
 9 **options may differ across context, time and scale of implementation (Table SM8.3) and includes line of sight upon which the assessment is based (Table SM8.4). The**
 10 **line of sight builds upon urban case studies in (Lamb et al. 2019) and assessments for land use and urban planning (IPCC 2018a) involving 414 references. The**
 11 **assessment method is further explained in Annex II, Section 11.**

1 **8.6 A roadmap for integrating mitigation strategies for different** 2 **urbanization typologies**

3 The most effective and appropriate packages of mitigation strategies will vary depending on several
4 dimensions of a city. This section brings together the urban mitigation options described in Section 8.4
5 and assesses the range of mitigation potentials for different types of cities. There is consensus in the
6 literature that mitigation strategies are most effective when multiple interventions are coupled together.
7 Urban-scale interventions that implement multiple strategies concurrently through policy packages are
8 more effective and have greater emissions savings than when single interventions are implemented
9 separately. This is because a citywide strategy can have cascading effects across sectors, that have
10 multiplicative effects on GHG emissions reduction within and outside a city's administrative
11 boundaries. Therefore, city-scale strategies can reduce more emissions than the net sum of individual
12 interventions, particularly if multiple scales of governance are included (see Sections 8.4 and 8.5).
13 Furthermore, cities have the ability to implement policy packages across sectors using an urban systems
14 approach, such as through planning, particularly those that affect key infrastructures (see Figures 8.15,
15 8.17 and 8.22).

16 The way that cities are laid out and built will shape the entry points for realising systemic transformation
17 across urban form and infrastructure, energy systems, and supply chains. Section 8.3.1 discusses the
18 ongoing trend of rapid urbanization—and how it varies through different forms of urban development
19 or 'typologies' (see Figure 8.6). Below, Figure 8.20 distils the typologies of urban growth across three
20 categories: emerging, rapidly growing, and established. Urban growth is relatively stabilized in
21 established urban areas with mature urban form while newly taking shape in emerging urban areas. In
22 contrast, rapidly growing urban areas experience pronounced changes in outward and/or upward
23 growth. These typologies are not mutually exclusive, and can co-exist within an urban system; cities
24 typically encompass a spectrum of development, with multiple types of urban form and various
25 typologies (Mahtta et al. 2019).

26 Taken together, urban form (Figure 8.16) and growth typology (Figure 8.20) can act as a roadmap for
27 cities or sub-city communities looking to identify their urban context and, by extension, the mitigation
28 opportunities with the greatest potential to reduction GHG emissions. Specifically, this considers
29 whether a city is established with existing and managed infrastructure, rapidly growing with new and
30 actively developing infrastructure, or emerging with large amounts of infrastructure build-up. The long
31 lifespan of urban infrastructure locks in behaviour and committed emissions. Therefore, the sequencing
32 of mitigation strategies is important for determining emissions savings in the short- and long-term.
33 Hence, different types of cities will have different mitigation pathways, depending upon a city's urban
34 form and state of that city's urban development and infrastructure; the policy packages and
35 implementation plan that provide the highest mitigation potential for rapidly growing cities with new
36 infrastructures will differ from those for established cities with existing infrastructure.

37 Mitigation options that involve spatial planning, urban form, and infrastructure—particularly co-located
38 and mixed land use, as well as TOD—provide the greatest opportunities when urban areas are rapidly
39 growing or emerging (see Section 8.4.2). Established urban areas that are already compact and walkable
40 have captured mitigation benefits from these illustrative strategies to various extents. Conversely,
41 established urban areas that are dispersed and auto-centric have foregone these opportunities with the
42 exception of urban infill and densification that can be used to transform or continue to transform the
43 existing urban form. Figure 8.21 underscores that urban mitigation options and illustrative strategies
44 differ by urban growth typologies and urban form. Cities can identify their entry points for sequencing
45 mitigation strategies.

46 The emissions reduction potential of urban mitigation options further varies based on governance
47 contexts, institutional capacity, economic structure, as well as human and physical geography.

1 According to the development level, for instance, urban form can remain mostly planned or unplanned,
 2 taking place spontaneously, with persistent urban infrastructure gaps remaining (Lwasa et al. 2018;
 3 Kareem et al. 2020). Measures for closing the urban infrastructure gap while addressing ‘leapfrogging’
 4 opportunities (see Glossary) for mitigation and providing co-benefits represent possibilities for shifting
 5 development paths for sustainability (see Cross-Chapter Box 5 in Chapter 4).

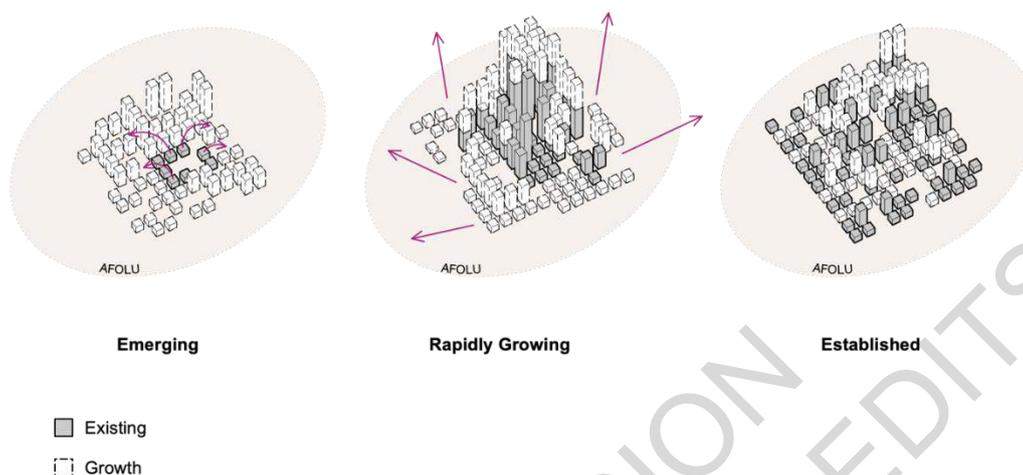

Figure 8.20 Urban Growth Typologies

Urban growth typologies define the main patterns of urban development, synthesized from Mahtta et al. (2019) and Lall et al. (2021)

Emerging urban areas are undergoing the build-up of new infrastructure. These are new urban areas that are budding out. Rapidly growing urban areas are undergoing significant changes in either outward and/or upward growth, accompanied by large-scale development of new urban infrastructure.

Established urban areas are relatively stable with mature urban form and existing urban infrastructures. Each of these typologies represents different levels of economic development and state of urbanization.

Rapidly growing urban areas that are building up through vertical development are often those with higher levels of economic development. Rapidly growing urban areas that are building outward through horizontal expansion occurs at lower levels of economic development and are land intensive. Like with urban form, different areas of a single city can undergo different growth typologies. Therefore a city will be comprised of multiple urban growth typologies.

Source: Synthesized and adapted from Mahtta et al. (2019) and Lall et al. (2021)

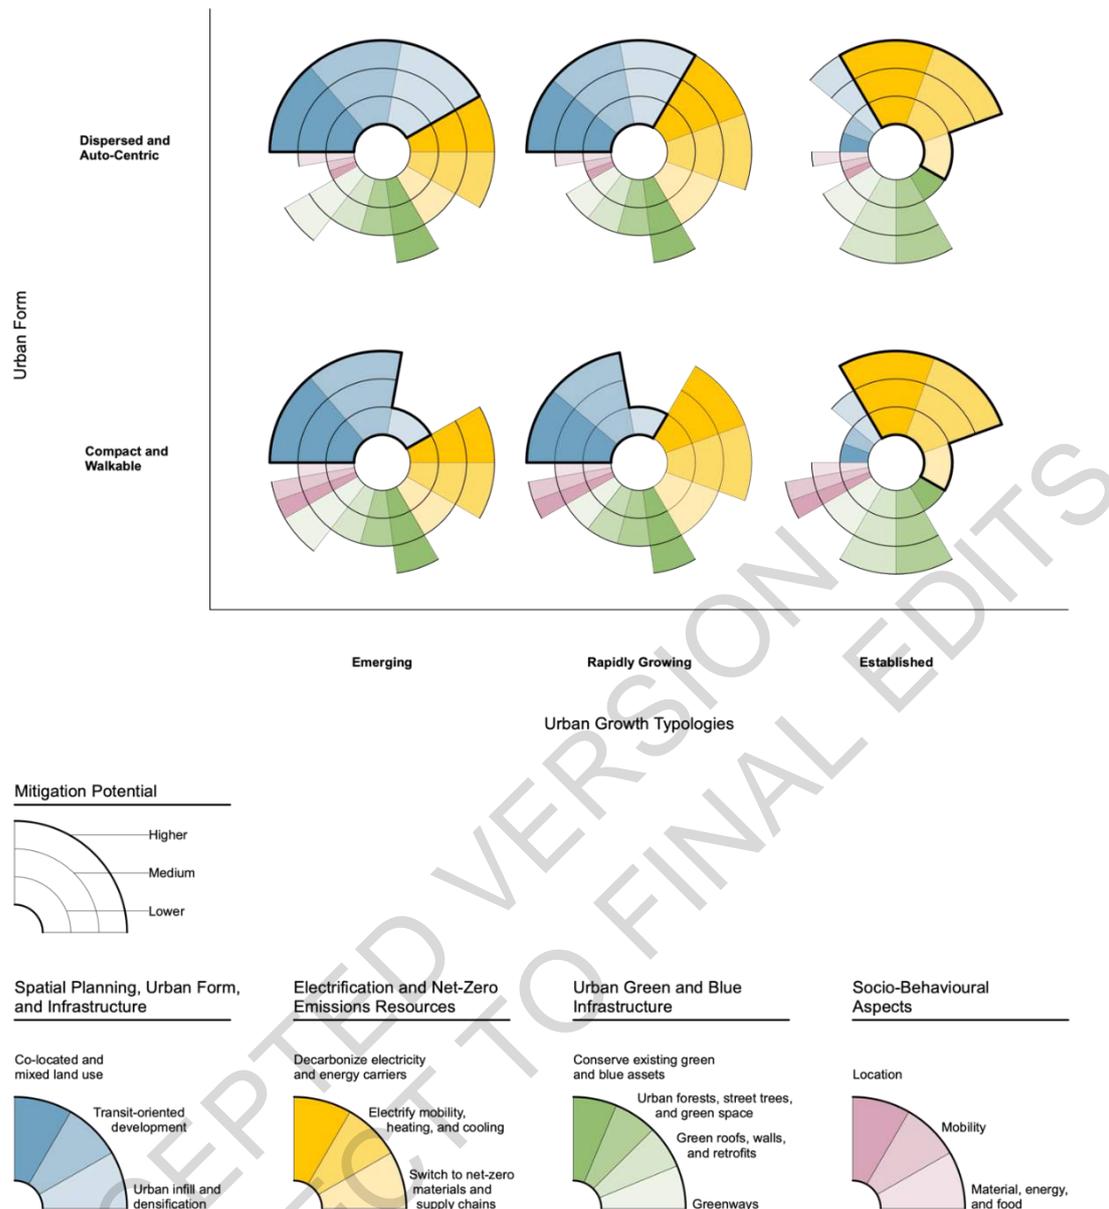

Figure 8.21 Priorities and potentials for packages of urban mitigation strategies across typologies of urban growth (Figure 8.20) and urban form (Figure 8.16)

The horizontal axis represents urban growth typologies based on emerging, rapidly growing, and established urban areas. The vertical axis shows the continuum of urban form, from compact and walkable, to dispersed and auto-centric. Urban areas can first locate their relative positioning in this space according to their predominant style of urban growth and urban form. The urban mitigation options are bundled across four broad sectors of mitigation strategies: (1) spatial planning, urban form, and infrastructure (blue); (2) electrification and net zero emissions resources (yellow); (3) urban green and blue infrastructure (green); and (4) socio-behavioural aspects (purple). The concentric circles indicate lower, medium, and higher mitigation potential considering the context of the urban area. For each city type (circular graphic) the illustrative urban mitigation strategy that is considered to provide the greatest cascading effects across mitigation opportunities is represented by a section that is larger relative to others; those strategy sections outlined in black are ‘entry points’ for sequencing of strategies. Within each of the larger strategy sections (i.e., spatial planning, urban green and blue infrastructure, etc.), the size of the sub-strategy sections are equal and do not suggest any priority or sequencing. The relative sizes of the strategies and extent of mitigation potential are illustrative and based on the authors' best understanding and assessment of the literature.

1

2 **8.6.1 Mitigation opportunities for *established* cities**

3 *Established cities will achieve the largest GHG emissions savings by replacing, repurposing, or*
4 *retrofitting the building stock, encouraging modal shift, electrifying the urban energy system, as well*
5 *as infilling and densifying urban areas.*

6 Shifting pathways to low-carbon development for established cities with existing infrastructures and
7 locked-in behaviours and lifestyles is admittedly challenging. Urban infrastructures such as buildings,
8 roads, and pipelines often have long lifetimes that lock-in emissions, as well as institutional and
9 individual behaviour. Although the expected lifetime of buildings varies considerably by geography,
10 design, and materials, typical lifespans are at minimum 30 years to more than 100 years.

11 Cities where urban infrastructure has already been built have opportunities to increase energy efficiency
12 measures, prioritize compact and mixed-use neighbourhoods through urban regeneration, advance the
13 urban energy system through electrification, undertake cross-sector synergies, integrate urban green and
14 blue infrastructure, encourage behavioural and lifestyle change to reinforce climate mitigation, and put
15 into place a wide range of enabling conditions as necessary to guide and coordinate actions in the urban
16 system and its impacts in the global system. Retrofitting buildings with state of the art deep energy
17 retrofit measures could reduce emissions of the existing stock by about 30–60% (Creutzig et al. 2016a)
18 and in some cases up to 80% (Ürge-Vorsatz et al. 2020) (see Section 8.4.3).

19 Established cities that are compact and walkable are likely to have low per capita emissions, and thus
20 can keep emissions low by focusing on electrification of all urban energy services and using urban green
21 and blue infrastructure to sequester and store carbon while reducing urban heat stress. Illustrative
22 mitigation strategies with the highest mitigation potential are decarbonizing electricity and energy
23 carriers while electrifying mobility, heating, and cooling (see Table 8.3 and Figure 8.19). Within
24 integrated strategies, the importance of urban forests, street trees, and green space as well as green roofs,
25 walls, and retrofits, also have high mitigation potential (see Section 8.4.4 and Figure 8.18).

26 Established cities that are dispersed and auto-centric are likely to have higher per capita emissions and
27 thus can reduce emissions by focusing on creating modal shift and improving public transit systems in
28 order to reduce urban transport emissions, as well as focusing on infilling and densifying. Only then
29 can the urban form constraints on locational and mobility options be increased. Among mitigation
30 options based on spatial planning, urban form, and infrastructure, urban infill and densification has
31 priority. For these cities, the use of urban green and blue infrastructure will be essential to offset residual
32 emissions that cannot be reduced because their urban form is already established and difficult to change.

33 System-wide energy savings and emissions reductions for low-carbon urban development is widely
34 recognized to require both behavioural and structural changes (Zhang and Li 2017). Synergies between
35 social and ecological innovation can reinforce the sustainability of urban systems while decoupling
36 energy usage and economic growth (Hu et al. 2018; Ma et al. 2018). In addition, an integrated
37 sustainable development approach that enables cross-sector energy efficiency, sustainable transport,
38 renewable energy, and local development in urban neighbourhoods can address issues of energy poverty
39 (Pukšec et al. 2018). In this context, cross-sectoral, multi-scale, and public-private collaborative action
40 is crucial to steer societies and cities closer to low-carbon futures (Hölscher et al. 2019). Such action
41 includes those for guiding residential living area per capita, limiting private vehicle growth, expanding
42 public transport, improving the efficiency of urban infrastructure, enhancing urban carbon pools, and
43 minimizing waste through sustainable, ideally circular, waste management (Lin et al. 2018). Through a
44 coordinated approach, urban areas can be transformed into hubs for renewable and distributed energy,
45 sustainable mobility, as well as inclusivity and health (Newman et al. 2017; Newman 2020).

1 Urban design for existing urban areas include strategies for urban energy transitions for carbon
2 neutrality based on renewable energy, district heating for the city centre and suburbs, as well as green
3 and blue interfaces (Pulselli et al. 2021). Integrated modelling approaches for urban energy system
4 planning, including land-use and transport and flexible demand-side options, is increased when
5 municipal actors are also recognized as energy planners (Yazdanie and Orehoung 2021) (see Section
6 8.4.3). Enablers for action can include the co-design of infill residential development through an
7 inclusive and participatory process with citizen utilities and disruptive innovation that can support net
8 zero carbon power while contributing to 1.5°C pathways, the SDGs, and affordable housing
9 simultaneously (Wiktorowicz et al. 2018). Cross-sectoral strategies for established cities, including
10 those taking place among 120 urban areas, also involve opportunities for sustainable development
11 (Kılış 2019, 2021b).

12 A shared understanding for urban transformation through a participatory approach can largely avoid
13 maladaptation and contribute to equity (Moglia et al. 2018). Transformative urban futures that are
14 radically different from the existing trajectories of urbanization, including in developing countries, can
15 remain within planetary boundaries while being inclusive of the urban poor (Friend et al. 2016). At the
16 urban policy level, an analysis of 12,000 measures in urban-level monitoring emissions inventories
17 based on the mode of governance further suggests that local authorities with lower population have
18 primarily relied on municipal self-governing while local authorities with higher population more
19 frequently adopted regulatory measures as well as financing and provision (Palermo et al. 2020b).
20 Policies that relate to education and enabling were uniformly adopted regardless of population size
21 (Palermo et al. 2020b). Multi-disciplinary teams, including urban planners, engineers, architects, and
22 environmental institutions, can support local decision-making capacities, including for increasing
23 energy efficiency and renewable energy considering building intensity and energy use (Mrówczyńska
24 et al. 2021) (see also Section 8.5).

25 **8.6.2 Mitigation opportunities for rapidly growing cities**

26 *Rapidly growing cities with new and actively developing infrastructures can avoid higher future*
27 *emissions through using urban planning to co-locate jobs and housing, and achieve compact urban*
28 *form; leapfrogging to low-carbon technologies; electrifying all urban services, including*
29 *transportation, cooling, heating, cooking, recycling, water extraction, wastewater recycling, etc.; and*
30 *preserving and managing existing green and blue assets.*

31 Rapidly growing cities have significant opportunities for integrating climate mitigation response
32 options in earlier stages of urban development, which can provide even greater opportunities for
33 avoiding carbon lock-in and shifting pathways towards net zero GHG emissions. In growing cities that
34 are expected to experience large increases in population, a significant share of urban development
35 remains to be planned and built. The ability to shift these investments towards low-carbon development
36 earlier in the process represents an important opportunity for contributing to net zero GHG emissions
37 at the global scale. In particular, evidence suggests that investment in low-carbon development
38 measures and re-investment based on the returns of the measures even without considering substantial
39 co-benefits can provide tipping points for climate mitigation action and reaching peak emissions at
40 lower levels while decoupling emissions from economic growth, even in fast-growing megacity
41 contexts with well-established infrastructure (Colenbrander et al. 2017).

42 At the same time, some of the rapidly growing cities in developing countries can have existing walkable
43 urban design that can be maintained and supported with electrified urban rail plus renewable-energy-
44 based solutions to avoid a shift to private vehicles (Sharma 2018). In addition, community-based
45 distributed renewable electricity can be applicable for the regeneration of informal settlements rather
46 than more expensive informal settlement clearance (Teferi and Newman 2018). Scalable options for
47 decentralized energy, water, and wastewater systems, as well as spatial planning and urban agriculture
48 and forestry, are applicable to urban settlements across multiple regions simultaneously (Lwasa 2017).

1 Rapidly urbanizing areas can experience pressure for rapid growth in urban infrastructure to address
2 growth in population. This challenge can be addressed with coordinated urban planning and support
3 from enabling conditions for pursuing effective climate mitigation (see Section 8.5 and Box 8.3). The
4 ability to mobilize low-carbon development will also increase opportunities for capturing co-benefits
5 for urban inhabitants while reducing embodied and operational emissions. Transforming urban growth,
6 including its impacts on energy and materials, can be carefully addressed with the integration of cross-
7 sectoral strategies and policies.

8 Rapidly growing cities have entry points into an integrated strategy based on spatial planning, urban
9 form and infrastructure (see Figure 8.21). For rapidly growing cities that may be co-located and
10 walkable at present, remaining compact is better ensured when co-location and mixed land use as well
11 as TOD continues to be prioritized (see Section 8.4.2). Concurrently, ensuring that electricity and
12 energy carriers are decarbonized while electrifying mobility, heating and cooling will support the
13 mitigation potential of these cities. Along with an integrated approach across other illustrative
14 strategies, switching to net zero materials and supply chains holds importance (see Section 8.4.3). Cities
15 that remain compact and walkable can provide a greater array of locational and mobility options to the
16 inhabitants that can be adopted for mitigation benefits. Rapidly growing cities that may currently be
17 dispersed and auto-centric can capture high mitigation potential through urban infill and densification.
18 Conserving existing green and blue assets, thereby protecting sources of carbon storage and
19 sequestration, as well as biodiversity, have high potential for both kinds of existing urban form,
20 especially when the rapid growth can be controlled.

21 **8.6.3 Mitigation opportunities for *new and emerging cities***

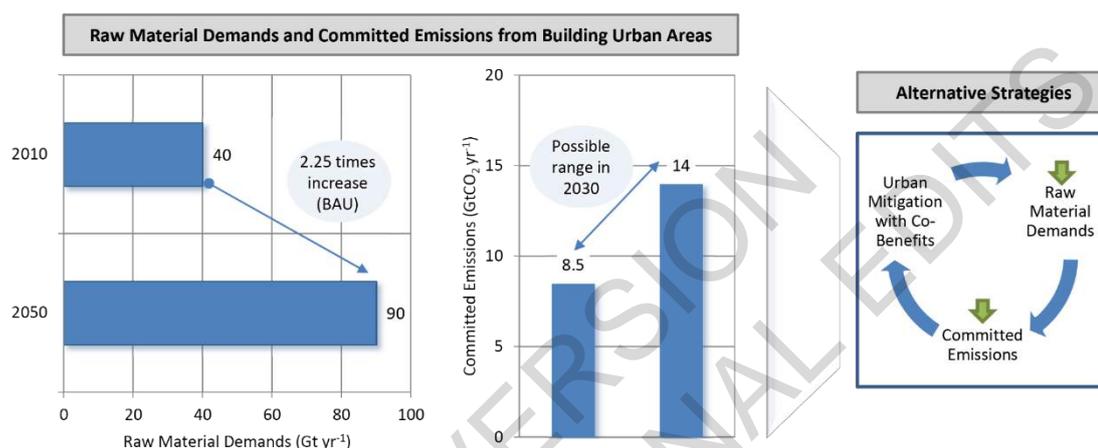

22 *New and emerging cities have unparalleled potential to become low or net zero emissions urban areas*
23 *while achieving high quality of life by creating compact, co-located, and walkable urban areas with*
24 *mixed land use and TOD, that also preserve existing green and blue assets.*

25 The fundamental building blocks that make up the physical attributes of cities, such as the layout of
26 streets, the size of the city blocks, the location of where people live versus where they work, can affect
27 and lock in energy demand for long time periods (Seto et al. 2016) (see Section 8.4.1). A large share of
28 urban infrastructures that will be in place by 2050 has yet to be constructed and their design and
29 implementation will determine both future GHG emissions as well as the ability to meet mitigation
30 goals (Creutzig et al. 2016a) (see Figure 8.10 and Table 8.1). Thus, there are tremendous opportunities
31 for new and emerging cities to be designed and constructed to be low-emissions while providing high
32 quality of life for their populations.

33 The UN International Resource Panel (IRP) estimates that building future cities under conventional
34 practices will require a more than doubling of material consumption, from 40 billion tonnes annually in
35 2010 to about 90 billion tonnes annually by 2050 (Swilling et al. 2018). Thus, the demand that new and
36 emerging cities will place on natural resource use, materials, and emissions can be minimized and
37 avoided only if urban settlements are planned and built much differently than today, including
38 minimized impacts on land use based on compact urban form, lowered use of materials, and related
39 cross-sector integration, including energy-driven urban design for sustainable urbanization.

40 Minimising and avoiding raw material demands depend on alternative options while accommodating
41 the urban population. In addition, operational emissions that can be committed by new urban
42 infrastructure can range between 8.5 GtCO₂ and 14 GtCO₂ annually up to 2030 (Erickson and Tempest
43 2015). Buildings and road networks are strongly influenced by urban layouts, densities, and specific
44 uses. Cities that are planned and built much differently than today through light-weighting, material
45 substitution, resource efficiency, renewable energy, and compact urban form, have the potential to
46 support more sustainable urbanization and provide co-benefits for inhabitants (see Figures 8.17 and
47 8.22).

1 In this context, illustrative mitigation strategies that can serve as a roadmap for emerging cities includes
 2 priorities for co-located and mixed land use, as well as TOD, within an integrated approach (see Table
 3 8.3 and Figure 8.19). This has cascading effects, including conserving existing green and blue assets
 4 (e.g., forests, grasslands, wetlands, etc.), many of which sequester and store carbon. Priorities for
 5 decarbonizing electricity and energy carriers while electrifying mobility, heating, and cooling take place
 6 within the integrated approach (see Section 8.4.3). Increasing greenways and permeable surfaces,
 7 especially from the design of emerging urban areas onward, can be pursued, also for adaptation co-
 8 benefits and linkages with the SDGs (see Section 8.4.4 and Figure 8.18).

10
11 **Figure 8.22 Raw material demands and committed emissions from building urban areas**

12 **The horizontal bars represent the projected increase in raw material demands in the year 2050. The**
 13 **vertical bars represent the possible range of committed CO₂ emissions in 2030. The importance of**
 14 **alternative solutions to reduce raw material demands and committed emissions while increasing co-**
 15 **benefits is represented by the circular process on the right side.**

16 Source: Drawn using data from Erickson and Tempest (2015) and Swilling et al. (2018)

17 In low energy-driven urban design, parameters are evaluated based on the energy performance of the
 18 urban area in the early design phase of future urban development (Shi et al. 2017b). Energy-driven
 19 urban design generates and optimizes urban form according to the energy performance outcome (Shi et
 20 al. 2017b). Beyond the impact of urban form on building energy performance, the approach focuses on
 21 the interdependencies between urban form and energy infrastructure in urban energy systems. The
 22 process can provide opportunities for both passive options for energy-driven urban design, such as the
 23 use of solar gain for space heating, or of thermal mass to moderate indoor temperatures, as well as active
 24 options that involve the use of energy infrastructure and technologies while recognising interrelations
 25 of the system. Future urban settlements can also be planned and built with net zero CO₂ or net zero
 26 GHG emissions, as well as renewable energy targets, in mind. Energy master planning of urban areas
 27 that initially target net zero operational GHG emissions can be supported with energy master planning
 28 from conceptual design to operation, including district scale energy strategies (Charani Shandiz et al.
 29 2021).

30
31 Integrated scenarios across sectors at the local level can decouple resource usage from economic growth
 32 (Hu et al. 2018) and enable 100% renewable energy scenarios (Zhao et al. 2017a; Bačeković and
 33 Østergaard 2018). Relative decoupling is obtained (Kalmykova et al. 2015) with increasing evidence
 34 for turning points in per capita emissions, total emissions, or urban metabolism (Chen et al. 2018b; Shen

1 et al. 2018). The importance of integrating energy and resource efficiency in sustainable and low-carbon
2 city planning (Dienst et al. 2015), structural changes, as well as forms of disruptive social innovation,
3 such as the ‘sharing economy’ (see Glossary), is also evident based on analyses for multiple cities,
4 including those that can be used to lower the carbon footprints of urban areas relative to sub-urban areas
5 (Chen et al. 2018a).

6 To minimize carbon footprints, new cities can utilize new intelligence functions as well as changes in
7 energy sources and material processes. Core design strategies of a compact city can be facilitated by
8 data-driven decision-making so that new urban intelligence functions are holistic and pro-active rather
9 than reactive (Bibri 2020). In mainstream practices, for example, many cities use environmental impact
10 reviews to identify potentially negative consequences of individual development projects on
11 environmental conditions in a piecemeal project basis.

12 New cities can utilize: system-wide analyses of construction materials, or renewable power sources,
13 that minimize ecosystem disruption and energy use, through the use of lifecycle assessments for
14 building types permitted in the new city (Ingrao et al. 2019); urban-scale metabolic impact assessments
15 for neighbourhoods in the city (Pinho and Fernandes 2019); strategic environmental assessments
16 (SEAs) that go beyond the individual project and assess plans for neighbourhoods (Noble and
17 Nwanekezie 2017); or the modelling of the type and location of building masses, tree canopies and
18 parks, and temperature (surface conditions) and prevailing winds profiles to reduce the combined effects
19 of climate change and UHI phenomena, thus minimising the need for air conditioning (Matsuo and
20 Tanaka 2019).

21 Resource-efficient, compact, sustainable, and liveable urban areas can be enabled with an integrated
22 approach across sectors, strategies, and innovations. From a geophysical perspective, the use of
23 materials with lower lifecycle GHG impacts, including the use of timber in urban infrastructure and the
24 selection of urban development plans, with lower material and land demand can lower the emission
25 impacts of existing and future cities (Müller et al. 2013; Carpio et al. 2016; Liu et al. 2016a; Ramage et
26 al. 2017; Shi et al. 2017a; Stocchero et al. 2017; Bai et al. 2018; Zhan et al. 2018b; Swilling et al. 2018;
27 Xu et al. 2018b; UNEP and IRP 2020) (see Figure 8.17). The capacity to implement relevant policy
28 instruments in an integrated and coordinated manner within a policy mix while leveraging multilevel
29 support as relevant can increase the enabling conditions for urban system transformation (Agyepong
30 and Nhamo 2017; Roppongi et al. 2017).

31 The integration of urban land use and spatial planning, electrification of urban energy systems,
32 renewable energy district heating and cooling networks, urban green and blue infrastructure, and
33 circular economy can also have positive impacts on improving air and environmental quality with
34 related co-benefits for health and well-being (Diallo et al. 2016; Nieuwenhuijsen and Khreis 2016;
35 Shakya 2016; Liu et al. 2017; Ramaswami et al. 2017a; Sun et al. 2018b; Tayarani et al. 2018; Park and
36 Sener 2019; González-García et al. 2021). Low-carbon development options can be implemented in
37 ways that reduce impacts on water use, including water use efficiency, demand management, and water
38 recycling, while increasing water quality (Koop and van Leeuwen 2015; Topi et al. 2016; Drangert and
39 Sharatchandra 2017; Lam et al. 2017, 2018; Vanham et al. 2017; Kim and Chen 2018). The ability for
40 enhancing biodiversity while addressing climate change depends on improving urban metabolism and
41 biophilic urbanism towards urban areas that are able to regenerate natural capital (Thomson and
42 Newman 2018; IPBES 2019b).

43 There are readily available solutions for low-carbon urban development that can be further supported
44 by new emerging ones, such as tools for optimising the impact of urban form on energy infrastructure
45 (Hu et al. 2015; Shi et al. 2017b; Xue et al. 2017; Dobler et al. 2018; Egusquiza et al. 2018; Pedro et al.
46 2018; Soilán et al. 2018). The costs of low-carbon urban development are manageable and enhanced
47 with a portfolio approach for cost-effective, cost-neutral, and re-investment options with evidence
48 across different urban typologies (Colenbrander et al. 2015, 2017; Gouldson et al. 2015;

1 Nieuwenhuijsen and Khreis 2016; Saujot and Lefèvre 2016; Sudmant et al. 2016; Brozynski and
2 Leibowicz 2018).

3 Low-carbon urban development that triggers economic decoupling can have a positive impact on
4 employment and local competitiveness (Kalmykova et al. 2015; Chen et al. 2018b; García-Gusano et
5 al. 2018; Hu et al. 2018; Shen et al. 2018). In addition, sustainable urban transformation can be
6 supported with participatory approaches that provide a shared understanding of future opportunities and
7 challenges where public acceptance increases with citizen engagement and citizen empowerment as
8 well as an awareness of co-benefits (Blanchet 2015; Bjørkelund et al. 2016; Flacke and de Boer 2017;
9 Gao et al. 2017; Neuvonen and Ache 2017; Sharp and Salter 2017; Wiktorowicz et al. 2018; Fastenrath
10 and Braun 2018; Gorissen et al. 2018; Herrmann et al. 2018; Moglia et al. 2018). Sustainable and low-
11 carbon urban development that integrates issues of equity, inclusivity, and affordability, while
12 safeguarding urban livelihoods, providing access to basic services, lowering energy bills, addressing
13 energy poverty, and improving public health can also improve the distributional effects of existing and
14 future urbanization (Friend et al. 2016; Claude et al. 2017; Colenbrander et al. 2017; Ma et al. 2018;
15 Mrówczyńska et al. 2018; Pukšec et al. 2018; Wiktorowicz et al. 2018) (see Section 8.2).

16 Information and communications technologies can play an important role for integrating mitigation
17 options at the urban systems level for achieving zero-carbon cities. Planning for decarbonisation at the
18 urban systems level involves integrated considerations of the interaction among sectors, including
19 synergies and trade-offs among households, businesses, transport, land use, and lifestyles. The
20 utilisation of big data, artificial intelligence and Internet of Things (IoT) technologies can be used to
21 plan, evaluate and integrate rapidly progressing transport and building technologies, such as
22 autonomous EVs, zero energy buildings and districts as an urban system, including energy-driven urban
23 design (Creutzig et al. 2020; Yamagata et al. 2020). Community level energy sharing systems will
24 contribute to realising the decarbonization potential of urban systems at community scale, including in
25 smart cities (see Section 4.2.5.9 in Chapter 4, Box 10.2 in Chapter 10 and Cross-Chapter Box 11 in
26 Chapter 16).

27

28 **8.5 Knowledge Gaps**

29 While there is growing literature on urban NBS, which encompasses urban green and blue infrastructure
30 in cities, there is still a knowledge gap regarding how these climate mitigation actions can be integrated
31 in urban planning and design, as well as their mitigation potential, especially for cities that have yet to
32 be built. In moving forward with the research agenda on cities and climate change science,
33 transformation of urban systems will be critical; however, understanding this transformation and how
34 best to assess mitigation action remain key knowledge gaps (Butcher-Gollach 2018; Pathak and
35 Mahadevia 2018; Rigolon et al. 2018; Anguelovski et al. 2019; Buyana et al. 2019; Trundle 2020;
36 Azunre et al. 2021).

37 There is a key knowledge gap in respect to the potential of the informal sector in developing country
38 cities. Informality extends beyond illegality of economic activities to include housing, locally developed
39 off-grid infrastructure, and alternative waste management strategies. Limited literature and
40 understanding of the mitigation potential of enhanced informal sector is highlighted in the key research
41 agenda on cities from the cities and climate change science conference (Prieur-Richard et al. 2018).

42 City-level models and data for understanding of urban systems is another knowledge gap. With
43 increased availability of open data systems, big data and computing capacities, there is an opportunity
44 for analysis of urban systems (Frantzeskaki et al. 2019).

45 While there is much literature on urban climate governance, there is still limited understanding of the
46 governance models and regimes that support multi-level decision making for mitigation and climate

1 action in general. Transformative climate action will require changing relationships between actors to
2 utilize the knowledge from data and models and deepen understanding of the urban system to support
3 decision-making.

5 **8.6.4 COVID-19 and cities**

6 The COVID-19 pandemic has disrupted many aspects of urban life while raising questions about urban
7 densities, transportation, public space, and other urban issues. The impact of COVID-19 on urban
8 activity and urban GHG emissions may offer insights into urban emissions and their behavioural drivers
9 and may include structural shifts in emissions that last into the future. The science is unclear as to the
10 links between urban characteristics and COVID-19, and involves multiple aspects. For example, some
11 research shows higher COVID-19 infection rates with city size (e.g., Dalziel et al. 2018; Stier et al.
12 2021), as well as challenges to epidemic preparedness due to high population density and high volume
13 of public transportation (Layne et al. 2020; Lee et al. 2020). Other research from 913 metropolitan areas
14 shows that density is unrelated to COVID-19 infection rates and, in fact, has been inversely related to
15 COVID-19 mortality rates when controlled by metropolitan population.

16 Dense counties are found to have significantly lower mortality rates, possibly due to such advantages
17 as better health care systems as well as greater adherence to social-distancing measures (Hamidi et al.
18 2020). Sustainable urbanization and urban infrastructure that address the SDGs can also improve
19 preparedness and resilience against future pandemics. For example, long-term exposure to air pollution
20 has been found to exacerbate the impacts of COVID-19 infections (Wu et al. 2020b), while urban areas
21 with cleaner air from clean energy and greenspace, can provide advantages.

22 Some studies indicate that socio-economic factors, such as poverty, racial and ethnic disparities, and
23 crowding are more significant than density in COVID-19 spread and associated mortality rate (Borjas
24 2020; Maroko et al. 2020; Lamb et al. 2021). The evidence for the connection between household
25 crowding and the risk of contagion from infectious diseases is also strong. A 2018 World Health
26 Organisation (WHO) systematic review of the effect of household crowding on health concluded that a
27 majority of studies of the risk of non-tuberculosis infectious diseases, including flu-related illnesses,
28 were associated with household crowding (Shannon et al. 2018).

29 Though preliminary, some studies suggest that urban areas saw larger overall declines in emissions
30 because of lower commuter activity and associated emissions. For example, researchers have explored
31 the COVID-19 impact in the cities of Los Angeles, Baltimore, Washington, DC, and San Francisco Bay
32 Area in the United States. In the San Francisco region, a decline of 30% in anthropogenic CO₂ was
33 observed, which was primarily due to changes in on-road traffic (Turner et al. 2020). Declines in the
34 Washington, DC/Baltimore region and in the Los Angeles urban area were 33% and 34%, respectively,
35 in the month of April compared to previous years (Yadav et al. 2021).

36 At the global scale COVID-related lock-down and travel restrictions reduced daily CO₂ emissions by -
37 17% in early April 2020 compared to 2019 values (Le Quéré et al. 2020; Liu et al. 2020b), though
38 subsequent studies have questioned the accuracy of the indirect proxy data used (Gurney et al. 2021b;
39 Oda et al. 2021). Research at the national scale in the United States found that daily CO₂ emissions
40 declined -15% during the late March to early June time period (Gillingham et al. 2020). Sector analysis
41 indicates that gasoline transportation and electricity generation contributed to the majority of the April-
42 May 2020 decline (Gurney et al. 2021b). Research in China estimated that the first quarter of 2020 saw
43 an 11.5% decline in CO₂ emissions relative to 2019 (Zheng et al. 2020; Han et al. 2021). In Europe,
44 estimates indicated a -12.5% decline in the first half of 2020 compared to 2019 (Andreoni 2021).
45 Rebound to pre-COVID trajectories has been evidenced following the ease of travel restrictions
46 (Gurney et al. 2021b; Le Quéré et al. 2021). It remains unclear to what extent COVID resulted in any
47 structural change in the underlying drivers of urban emissions.

1 Changes in local air pollution emissions, particularly due to altered transportation patterns, have caused
2 temporary air quality improvements in many cities around the world (see critical review by a Adam et
3 al. 2021). Many outdoor air pollutants, such as particulates, nitrogen dioxide, carbon monoxide, and
4 volatile organic compounds declined during national lockdowns. Levels of tropospheric ozone,
5 however, remained constant or increased. A promising transformation that has been observed in many
6 cities is an increase in the share of active travel modes such as cycling and walking (Sharifi and
7 Khavarian-Garmsir 2020). While this may be temporary, other trends, such as increased rates of
8 teleworking and/or increased reliance on smart solutions that allow remote provision of services provide
9 an unprecedented opportunity to transform urban travel patterns (Belzunegui-Eraso and Erro-Garcés
10 2020; Sharifi and Khavarian-Garmsir 2020).

11 Related to the transport sector, the pandemic has resulted in concerns regarding the safety of public
12 transport modes, which has resulted in significant reductions in public transport ridership in some cities
13 (Bucsky 2020; de Haas et al. 2020) while providing opportunities for urban transitions in others
14 (Newman AO 2020). Considering the significance of public transportation for achieving low-carbon
15 and inclusive urban development, appropriate response measures could enhance health safety of public
16 transport modes and regain public trust (Sharifi and Khavarian-Garmsir 2020). Similarly, there is a
17 perceived correlation between the higher densities of urban living and the risk of increased virus
18 transmission (Hamidi et al. 2020; Khavarian-Garmsir et al. 2021).

19 While city size could be a risk factor with higher transmission in larger cities (Hamidi et al. 2020; Stier
20 et al. 2021), there is also evidence showing that density is not a major risk factor and indeed cities that
21 are more compact have more capacity to respond to and control the pandemic (Hamidi et al. 2020).
22 Considering the spatial pattern of density, even distribution of density can reduce the possibility of
23 crowding that is found to contribute to the scale and length of virus outbreak in cities. Overall, more
24 research is needed to better understand the impacts of density on outbreak dynamics and address public
25 health concerns for resilient cities.

26 Cities could seize this opportunity to provide better infrastructure to further foster active transportation.
27 This could, for example, involve measures, such as expanding cycling networks and restricting existing
28 streets to make them more pedestrian- and cycling-friendly contributing to health and adaptation co-
29 benefits as discussed in Section 8.2 (Sharifi 2021). Strengthening the science-policy interface is another
30 consideration that could support urban transformation (also see Cross-chapter Box 1 in Chapter 1).

31

32 **8.6.5 Future urban emissions scenarios**

33 The urban share of global emissions is significant and is expected to increase in the coming decades.
34 This places emphasis on the need to expand development of urban emissions scenarios within climate
35 mitigation scenarios (Gurney et al. 2021a). The literature on globally comprehensive analysis of urban
36 emissions within the existing IPCC scenario framework remain very limited curtailing understanding
37 of urban emissions tipping points, mitigation opportunities and overall climate policy complexity. A
38 recent review of the applications of the SSP/RCP scenario framework recommends downscaling global
39 SSPs to improve the applicability of this framework to regional and local scales (O'Neill et al. 2020).
40 This remains an urgent need and will require multi-disciplinary research efforts, particularly as net zero
41 emissions targets are emphasized.

42

43 **8.6.6 Urban emissions data**

44 Though there has been a rapid rise in quantification and analysis of urban emissions, gaps remain in
45 comprehensive global coverage, particularly in the Global South, and reliance on standardized
46 frameworks and systematic data is lacking (Gurney and Shepson 2021; Mueller et al. 2021). The

1 development of protocols by (BSI 2013; Fong et al. 2014; ICLEI 2019b) that urban areas can use to
2 organize emissions accounts has been an important step forward, but no single agreed-upon reporting
3 framework exists (Lombardi et al. 2017; Chen et al. 2019b; Ramaswami et al. 2021). Additionally, there
4 is no standardisation of emissions data and limited independent validation procedures (Gurney and
5 Shepson 2021). This is partly driven by the recognition that urban emissions can be conceptualized
6 using different frameworks, each of which has a different meaning for different urban communities (see
7 section 8.1.6.2). Equally important is the recognition that acquisition and analysis of complex data used
8 to populate urban GHG inventory protocols remains a barrier for local practitioners (Creutzig et al.
9 2019). The limited standardization has also led to incomparability of the many individual or city cluster
10 analyses that have been accomplished since AR5. Finally, comprehensive, global quantification of
11 urban emissions remains incomplete in spite of recent efforts (Moran et al. 2018; Zheng et al. 2018;
12 Harris et al. 2020; Jiang et al. 2020; Wei et al. 2021; Wiedmann et al. 2021).

13 Similarly, independent verification or evaluation of urban GHG emissions has seen a large number of
14 research studies (e.g., Wu et al. 2016; Sargent et al. 2018; Whetstone 2018; Lauvaux et al. 2020). This
15 has been driven by the recognition that self-reported approaches may not provide adequate accuracy to
16 track emissions changes and provide confidence for mitigation investment (Gurney and Shepson 2021).

17 The most promising approach to independent verification of urban emissions has been the use of urban
18 atmospheric monitoring (direct flux and/or concentration) as a means to assess and track urban GHG
19 emissions (Davis et al. 2017). However, like the basic accounting approach itself, standardization and
20 practical deployment and scaling is an essential near-term need.

21

22 **Frequently Asked Questions**

23 **FAQ 8.1 Why are urban areas important to global climate change mitigation?**

24 Over half of the world's population currently resides in urban areas—a number forecasted to increase
25 to nearly 70% by 2050. Urban areas also account for a growing proportion of national and global
26 emissions depending on emissions scope and geographic boundary. These trends are projected to grow
27 in the coming decades; in 2100, some scenarios show the urban share of global emissions above 80%,
28 with 63% being at the minimum for any scenario (with the shares being in different contexts of
29 emissions reduction or increase) (Sections 8.3.3 and 8.3.4). As such, urban climate change mitigation
30 considers the majority of the world's population, as well some of the key drivers of global emissions.
31 In general, emissions scenarios with limited outward urban land expansion are also associated with a
32 smaller rise in global temperature (Section 8.3.4).

33 The urban share of global emissions and its projected growth stem in part from urban carbon lock-in—
34 that is, the path dependency and inertia of committed emissions through the long lifespan of urban
35 layout, infrastructures, and behaviour. As such, urban mitigation efforts that address lock-in can
36 significantly reduce emissions (Section 8.4.1). Electrification of urban energy systems in tandem with
37 implementing multiple urban-scale mitigation strategies, could reduce urban emissions by 90% by
38 2050--thereby significantly reducing global emissions (Section 8.3.4). Urban areas can also act as points
39 of intervention to amplify synergies and co-benefits for accomplishing the Sustainable Development
40 Goals (Section 8.2).

41 **FAQ 8.2 What are the most impactful options cities can take to mitigate urban emissions, and** 42 **how can these be best implemented?**

43 The most impactful urban mitigation plans reduce urban GHG emissions by considering the long
44 lifespan of urban layout and urban infrastructures (Section 8.4.1 and 8.6). Chapter 8 identifies three
45 overarching mitigation strategies with the largest potential to decrease current, and avoid future, urban

1 emissions: (1) reduce urban energy consumption across all sectors including through spatial planning
2 and infrastructure that supports compact, walkable urban form (Section 8.4.2); (2) decarbonize through
3 electrification of the urban energy system, and switch to net zero emissions resources (i.e., low-carbon
4 infrastructure) (Section 8.4.3); and (3) enhance carbon sequestration through urban green and blue
5 infrastructure (e.g., green roofs, urban forests and street trees, etc.), which can also offer multiple co-
6 benefits like reducing ground temperatures and supporting public health and well-being (Section 8.4.4).
7 Integrating these mitigation strategies across sectors, geographic scales, and levels of governance will
8 yield the greatest emissions savings (Sections 8.4 and 8.5).

9 A city's layout, patterns, and spatial arrangements of land use, transportation systems, and built
10 environment (urban form), as well as its state and form(s) of development (urban growth typology), can
11 inform the most impactful emissions savings 'entry point' and priorities for urban mitigation strategies
12 (Sections 8.4.2 and 8.6). For rapidly growing and emerging urban areas, there is the opportunity to
13 avoid carbon lock-in by focusing on urban form that promotes low-carbon infrastructure and enables
14 low-impact behaviour facilitated by co-located medium to high densities of jobs and housing,
15 walkability, and transit-oriented development (Sections 8.6.2 and 8.6.3). For established cities,
16 strategies include electrification of the grid and transport, and implementing energy efficiency across
17 sectors (Section 8.6.1).

18 **FAQ 8.3 How do we estimate global emissions from cities, and how reliable are the estimates?**

19 There are two different emissions estimation techniques applied, individually or in combination, to the
20 four frameworks outlined in Section 8.1.6.2 to estimate urban GHG emissions: 'top-down' and 'bottom-
21 up.' The top-down technique uses atmospheric GHG concentrations and atmospheric modelling to
22 estimate direct (scope 1) emissions (see Glossary). The bottom-up technique estimates emissions using
23 local activity data or direct measurements such as in smokestacks, traffic data, energy consumption
24 information, and building use. Bottom-up techniques will often include 'indirect emissions (see
25 Glossary) from purchased electricity (scope 2) and the urban supply chain (scope 3). Inclusion of
26 supply-chain emissions often requires additional data such as consumer purchasing data and supply
27 chain emission factors. Some researchers also take a hybrid approach combining top-down and bottom-
28 up estimation techniques to quantify territorial emissions. Individual self-reported urban inventories
29 from cities have shown chronic underestimation when compared to estimates using combined top-
30 down/bottom-up atmospherically calibrated estimation techniques.

31 No approach has been systematically applied to all cities worldwide. Rather, they have been applied
32 individually or in combination to subsets of global cities. Considerable uncertainty remains in
33 estimating urban emissions. However, top-down approaches have somewhat more objective techniques
34 for uncertainty estimation in comparison to bottom-up approaches. Furthermore, supply chain
35 estimation typically has more uncertainty than direct or territorial emission frameworks.

3	Chapter 9: Buildings	9-1
4	Executive summary	9-4
5	9.1 Introduction.....	9-7
6	9.2 Services and components	9-10
7	9.2.1 Building types	9-11
8	9.2.2 Building components and construction methods	9-11
9	9.2.3 Building services.....	9-13
10	9.3 New developments in emission trends and drivers	9-15
11	9.3.1 Past and future emission trends.....	9-15
12	9.3.2 Drivers of CO ₂ emissions and their climate impact	9-19
13	9.3.3 Energy demand trends.....	9-25
14	9.4 Mitigation technological options and strategies towards zero carbon buildings.....	9-32
15	9.4.1 Key points from AR5 and special reports	9-32
16	9.4.2 Embodied energy and embodied carbon.....	9-32
17	9.4.3 Technological developments since AR5.....	9-39
18	9.4.4 Case studies.....	9-43
19	9.4.5 Low- and net zero energy buildings – exemplary buildings	9-44
20	9.5 Non-technological and behavioural mitigation options and strategies	9-47
21	9.5.1 Non-technological determinants of energy demand and carbon emissions	9-47
22	9.5.2 Insights from non-technological and behavioural interventions	9-48
23	9.5.3 Adoption of climate mitigation solutions– reasons and willingness.....	9-50
24	9.6 Global and regional mitigation potentials and costs	9-54
25	9.6.1 Review of literature calculating potentials for different world countries	9-54
26	9.6.2 Assessment of the potentials at regional and global level.....	9-57
27	9.6.3 Assessment of the potential costs.....	9-59
28	9.6.4 Determinants of the potentials and costs.....	9-62
29	9.7 Links to adaptation.....	9-65
30	9.7.1 Climate change impacts and adaptation in buildings	9-65
31	9.7.2 Links between mitigation and adaptation in buildings	9-67
32	9.8 Links to sustainable development	9-68
33	9.8.1 Overview of contribution of mitigation options to sustainable development	9-68
34	9.8.2 Climate mitigation actions in buildings and health impacts	9-71
35	9.8.3 Other environmental benefits of mitigation actions.....	9-75
36	9.8.4 Social well-being.....	9-76

1	9.8.5	Economic implications of mitigation actions.....	9-77
2	9.9	Sectoral barriers and policies	9-79
3	9.9.1	Barriers, feasibility, and acceptance.....	9-79
4	9.9.2	Rebound effects.....	9-82
5	9.9.3	Policy packages for the decarbonisation of buildings.....	9-82
6	9.9.4	Financing mechanisms and business models for reducing energy demand	9-89
7	9.9.5	Policies mechanisms for financing for on-site renewable energy generation	9-90
8	9.9.6	Investment in building decarbonisation	9-93
9	9.9.7	Governance and Institutional Capacity	9-93

1 **Executive summary**

2 **Global Greenhouse Gas (GHG) emissions from buildings were in 2019 at 12 GtCO₂eq, equivalent**
3 **to 21% of global GHG emissions that year, out of which 57% were indirect emissions from offsite**
4 **generation of electricity and heat, 24% direct emissions produced onsite and 18% were embodied**
5 **emissions from the use of cement and steel (*high evidence, high agreement*). More than 95% of**
6 **emissions from buildings were CO₂ emissions, CH₄ and N₂O represented 0.08%, and emissions from**
7 **halocarbon contributed by 3% to global GHG emissions from buildings. If only CO₂ emissions would**
8 **be considered, the share of CO₂ emissions from buildings out of global CO₂ emissions increases to 31%.**
9 **Global final energy demand from buildings reached 128.8 EJ in 2019, and global electricity demand**
10 **was slightly above 43 EJ. The former accounted for 31% of global final energy demand and the latter**
11 **for 18% of global electricity demand. Residential buildings consumed 70% of global final energy**
12 **demand from buildings. Over the period 1990-2019, global CO₂ emissions from buildings increased by**
13 **50%, global final energy demand grew by 38 and global final electricity demand increased by 161%**
14 **(*high evidence, high agreement*) {9.3}.**

15 **Drivers of GHG emissions in the building sector were assessed using the SER (Sufficiency,**
16 **Efficiency, Renewable) framework. Sufficiency measures tackle the causes of GHG emissions by**
17 **avoiding the demand for energy and materials over the lifecycle of buildings and appliances.**
18 **Sufficiency differs from efficiency in that the latter is about the continuous short-term marginal**
19 **technological improvements, which allows doing less with more in relative terms without considering**
20 **the planetary boundaries, while the former is about long-term actions driven by non-technological**
21 **solutions (i.e., land use management and planning), which consume less in absolute term and are**
22 **determined by biophysical processes. Sufficiency addresses the issue of a fair consumption of space**
23 **and resources. The remaining carbon budget, and its normative target for distributional equity, is the**
24 **upper limit of sufficiency, while requirements for a decent living standard define the minimum level of**
25 **sufficiency. The SER framework introduces a hierarchical layering which reduces the cost of**
26 **constructing and using buildings without reducing the level of comfort of the occupant. Sufficiency**
27 **interventions in buildings include the optimisation of the use of building, repurposing unused existing**
28 **buildings, prioritising multi-family homes over single-family buildings, and adjusting the size of**
29 **buildings to the evolving needs of households by downsizing dwellings. Sufficiency measures do not**
30 **consume energy during the use phase of buildings.**

31 **In most regions, historical improvements in efficiency have been approximately matched by**
32 **growth in floor area per capita. Implementing sufficiency measures that limit growth in floor area**
33 **per capita, particularly in developed regions, reduces the dependence of climate mitigation on**
34 **technological solutions (*medium evidence, medium agreement*). At a global level, up to 17% of the**
35 **mitigation potential could be captured by 2050 through sufficiency interventions (*medium evidence,***
36 ***medium agreement*). Sufficiency is an opportunity to avoid locking buildings in carbon-intensive**
37 **solutions. Density, compactness, building typologies, bioclimatic design, multi-functionality of space,**
38 **circular use of materials, use of the thermal mass of buildings (to store heat for the cold season and to**
39 **protect occupants from high temperatures (i.e. heatwaves), when designing energy services, moving**
40 **from ownership to usership of appliances and towards more shared space, are among the sufficiency**
41 **measures already implemented in the leading municipalities. At the global level, the main drivers of**
42 **emissions include (i) population growth, especially in developing countries, (ii) increase in floor area**
43 **per capita, driven by the increase of the size of dwellings while the size of households kept decreasing,**
44 **especially in developed countries, (iii) the inefficiency of the newly constructed buildings, especially**
45 **in developing countries, and the low renovation rates and ambition level in developed countries when**
46 **existing buildings are renovated, iv) the increase in use, number and size of appliances and equipment,**
47 **especially ICT and cooling, driven by the growing welfare (income), and (v) the continued reliance on**
48 **fossil fuel based electricity and heat slow decarbonisation of energy supply. These factors taken together**

1 are projected to continue driving GHG emissions in the building sector in the future (*high evidence,*
2 *high agreement*) {9.2, 9.3, 9.4, 9.5, 9.6, and 9.9}.

3 **Bottom-up studies show a mitigation potential up to 85% in Europe and North America and up**
4 **to 45% in Asia Pacific Developed compared to the baselines by 2050, even though they sometimes**
5 **decline (*robust evidence, high agreement*). In developing countries, bottom-up studies estimate the**
6 **potential of up to 40-80% in 2050, as compared to their sharply growing baselines (*medium***
7 ***evidence, high agreement*). The aggregation of results from all these bottom-up studies translates**
8 **into a global mitigation potential by 2050 of at least 8.2 GtCO₂, which is equivalent to 61% of**
9 **their baseline scenario.** The largest mitigation potential (5.4 GtCO₂) is available in developing
10 countries while developed countries will be able to mitigate 2.7 GtCO₂. These potentials represent the
11 low estimates, and the real potential is likely to be higher. These estimated potentials would be higher
12 if embodied emissions in buildings and those from halocarbons would be included (*low evidence, high*
13 *agreement*) {9.3, 9.6,}.

14 **The development, since Assessment Report 5 (AR5), of integrated approaches to construction and**
15 **retrofit of buildings has led to the widespread of zero energy/carbon buildings in all climate zones.**
16 The complementarity and the interdependency of measures lead to cost reduction while optimising the
17 mitigation potential grasped and avoiding the lock-in-effect. The growing consideration of integrated
18 approach to construction of new buildings as well as to the renovation of existing buildings results in a
19 lower relevance of the step-by-step approach to renovate buildings and to breaking down the potential
20 into cost categories, as to deliver deep mitigation and cost savings technologies and approaches shall
21 be applied together in an integrated and interdependent manner (*medium evidence, high agreement*).
22 The potential associated with the sufficiency measures as well as the exchange of appliances,
23 equipment, and lights with efficient ones is at cost below USD0 tCO₂⁻¹ (*high evidence, high agreement*).
24 The construction of high-performance buildings will become by 2050 a business-as-usual technology
25 with costs below USD20 tCO₂⁻¹ in developed countries and below USD100 tCO₂⁻¹ in developing
26 countries (*medium evidence, high agreement*). For existing buildings, there have been many examples
27 of deep retrofits where additional costs per CO₂ abated are not significantly higher than those of shallow
28 retrofits. However, for the whole stock they tend to be in cost intervals of 0-200USD tCO₂⁻¹ and
29 >200USD tCO₂⁻¹ (*medium evidence, medium agreement*). Literature emphasizes the critical role of the
30 decade between in 2020 and 2030 in accelerating the learning of know-how and skills to reduce the
31 costs and remove feasibility constrains for achieving high efficiency buildings at scale and set the sector
32 at the pathway to realize its full potential (*high evidence, high agreement*) {9.6, 9.9}.

33 **The decarbonisation of buildings is constrained by multiple barriers and obstacles as well as**
34 **limited flow of finance (*robust evidence, high agreement*). The lack of institutional capacity,**
35 **especially in developing countries, and appropriate governance structures slow down the**
36 **decarbonisation of the global building stock (*medium evidence, high agreement*). The building**
37 **sector stands out for its high heterogeneity, with many different building types, sizes, and operational**
38 **uses. Its segment representing rented property faces principal/agent problems where the tenant benefits**
39 **from the decarbonisation investment made by the landlord. The organisational context and the**
40 **governance structure could trigger or hinder the decarbonisation of buildings (*high evidence, high***
41 ***agreement*). Global investment in the decarbonisation of buildings was estimated at USD164 billion in**
42 **2020, not enough to close the investment gap (*robust evidence, high agreement*) {9.9}.**

43 **Policy packages based on the SER (Sufficiency, Efficiency, Renewables) framework could grasp**
44 **the full mitigation potential of the global building stock (*medium evidence, high agreement*). Low**
45 **ambitious policies will lock buildings in carbon for decades as buildings last for decades if not**
46 **centuries (*high evidence, high agreement*). Building energy codes is the main regulatory**
47 **instrument to reduce emissions from both new and existing buildings (*high evidence, high***
48 ***agreement*). Most advanced building energy codes include bioclimatic design requirements to capture**

1 the sufficiency potential of buildings, efficiency requirements by using the most efficient technologies
2 and requirements to increase the integration of renewable energy solutions to the building shape. Some
3 announced building energy codes extend these requirements from the use phase to the whole building
4 lifecycle. Building energy codes are proven to be especially effective if compulsory and combined with
5 other regulatory instruments such as minimum energy performance standard for appliances and
6 equipment, especially if the performance level is set at the level of the best available technologies in
7 the market (*robust evidence, high agreement*). Market-based instruments such as carbon taxes with
8 recycling of the revenues and personal or building carbon allowances also contribute to foster the
9 decarbonisation of the building sector (*robust evidence, high agreement*). Requirements to limit the
10 use of land and property taxes are also considered effective policies to limit urban sprawl and to
11 prioritise multi-family buildings over single-family homes (*medium evidence, high agreement*) {9.9}.

12 **Actions are needed to adapt buildings to future climate while ensuring wellbeing for all. The**
13 **expected heatwaves will inevitably increase cooling needs to limit the health impacts of climate**
14 **change (*medium evidence, high agreement*).** Global warming will impact cooling and heating needs
15 but also the performance, durability and safety of buildings, especially historical and coastal ones,
16 through changes in temperature, humidity, concentrations of CO₂ and chloride, and sea level rise.
17 Adaptation measures to cope with climate change may increase the demand for energy and materials
18 leading to an increase in GHG emissions if not mitigated. Sufficiency measures such as bioclimatic
19 design of buildings, which consider the expected future climate, and includes natural ventilation, white
20 walls and nature-based solutions (i.e., green roofs) will decrease the demand for cooling. Shared cooled
21 spaces with highly efficient cooling solutions are among the mitigation strategies which can limit the
22 effect of the expected heatwaves on people health. Sufficiency, efficiency, and renewable energy can
23 be designed to reduce buildings' vulnerability to climate change impacts (*medium evidence, high*
24 *agreement*) {9.7, 9.8}.

25 **Well-designed and effectively implemented mitigation actions in the buildings sector have**
26 **significant potential for achieving the United Nations Sustainable Development Goals.** The
27 impacts of mitigation actions in the building sector go far beyond the goal of climate action (SDG13)
28 and contribute to further meeting fifteen other SDGs. Mitigation actions in the building sector bring
29 health gains through improved indoor air quality and thermal comfort as well as reduced financial
30 stresses in all world regions. Overall decarbonised building stock contribute to wellbeing and has
31 significant macro- and micro-economic effects, such as increased productivity of labour, job creation,
32 reduced poverty, especially energy poverty, and improved energy security that ultimately reduces net
33 costs of mitigation measures in buildings (*high evidence, high agreement*) {9.8}.

34 **COVID-19 emphasised the importance of buildings for human wellbeing. However, the lockdown**
35 **measures implemented to avoid the spread of the virus have also stressed the inequalities in the**
36 **access for all to suitable and healthy buildings, which provide natural daylight and clean air to**
37 **their occupants (*low evidence, high agreement*).** Meeting the new WHO health requirements, has also
38 put an emphasis on indoor air quality, preventive maintenance of centralised mechanical heating,
39 ventilation, and cooling systems. Moreover, the lockdown measures have led to spreading the South
40 Korean concept of *officetel* (office-hotel) to many countries and to extending it to *officetelschool*. The
41 projected growth, prior to the COVID-19, of 58% of the global residential floor area by 2050 compared
42 to the 290 billion m²yr⁻¹ in 2019 might well be insufficient. Addressing the new needs for more
43 residential buildings may not, necessarily mean constructing new buildings, especially in the global
44 North. Repurposing existing non-residential buildings, no longer in use due to the expected spread of
45 teleworking triggered by the health crisis and enabled by digitalization, could be the way to overcome
46 the new needs for *officetelschool* buildings triggered by the health crisis (*low evidence, high confidence*)
47 {9.1, 9.2}.

48

1 **9.1 Introduction**

2 Total GHG emissions in the building sector reached 12 GtCO₂eq. in 2019, equivalent to 21% of global
3 GHG emissions that year, of which 57% were indirect CO₂ emissions from offsite generation of
4 electricity and heat, followed by 24% of direct CO₂ emissions produced on-site and 18% from the
5 production of cement and steel used for construction and/or refurbishment of buildings. If only CO₂
6 emissions would be considered, the share of buildings CO₂ emissions increases to 31% out of global
7 CO₂ emissions. Energy use in residential and non-residential buildings contributed 50% and 32%
8 respectively, while embodied emissions contributed 18% to global building CO₂ emissions. Global final
9 energy demand from buildings reached 128.8 EJ in 2019, equivalent to 31% of global final energy
10 demand. Residential buildings consumed 70% out of global final energy demand from buildings.
11 Electricity demand from buildings was slightly above 43 EJ in 2019, equivalent to more than 18% of
12 global electricity demand. Over the period 1990-2019, global CO₂ emissions from buildings increased
13 by 50%, global final energy demand grew by 38%, with 54% increase in non-residential buildings and
14 32% increase in residential ones. Among energy carriers, the growth in global final energy demand was
15 strongest for electricity, which increased by 161%.

16 There is growing scientific evidence about the mitigation potential of the building sector and its
17 contribution to the decarbonisation of global and regional energy systems, and to meeting Paris
18 Agreement goals and Sustainable Development Goals (SDGs) (IPCC, 2018; IEA, 2019b; IEA 2019c).
19 Mitigation interventions in buildings are heterogeneous in many different aspects, from building
20 components (envelope, structure, materials, etc.) to services (shelter, heating, etc.), to building types
21 (residential and non-residential, sometimes also called commercial and public), to building size,
22 function, and climate zone. There are also variations between developed and developing countries in
23 mitigation interventions to implement, as the former is challenged by the renovation of existing
24 buildings while the latter is challenged by the need to accelerate the construction of new buildings.

25 This chapter aims at updating the knowledge on the building sector since the Intergovernmental Panel
26 on Climate Change (IPCC) Fifth Assessment Report (AR5) (Ürge-Vorsatz et al. 2014). Changes since
27 AR5 are reviewed, including: the latest development of building service and components (Section 9.2),
28 findings of new building related GHG emission trends (Section 9.3), latest technological (Section 9.4)
29 and non-technological (Section 9.5) options to mitigate building GHG emissions, potential emission
30 reduction from these measures at global and regional level (Section 9.6), links to adaptation (Section
31 9.7) and sustainable development (Section 9.8), and sectoral barriers and policies (Section 9.9).

32 The chapter introduces the concept of sufficiency, identified in the literature as a mitigation strategy
33 with high potential, and is organised around the Sufficiency-Efficiency-Renewables (SER) framework
34 (Box 9.1).

35

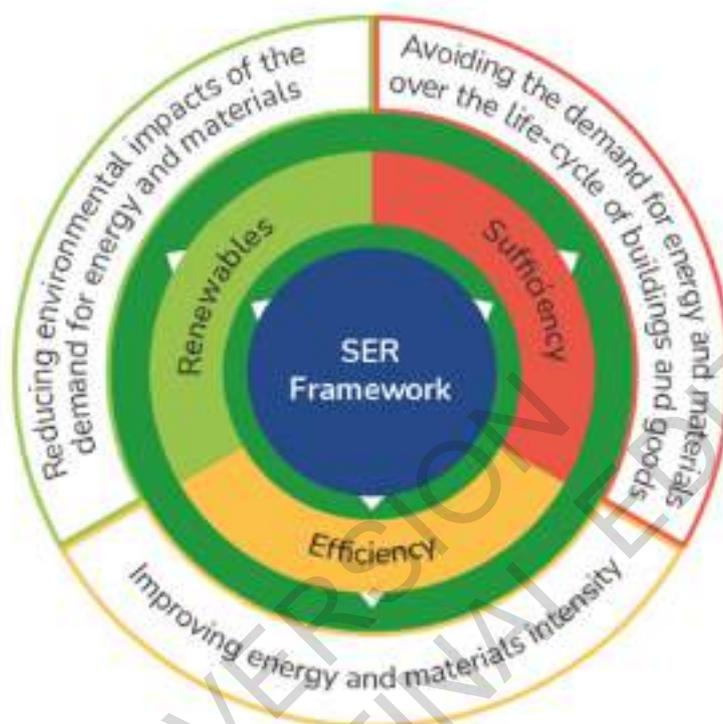

36 **START BOX 9.1 HERE**

37 **Box 9.1 SER (sufficiency-efficiency-renewables) framework**

38 The SER framework was introduced, late nineties, by a French NGO (Negawatt) (Negawatt 2017)
39 advocating for a decarbonised energy transition. In 2015, the SER framework was considered in the
40 design of the French energy transition law and the French energy transition agency (ADEME) is
41 developing its 2050 scenario based on the SER framework.

42 The three pillars of the SER framework include (i) sufficiency, which tackles the causes of the
43 environmental impacts of human activities by avoiding the demand for energy and materials over the
44 lifecycle of buildings and goods, (ii) efficiency, which tackles the symptoms of the environmental
45 impacts of human activities by improving energy and material intensities, and (iii) the renewables pillar,

1 which tackles the consequences of the environmental impacts of human activities by reducing the
 2 carbon intensity of energy supply (Box 9.1 Figure 1). The SER framework introduces a hierarchical
 3 layering, sufficiency first followed by efficiency and renewable, which reduces the cost of constructing
 4 and using buildings without reducing the level of comfort of the occupant.

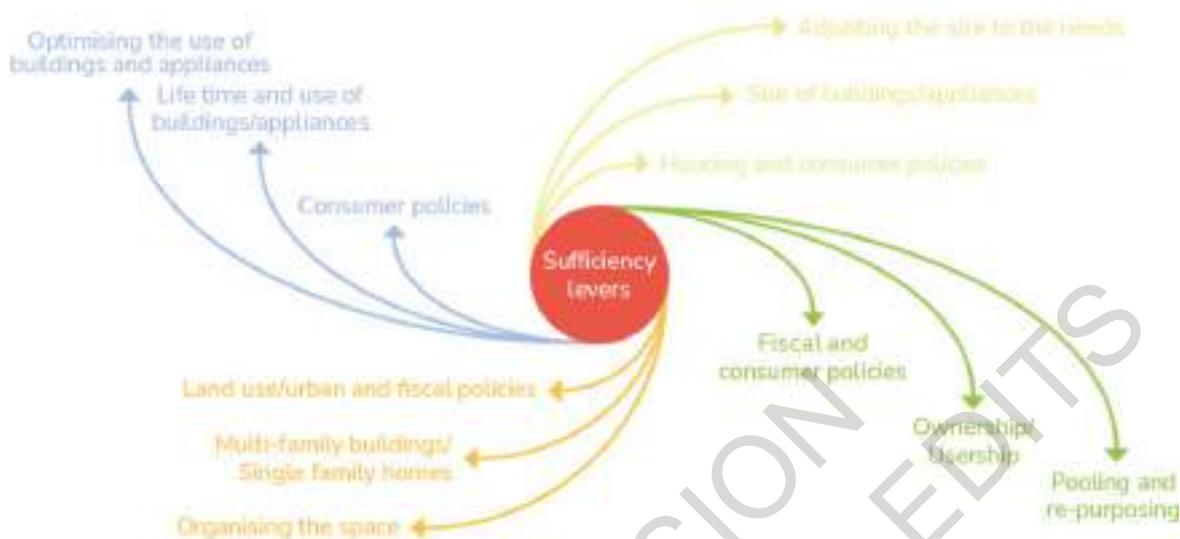

5
 6 **Box 9.1 Figure 1 SER framework applied to the building sector**

7 Source: Saheb 2021

8 Sufficiency is not a new concept, its root goes back to the Greek word “*sôphrosunê*”, which was
 9 translated in Latin to “*sobrietas*”, in a sense of “*enough*” (Cézard and Mourad 2019). The sufficiency
 10 concept was introduced to the sustainability policy debate by (Sachs 1993) and to academia by (Princen
 11 2003a). Since 1997, Thailand considers sufficiency, which was framed already in 1974 as Sufficiency
 12 Economy Philosophy, as a new paradigm for development with the aim of improving human wellbeing
 13 for all by shifting development pathways towards sustainability (Mongsawad 2012). The Thai approach
 14 is based on three principles (i) moderation, (ii) reasonableness, and (iii) self-immunity. Sufficiency goes
 15 beyond the dominant framing of energy demand under efficiency and behaviour. Sufficiency is defined
 16 as avoiding the demand for materials, energy, land, water and other natural resources while delivering
 17 a decent living standard for all within the planetary boundaries (Saheb 2021b, Princen 2005). Decent
 18 living standards are a set of essential material preconditions for human wellbeing which includes
 19 shelter, nutrition, basic amenities, health care, transportation, information, education, and public space
 20 (Rao and Baer 2012; Rao and Min 2018; Rao et al. 2019). Sufficiency addresses the issue of a fair
 21 consumption of space and resources. The remaining carbon budget, and its normative target for
 22 distributional equity, is the upper limit of sufficiency, while requirements for a decent living standard
 23 define the minimum level of sufficiency. Sufficiency differs from efficiency in that the latter is about
 24 the continuous short-term marginal technological improvements which allow doing more with less in
 25 relative terms without considering the planetary boundaries, while the former is about long-term actions
 26 driven by non-technological solutions (i.e. land use management and planning), which consume less in
 27 absolute-term and are determined by the biophysical processes (Princen 2003b).

28 Applying sufficiency principles to buildings requires (i) optimising the use of buildings, (ii) repurposing
 29 unused existing ones, (iii) prioritising multi-family homes over single-family buildings, and (iv)
 30 adjusting the size of buildings to the evolving needs of households by downsizing dwellings (Box 9.1

1 Figure 2) (Sandberg 2018) (Stephan et al. 2013)(Duffy 2009)(Fuller and Crawford 2011)(Wilson and
 2 Boehland 2005)(McKinlay et al. 2019)(Sandberg 2018)(Huebner and Shipworth 2017)(Ellsworth-
 3 Krebs 2020) (Berrill et al. 2021).

4
 5 **Box 9.1 Figure 2 Sufficiency interventions and policies in the building sector**

6 Source: Saheb 2021

7 Downsizing dwellings through cohousing strategies by repurposing existing buildings and clustering
 8 apartments when buildings are renovated and by prioritising multi-family buildings over single-family
 9 homes in new developments (Sandberg 2018) (Stephan et al. 2013)(Duffy 2009)(Fuller and Crawford
 10 2011)(Wilson and Boehland 2005)(McKinlay et al. 2019)(Sandberg 2018)(Huebner and Shipworth
 11 2017)(Ellsworth-Krebs 2020) (Ivanova and Büchs 2020) (Berrill and Hertwich 2021) are among the
 12 sufficiency measures that avoid the demand for materials in the construction phase and energy demand
 13 for heating, cooling and lighting in the use phase, especially if the conditioned volume and window
 14 areas are reduced (Duffy 2009) (Heinonen and Junnila 2014). Less space also means less appliances
 15 and equipment and changing preferences towards smaller ones (Aro 2020). Cohousing strategies
 16 provide users, in both new and existing buildings, a shared space (i.e. for laundry, offices, guest rooms
 17 and dining rooms) to complement their private space. Thus, reducing per capita consumption of
 18 resources including energy, water and electricity (Klocker et al. 2012)(Natascha Klocker 2017), while
 19 offering social benefits such as limiting loneliness of elderly people and single parents (Riedy et al.
 20 2019)(Wankiewicz 2015). Senior cooperative housing communities and eco-villages are considered
 21 among the cohousing examples to scale-up (Kuhnhehn et al. 2020). Local authorities have an important
 22 role to play in the metamorphosis of housing by proposing communal spaces to be shared (J. Williams
 23 2008)(Marckmann et al. 2012) through urban planning and land use policies (Duffy 2009)(Newton et
 24 al. 2017). Thus, encouraging inter-generational cohousing as well as interactions between people with
 25 different social backgrounds (Lietaert 2010)(J. Williams 2008). Progressive tax properties based on a
 26 cap in the per-capita floor area are also needed to adapt the size of dwellings to households' needs
 27 (Murphy 2015) (Akenji 2021).

28 Efficiency, and especially energy efficiency and more recently resource efficiency, and the integration
 29 of renewable to buildings are widespread concepts since the oil crisis of the seventies, while only most

1 advanced building energy codes consider sufficiency measures (IEA 2013). Efficiency and renewable
2 technologies and interventions are described in 9.4 and 9.9.

3 A systematic categorisation of policy interventions in the building sector through the SER framework
4 (Box 9.1 Figure 1) enables identification of the policy areas and instruments to consider for the
5 decarbonisation of the building stock, their overlaps as well as their complementarities. It also shows
6 that sufficiency policies go beyond energy and climate policies to include land use and urban planning
7 policies as well as consumer policies suggesting a need for a different governance including local
8 authorities and a bottom-up approach driven by citizen engagement.

9 **END BOX 9.1 HERE**

10 Compared to AR5, this assessment introduces four novelties (i) the scope of CO₂ emissions has been
11 extended from direct and indirect emissions considered in AR5 to include embodied emissions, (ii)
12 beyond technological efficiency measures to mitigate GHG emissions in buildings, the contribution of
13 non-technological, in particular of sufficiency measures to climate mitigation is also considered, (iii)
14 compared to SR1.5, the link to sustainable development, well-being and decent living standard for all
15 has been further developed and strengthened, and finally (iv) the active role of buildings in the energy
16 system by making passive consumers prosumers is also assessed.

17 COVID-19 emphasised the importance of buildings for human wellbeing, however, the lockdown
18 measures implemented to avoid the spread of the virus has also stressed the inequalities in the access
19 for all to suitable and healthy buildings, which provide natural daylight and clean air to their occupants
20 (see also Cross-Chapter Box 1 in Chapter 1). COVID-19 and the new health recommendations (World
21 Health Organization 2021) emphasised the importance of ventilation and the importance of indoor air
22 quality (Wei et al. 2020)(J. et al. 2011)(Guyot et al. 2018)(William 2013)(Fisk 2015). The health crisis
23 has also put an emphasis on preventive maintenance of centralised mechanical heating, ventilation, and
24 cooling systems. Moreover, the lockdown measures have led to spreading the South Korean concept of
25 *officetel* (office-hotel) (Gohaud and Baek 2017) to many countries and to extending it to *officetelschool*.
26 Therefore, the projected growth, prior to the COVID-19, of 58% of the global residential floor area by
27 2050 compared to the 290 billion m² yr⁻¹ in 2019 might well be insufficient. However, addressing the
28 new needs for more residential buildings may not, necessarily mean constructing new buildings. In fact,
29 repurposing existing non-residential buildings, no longer in use due to the expected spread of
30 teleworking triggered by the health crisis and enabled by digitalisation, could be the way to overcome
31 the new needs for *officetelschool* triggered by the health crisis.

32 The four novelties introduced in this assessment link the building sector to other sectors and call for
33 more sectoral coupling when designing mitigation solutions. Guidelines and methodologies developed
34 in Chapters 1, 2, 3, 4 and 5 are adopted in this chapter. Detailed analysis in building GHG emissions is
35 discussed based on Chapter 2 and scenarios to assess future emissions and mitigation potentials were
36 selected based on Chapters, 3 and 4. There are tight linkages between this chapter and Chapter 6, 7, 8,
37 10 and 11, which are sectoral sectors. This chapter focusses more on individual buildings and building
38 clusters, while Chapter 8 discusses macro topics in urban areas. Findings of this chapter provides
39 contribution to cross-sectoral prospection (Chapter 12), policies (Chapter 13), international cooperation
40 (Chapter 14), investment and finance (Chapter 15), innovation (Chapter 16), and sustainable
41 development (Chapter 17).

42

43 **9.2 Services and components**

44 This section mainly details the boundaries of the building sector; mitigation potentials are evaluated in
45 the following sections.

1 **9.2.1 Building types**

2 Building types and their composition affect the energy consumption for building operation as well as
3 the GHG emissions (Hachem-Vermette and Singh 2019). They also influence the energy cost
4 (MacNaughton et al. 2015) therefore, an identification of building type is required to understand the
5 heterogeneity of this sector. Buildings are classified as residential and non-residential buildings.
6 Residential buildings can be classified as slums, single-family house and multi-family house or
7 apartment/flats building. Single-family house can be divided between single-family detached (including
8 cottages, house barns, etc.) and single-family attached (or terrace house, small multi-family, etc.).
9 Another classification is per ownership: owner-occupiers, landlords, and owners'
10 association/condominiums.

11 Non-residential buildings have a much broader use. They include cultural buildings (which include
12 theatres and performance, museums and exhibits, libraries, and cultural centres), educational buildings
13 (kindergarten, schools, higher education, research centre, and laboratories), sports (recreation and
14 training, and stadiums), healthcare buildings (health, wellbeing, and veterinary), hospitality (hotel,
15 casino, lodging, nightlife buildings, and restaurants and bars), commercial buildings and offices
16 (institutional buildings, markets, office buildings, retail, and shopping centres), public buildings
17 (government buildings, security, and military buildings), religious buildings (including worship and
18 burial buildings), and industrial buildings (factories, energy plants, warehouses, data centres,
19 transportation buildings, and agricultural buildings).

20

21 **9.2.2 Building components and construction methods**

22 An understanding of the methods for assembling various materials, elements, and components is
23 necessary during both the design and the construction phase of a building. A building can be broadly
24 divided into parts: the substructure which is the underlying structure forming the foundation of a
25 building, and the superstructure, which is the vertical extension of a building above the foundation.

26 There is not a global classification for the building components. Nevertheless, Figure 9.1 tries to
27 summarise the building components found in literature (Asbjørn 2009; Ching 2014; Mañá Reixach
28 2000). The buildings are divided in the substructure and the superstructure. The substructure is the
29 foundation of the building, where the footing, basement, and plinth are found. The superstructure
30 integrates the primary elements (heavyweight walls, columns, floors and ceilings, roofs, sills and lintels,
31 and stairs), the supplementary components (lightweight walls and curtain walls), the completion
32 components (doors and windows), the finishing work (plastering and painting), and the buildings
33 services (detailed in Section 9.3).

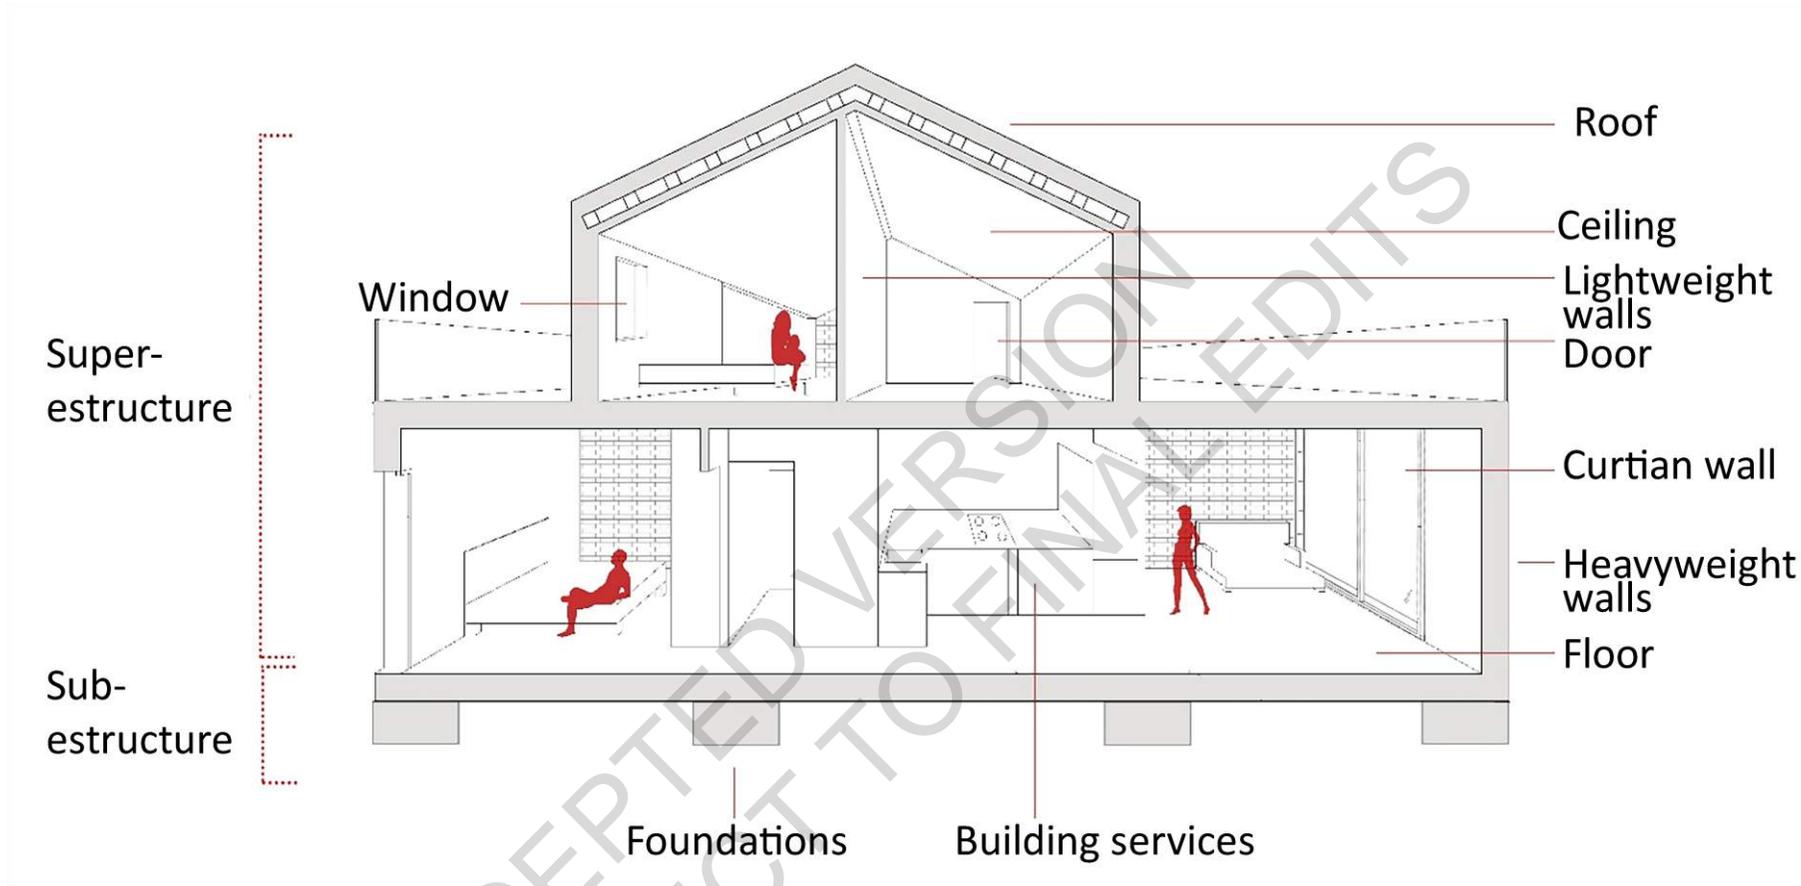

Figure 9.1 The main building components

1
2
3

1 At a global level, from historical perspective (from the Neolithic to the present), building techniques
2 have evolved to be able to solve increasingly complex problems. Vernacular architecture has evolved
3 over many years to address problems inherent in housing. Through a process of trial and error,
4 populations have found ways to cope with the extremes of the weather. The industrial revolution was
5 the single most important development in human history over the past three centuries. Previously,
6 building materials were restricted to a few manmade materials (lime mortar and concrete) along with
7 those available in nature as timber and stone. Metals were not available in sufficient quantity or
8 consistent quality to be used as anything more than ornamentation. The structure was limited by the
9 capabilities of natural materials; this construction method is called on-site construction which all the
10 work is done sequentially at the buildings site. The Industrial Revolution changed this situation
11 dramatically, new building materials emerged (cast-iron, glass structures, steel-reinforced concrete,
12 steel). Iron, steel and concrete were the most important materials of the nineteenth century (De
13 Villanueva Domínguez 2005; Wright 2000). In that context, prefabricated buildings (prefabrication also
14 known as pre-assembly or modularization) appeared within the so-called off-site construction.
15 Prefabrication has come to mean a method of construction whereby building elements and materials,
16 ranging in size from a single component to a complete building, are manufactured at a distance from
17 the final building location. Prefabricated buildings have been developed rapidly since World War II and
18 are widely used all over the world (Pons 2014; Moradiboustouni et al. 2018)

19 Recently, advances in technology have produced new expectations in terms of design possibilities. In
20 that context, 3D printing seems to have arrived. 3D printing may allow in the future to build faster,
21 cheaper and more sustainable (Agustí-Juan et al. 2017; García de Soto et al. 2018). At the same time, it
22 might introduce new aesthetics, new materials, and complex shapes that will be printed at the click of
23 a mouse on our computers. Although 3D printing will not replace architectural construction, it would
24 allow optimization of various production and assembly processes by introducing new sustainable
25 construction processes and tools (De Schutter et al. 2018). Nevertheless, what is clear is that 3D printing
26 is a technology still in development, with a lot of potentials and that it is advancing quite quickly (Hager
27 et al. 2016; Stute et al. 2018; Wang et al. 2020).

28 **9.2.3 Building services**

29 Building services make buildings more comfortable, functional, efficient, and safe. In a generic point
30 of view, building services include shelter, nutrition, sanitation, thermal, visual, and acoustic comfort,
31 entertainment, communications, elevators, and illumination. In a more holistic view building services
32 are classified as shown in Figure 9.2.

Figure 9.2 Classification of building services.

The coloured small rectangles to the left of each building service denote to which other classifications that building service may relate to a lesser extent.

Source: adapted from Vézec and Cabeza 2021a

1
2
3
4

1 A building management system is a system of devices configured to control, monitor, and manage
2 equipment in or around a building or building area and is meant to optimize building operations and
3 reduce cost (Kelsey Carle Schuster, Youngchoon Park 2019). Recent developments include the
4 integration of the system with the renewable energy systems (D.Arnone, V.Croce, G.Paterno 2016),
5 most improved and effective user interface (Rabe et al. 2018), control systems based on artificial
6 intelligence and IoT (Farzaneh et al. 2021).

7 The use of air conditioning systems in buildings will increase with the experienced rise in temperature
8 (Davis and Gertler 2015; De Falco et al. 2016) (Figure 9.8). This can ultimately lead to high energy
9 consumption rates. Therefore, adoption of energy efficient air conditioning is pertinent to balance the
10 provision of comfortable indoor conditions and energy consumption. Some of the new developments
11 that have been done include ice refrigeration (Xu et al. 2017), the use of solar photovoltaic power in the
12 air conditioning process (Burnett et al. 2014), and use of common thermal storage technologies (De
13 Falco et al. 2016) all of which are geared towards minimizing energy consumption and greenhouse gas
14 emissions.

15 Building designs have to consider provision of adequate ventilation. Natural ventilation reduces energy
16 consumption in buildings in warm climates compared to air conditioning systems (Azmi et al. 2017;
17 Taleb 2015). Enhanced ventilation has higher benefits to the public health than the economic costs
18 involved (MacNaughton et al. 2015).

19 On the refrigeration systems, the recent developments include the use of solar thermoelectric cooling
20 technologies as an energy efficient measure (Liu et al. 2015b); use of nanoparticles for energy saving
21 (Azmi et al. 2017) to mention some.

22 (Lambertz et al. 2019) stated that when evaluating the environmental impact of buildings, building
23 services are only considered in a very simplified way. Moreover, it also highlights that the increasing
24 use of new technologies such as Building Information Modelling (BIM) allows for a much more
25 efficient and easier calculation process for building services, thus enabling the use of more robust and
26 complete models. Furthermore, recent studies on building services related to climate change (Vérez and
27 Cabeza 2021a) highlight the importance of embodied energy (Parkin et al. 2019) (see Section 9.4).

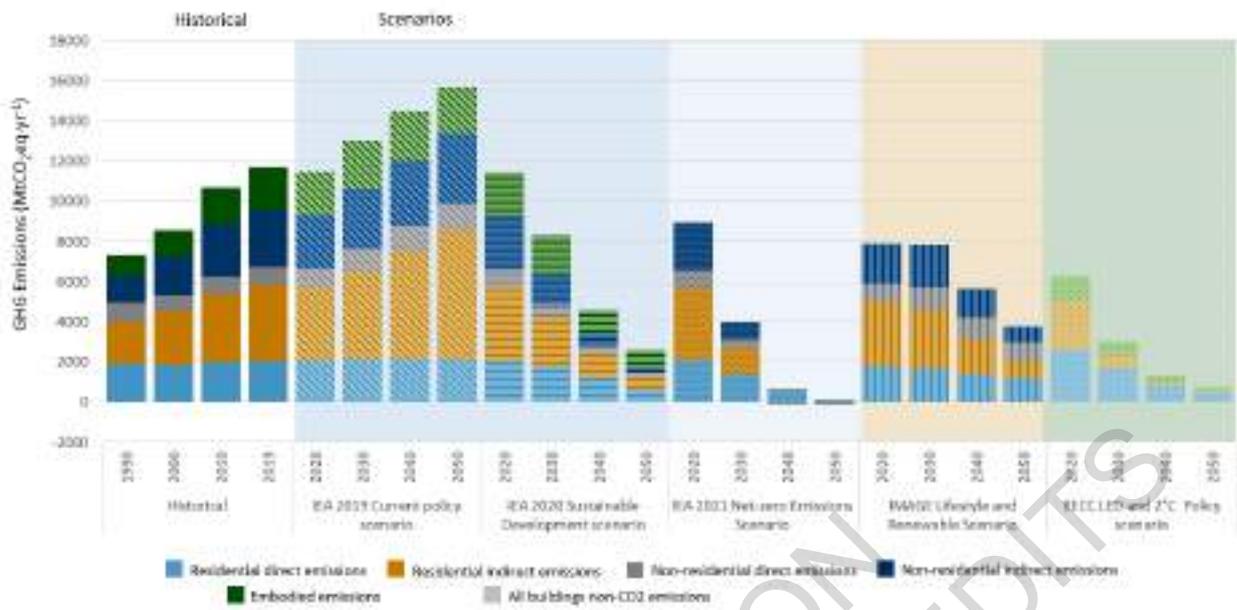

29 **9.3 New developments in emission trends and drivers**

30 **9.3.1 Past and future emission trends**

31 Total GHG emissions in the building sector reached 12 GtCO₂eq. in 2019, equivalent to 21% of global
32 GHG emissions that year. 57% of GHG emissions from buildings were indirect CO₂ emissions from
33 generation of electricity and heat off-site, 24% were direct CO₂ emissions produced on-site, and 18%
34 were from the production of cement and steel used for construction and refurbishment of buildings
35 (Figure 9.3a) (see Cross-Chapter Box 3 and Cross-Working Group Box 1 in Chapter 3). Halocarbon
36 emissions were equivalent to 3% of global building GHG emissions in 2019. In the absence of the
37 breakdown of halocarbon emissions per end-use sectors, they have been calculated for the purpose of
38 this chapter, by considering that 60% of global halocarbon emissions occur in buildings (Hu et al. 2020).
39 CH₄ and N₂O emissions were negligible, representing 0.08% each out of the 2019 global building GHG
40 emissions. Therefore, this chapter considers only CO₂ emissions from buildings. By limiting the scope
41 of the assessment to CO₂ emissions, the share of emissions from buildings increases to 31% of global
42 2019 CO₂ emissions. Energy use in residential and non-residential buildings contributed 50% and 32%
43 respectively, while embodied emissions contributed 18% to global building CO₂ emissions.

(a) Global

2
3
4

(b) Regional

5
6
7
8
9
10

Figure 9.3 Building GHG emissions: historical based on IEA data and future emissions based on two IEA scenarios (sustainable development, and net zero emissions), IMAGE Lifestyle-Renewable scenario and Resource Efficiency and Climate Change-Low Energy Demand scenario (RECC-LED). RECC-LED data include only space heating and cooling and water heating in residential buildings. The IEA current policies scenario is included as a baseline scenario (IEA current policies scenario)

11 Over the period 1990-2019, global CO₂ emissions from buildings increased by 50%. Global indirect
12 CO₂ emissions increased by 92%, driven by the increase of fossil fuels-based electrification, while
13 global direct emissions decreased by 1%. At regional level, emissions in residential buildings decreased
14 in developed countries, except in Asia-Pacific developed, while they increased in developing countries.

1 The highest decrease was observed in Europe and Eurasia, with 13.6% decrease of direct emissions and
2 33% decrease of indirect emissions, while the highest increase of direct emissions occurred in Middle
3 East, 198%, and the highest increase of indirect emissions occurred in Eastern Asia, 2258%. Indirect
4 emissions from non-residential buildings increased in all regions. The highest increase occurred in
5 Eastern Asia, 1202%, and the lowest increase occurred in Europe and Central Asia, 4%, where direct
6 emissions from non-residential buildings decreased by 51%. Embodied emissions have also increased
7 in all regions. The highest increase occurred in Southern Asia, 334%, while the lowest increase occurred
8 in North America, 4%. (Figure 9.3b).

9 Future emissions were assessed using four global scenarios and their respective baselines (Box 9.2).
10 The selection of the scenarios was based on the features of each scenario, the geographic scope, and the
11 data availability to analyse future building emissions based on the SER framework (Box 9.1).

12

13 **START BOX 9.2 HERE**

14 **Box 9.2 Scenarios used for the purpose of this chapter**

15 Three out of the four scenarios selected, and their related baselines, are based on top-down modelling
16 and were submitted to AR6 scenario database, which includes in total 931 scenarios with a building
17 module (Annex III; see also Cross-Chapter Box 3, Box 3.1, and Box 3.2 in Chapter 3). A fourth
18 scenario, not included in AR6 scenario database, and based on a bottom-up modelling approach was
19 added.

20 The main features of these scenarios are shortly described below while the underlying modelling
21 approaches are described in Annex III. Each scenario is assessed compared to its baseline scenario:

22 International Energy Agency (IEA) scenarios:

23 **2021 Net Zero Emissions by 2050 Scenario (NZE)** is a normative scenario, which sets out a narrow
24 but achievable pathway for the global energy sector to achieve net zero CO₂ emissions by 2050 (IEA
25 2021a)

26 **2020 Sustainable Development Scenario (SDS)**, which integrates the impact of COVID-19 on health
27 outcomes and economies. It is also a normative scenario, working backwards from climate, clean air,
28 and energy access goals. SDS examines what actions would be necessary to achieve these goals. The
29 near-term detail is drawn from the IEA Sustainable Recovery Plan, which boosts economies and
30 employment while building cleaner and more resilient energy systems (IEA 2020a).

31 Analysis of the IEA scenarios above was conducted compared to the 2019 Current Policies Scenario,
32 which shows what happens if the world continues along its present path (IEA 2020a), and considered
33 as a baseline scenario.

34 **IMAGE-Lifestyle-Renewable (LiRE)** scenario is based on an updated version of the SSP2 baseline,
35 while also meeting the RCP2.6 radiative forcing target using carbon prices, together with the increased
36 adoption of additional lifestyle changes, by limiting the growth in the floor area per capita in developed
37 countries as well as the use of appliances. Regarding energy supply, IMAGE-LiRE assumes increased
38 electrification and increased share of renewable in the energy mix (Detlef Van Vuuren et.al 2021).

39 **Resource Efficiency and Climate Change-Low Energy Demand (RECC-LED) scenario** is produced
40 by a global bottom-up model, which assesses contributions of resource efficiency to climate change
41 mitigation. RECC-LED estimates the energy and material flows associated with housing stock growth,
42 driven by population and the floor area per capita (Pauliuk et al. 2021). This scenario is informed by
43 the Low Energy Demand Scenario (LED), which seeks convergence between developed and developing
44 countries in the access to decent living standard (Grubler et al. 2018).

1 For consistency between the four scenarios, aggregation of regions in this chapter differs from the one
2 of the IPCC. Europe and Eurasia have been grouped into one single region.

3 **END BOX 9.2 HERE**

4

5 The IEA-NZE scenario projects emissions from the global building stock to be lowered to 29 MtCO₂
6 by 2050 against 1.7 GtCO₂ in the IEA-SDS and 3.7 GtCO₂ in IMAGE-LiRE Scenario. These projections
7 can be compared to IEA-CPS in which global emissions from buildings were projected to be at 13.5
8 GtCO₂ in 2050, which is equivalent to the 2018 emissions level (Figure 9.3a). By 2050, direct emissions
9 from residential buildings are projected to be lowered to 108 MtCO₂ in the IEA-NZE, this is four times
10 less than the projected direct emissions in RECC-LED scenario, six times less than those under the IEA-
11 SDS and eleven times less than those in the IMAGE-LiRE scenario.

12 In the IEA-NZE scenario, indirect emissions are projected to be below zero by 2050 for both residential
13 and non-residential buildings, while residual indirect emissions from residential buildings are projected
14 to be 125 MtCO₂ in RECC-LED, 634 MtCO₂ in IEA-SDS, and 842GtCO₂ in IMAGE-LiRE. Residual
15 indirect emissions from non-residential buildings are projected to be at 1.7 GtCO₂ in IEA SDS and
16 double of this in IMAGE-LiRE scenario (Figure 9.3a). Compared to IEA-SDS, the highest decrease of
17 emissions in IEA-NZE is expected to occur after 2030. Direct emissions from residential buildings in
18 IEA-NZE are projected to be, by 2030, at 1.37 GtCO₂, against 1.7 GtCO₂ in the three other scenarios.
19 The highest cut in emissions in IEA-NZE and in IMAGE-LiRE occur through the decarbonisation of
20 energy supply.

21 At regional level, by 2050, the lowest emissions are projected to occur in developed Asia and Pacific,
22 with 6.73 MtCO₂ under RECC-LED scenario and 12.4 MtCO₂ under the IEA-SDS, and the highest
23 emissions are projected to occur in Europe and Eurasia in all three scenarios, with 152 MtCO₂ in IEA-
24 SDS, 199 MtCO₂ in RECC-LED scenario and 381 MtCO₂ in IMAGE-LiRE scenario. Emissions in
25 Africa are projected to decrease to 10 MtCO₂ in RECC-LED, this is nine time less than those of 2019,
26 while they are projected to increase by 25% in IEA-SDS compared to those of 2019. Compared to IEA-
27 SDS and IMAGE-LiRE, RECC-LED projects the highest decreases, over the period 2020-2030, of
28 direct emissions in residential buildings in all regions, up to 45% in Asia-Pacific developed and Eastern
29 Asia and the highest decreases of indirect emissions, ranging from 52% in Eastern Asia to 86% in Latin
30 America and Caribbean. Over the same period, the IEA-SDS projects the highest decreases of indirect
31 emissions to occur in Asia Pacific developed and North America. IMAGE-LiRE projects the lowest
32 decreases of emissions over the same decade in almost all regions (Figure 9.3b).

33 Emissions per capita from residential buildings at a global level reached 0.85 tCO₂ per person in 2019.
34 The four scenarios assessed projects a decrease of the global per capita emissions by 2050, ranging
35 from 0 tCO₂ in IEA NZE 0.21 tCO₂ per person in IMAGE-LiRE, a 75% lower than those of 2019
36 (Figure 9.4a). There are great differences in the projected per capita emissions under each scenario
37 different scenarios across the regions (Figure 9.4b). Compared to IEA SDS and IMAGE-LiRE
38 scenarios, RECC-LED projects the lowest emissions per capita in all regions by 2050. Emissions per
39 capita in Europe and Eurasia are projected to be the highest in all scenarios by 2050, ranging from 0.26
40 tCO₂ in RECC-LED and 0.31tCO₂ in IEA SDS to 0.65 tCO₂ in IMAGE-LiRE.

7 **Figure 9.4 Per capita emissions: historical based on IEA data and future emissions based on two IEA**
 8 **scenarios (sustainable development, and net zero emissions), IMAGE Lifestyle-Renewable scenario and**
 9 **Resource Efficiency and Climate Change-Low Energy Demand scenario (RECC-LED). RECC-LED data**
 10 **include only space heating and cooling and water heating in residential buildings. The IEA current**
 11 **policies scenario is included as a baseline scenario (IEA current policies scenario)**

12 **9.3.2 Drivers of CO₂ emissions and their climate impact**

13 Building specific drivers of GHG emissions in the four scenarios described above are assessed using an
 14 index decomposition analysis with building specific identities and reflecting the three pillars of the SER
 15 framework (sufficiency, efficiency, renewables). Broad drivers of GHG emissions such as GDP and
 16 population are analysed using a Kaya decomposition in Chapter 2. Previous decompositions analysing
 17 drivers of global GHG emissions in the building sector have either assessed only the impact of GDP

1 and population as drivers of GHG emissions (Lamb et al. 2021) or the impact of building specific drivers
 2 on energy demand and not on CO₂ emissions (Ürge-Vorsatz et al., 2015, IPCC AR5, 2014, IEA, 2020,
 3 ODYSSEE, 2020). For this assessment, the decomposition was conducted for energy-related CO₂
 4 emissions for residential buildings only, due to lack of data for non-residential buildings.

5 The attribution of changes in emissions in the use phase to changes in the drivers of population,
 6 sufficiency, efficiency, and carbon intensity of energy supply is calculated using additive log-mean
 7 divisia index decomposition analysis (Ang and Zhang 2000). The decomposition of emissions into four
 8 driving factors is shown in Eq. 1, where m^2 refers to total floor area, EJ refers to final energy demand,
 9 and Mt_{CO_2} refers to the sum of direct and indirect CO₂ emissions in the use phase. The allocation of
 10 changes in emissions between two cases k and $k-1$ to changes in a single driving factor D is shown in
 11 Eq. 2. To calculate changes in emissions due to a single driver such as population growth, D will take
 12 on the value of population in the two compared cases. The superscript k stands for the case, defined by
 13 the time period and scenario of the emissions, e.g., IEA CPS Baseline scenario in 2050. When
 14 decomposing emissions between two cases k and $k-1$, either the time-period, or the scenario remains
 15 constant. The decomposition was done at the highest regional resolution available from each model
 16 output, and then aggregated to regional or global level. For changes in emissions within a scenario over
 17 time, the decomposition is done for every decade, and the total 2020-2050 decomposition is then
 18 produced by summing decompositions of changes in emissions each decade.

19 **Equation 9.1**

$$20 \quad CO2_{total}^k = Pop \times \frac{m^2}{Pop} \times \frac{EJ}{m^2} \times \frac{Mt_{CO_2}}{EJ} = Pop \times Suff \times Eff \times Ren$$

21 **Equation 9.2**

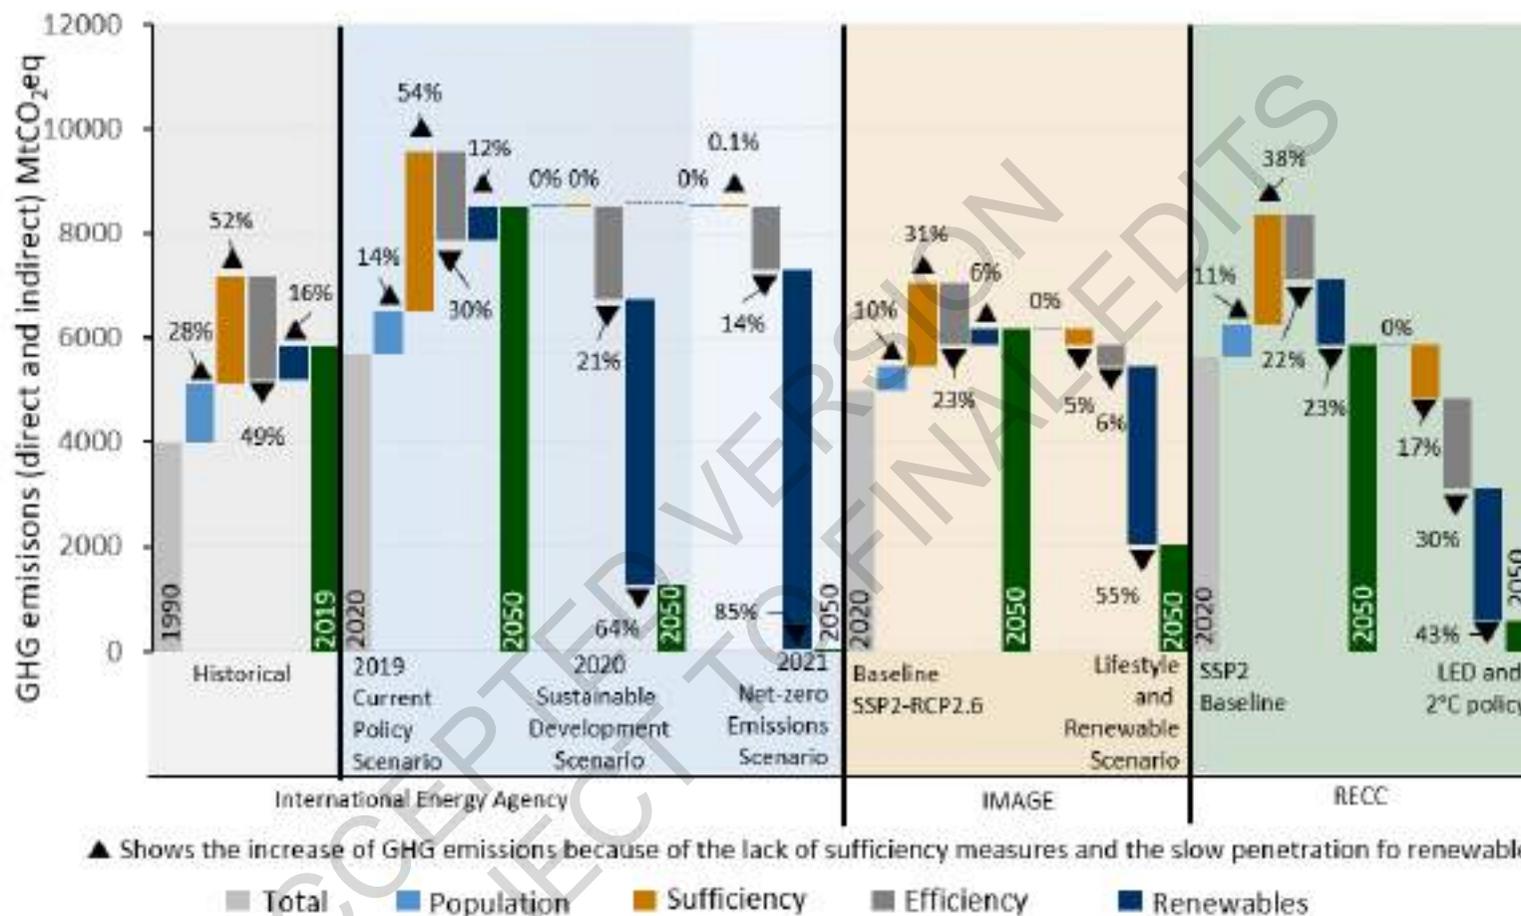

$$22 \quad \Delta CO2_{,D}^{k,k-1} = \frac{CO2 - CO2_{total}^{k-1}}{\ln(CO2_{total}^k) - \ln(CO2_{total}^{k-1})} \times \ln\left(\frac{D^k}{D^{k-1}}\right)$$

23 Over the period 1990-2019, population growth accounted for 28% of the growth in global emissions in
 24 residential buildings, the lack of sufficiency policies (growth in floor area per capita) accounted for
 25 52% and increasing carbon intensity of the global energy mix accounted for 16%. Efficiency
 26 improvement contributed to decreasing global emissions from residential buildings by 49% (

27 a). The sufficiency potential was untapped in all regions over the same period while the decarbonisation
 28 of the supply was untapped in developing countries and to some extent in Asia Pacific developed. The
 29 highest untapped sufficiency and supply decarbonisation potentials occurred in Southern Asia where
 30 the lack of sufficiency measures has led to increasing emissions by 185% and the high carbon intensity
 31 of the energy mix has led to increasing emissions by 340%. In developed countries, the highest untapped
 32 sufficiency potential occurred in Asia Pacific developed region. Middle East is the only region where
 33 efficiency potential remained untapped (Figure 9.5b).

4 Figure 9.5 Decompositions of changes in historical residential energy emissions 1990-2019, changes in emissions projected by baseline scenarios for 2020-2050, and
5 differences between scenarios in 2050 using scenarios from three models: IEA, IMAGE, and RECC. RECC-LED data include only space heating and cooling and
6 water heating in residential buildings (a) Global resolution, and (b) for nine world regions. Emissions are decomposed based on changes in driver variables of
7 population, sufficiency (floor area per capita), efficiency (final energy per floor area), and renewables (GHG emissions per final energy). ‘Renewables’ is a
8 summary term describing changes in GHG intensity of energy supply. Emission projections to 2050, and differences between scenarios in 2050, demonstrate
9 mitigation potentials from the dimensions of the SER framework realised in each model scenario. In most regions, historical improvements in efficiency have been
10 approximately matched by growth in floor area per capita. Implementing sufficiency measures that limit growth in floor area per capita, particularly in developed
11 regions, reduces the dependence of climate mitigation on technological solutions

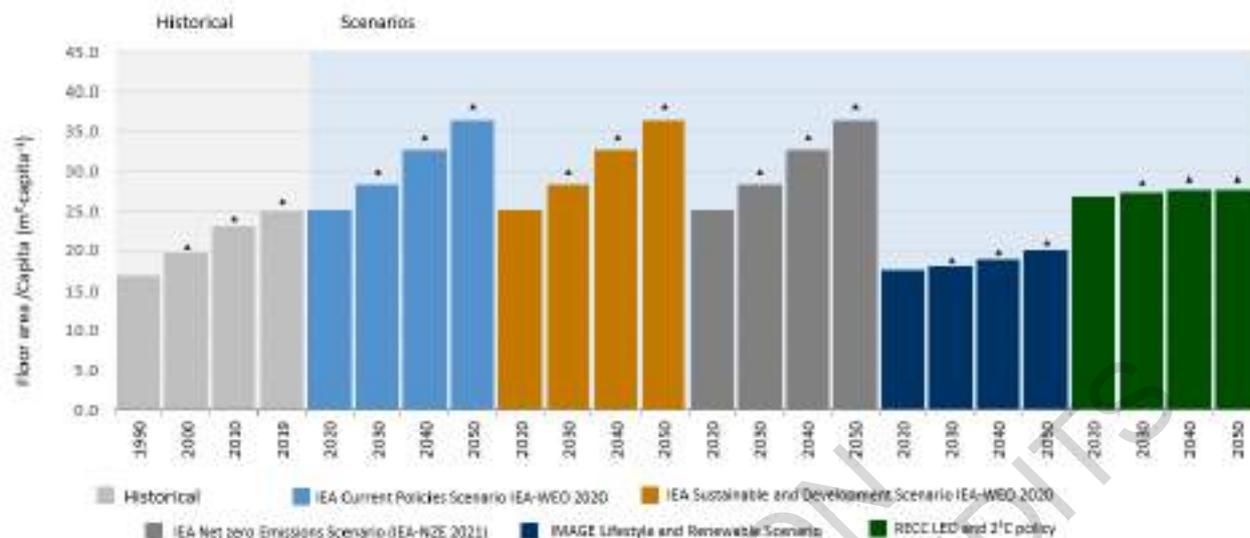

1 Scenarios assessed show an increase of the untapped sufficiency potential at the global level over the
2 period 2020-2050. The highest untapped sufficiency potential occurs in IEA scenarios as there are no
3 changes in the floor area per capita across different scenarios. The lack of sufficiency measures in
4 current policies will contribute to increasing emissions by 54%, offsetting the efficiency improvement
5 effect. By setting a cap in the growth of the floor area per capita in developed countries, 5% of emission
6 reductions in IMAGE-LiRE scenario derives from sufficiency. However, compared to 2020, the lack
7 of sufficiency measures in the baseline scenario will contribute to increasing emissions by 31%. RECC-
8 LED scenario shows the highest global sufficiency potential captured compared to its baseline scenario
9 in 2050 as this scenario assumes a reduction in the floor area per capita in developed countries and
10 slower floor area growth in emerging economies. The four scenarios show a higher contribution of the
11 decarbonisation of energy supply to reducing emissions than the reduction of energy demand through
12 sufficiency and efficiency measures (Figure 9.6a). At regional level, the emissions reduction potential
13 from sufficiency is estimated at 25% in North America under both IMAGE-LiRE and RECC-LED
14 scenarios and at 19% in both Eastern Asia and Europe/Eurasia regions (Figure 9.6b). The highest
15 decarbonisation potential due to growth of renewable energy is 75% in Southern Asia under IMAGE-
16 LiRE scenario.

17 There is a growing literature on the decarbonisation of end-use sectors while providing decent living
18 standard for all (Rao and Min 2018)(Rao et al. 2019)(Rao and Pachauri 2017) (Grubler et al. 2018),
19 (Millward-Hopkins et al. 2020). The floor area per capita is among the gaps identified in the
20 convergence between developed and developing countries in the access to decent living (Kikstra et al.
21 2021) while meeting energy needs. In the Low Energy Demand (LED) scenario, 30 m² per capita is the
22 converging figure assumed by 2050 (Grubler et al. 2018) while in the Decent Living with minimum
23 Energy (DLE) scenario, (Millward-Hopkins et al. 2020) assumes 15 m² per capita.

24

10

Figure 9.6 Per capita floor area: historical based on IEA data and future emissions based on two IEA scenarios (sustainable development, and net zero emissions), IMAGE Lifestyle-Renewable scenario and Resource Efficiency and Climate Change-Low Energy Demand scenario (RECC-LED). RECC-LED data include only space heating and cooling and water heating in residential buildings. The IEA current policies scenario is included as a baseline scenario (IEA current policies scenario)

11 Overall, the global residential building stock grew by almost 30% between 2005 and 2019. However,
12 this growth was not distributed equally across regions and three out of the four scenarios assessed do
13 not assume a convergence, by 2050, in the floor area per capita, between developed and developing
14 countries. Only RECC-LED implements some convergence between developed countries and emerging

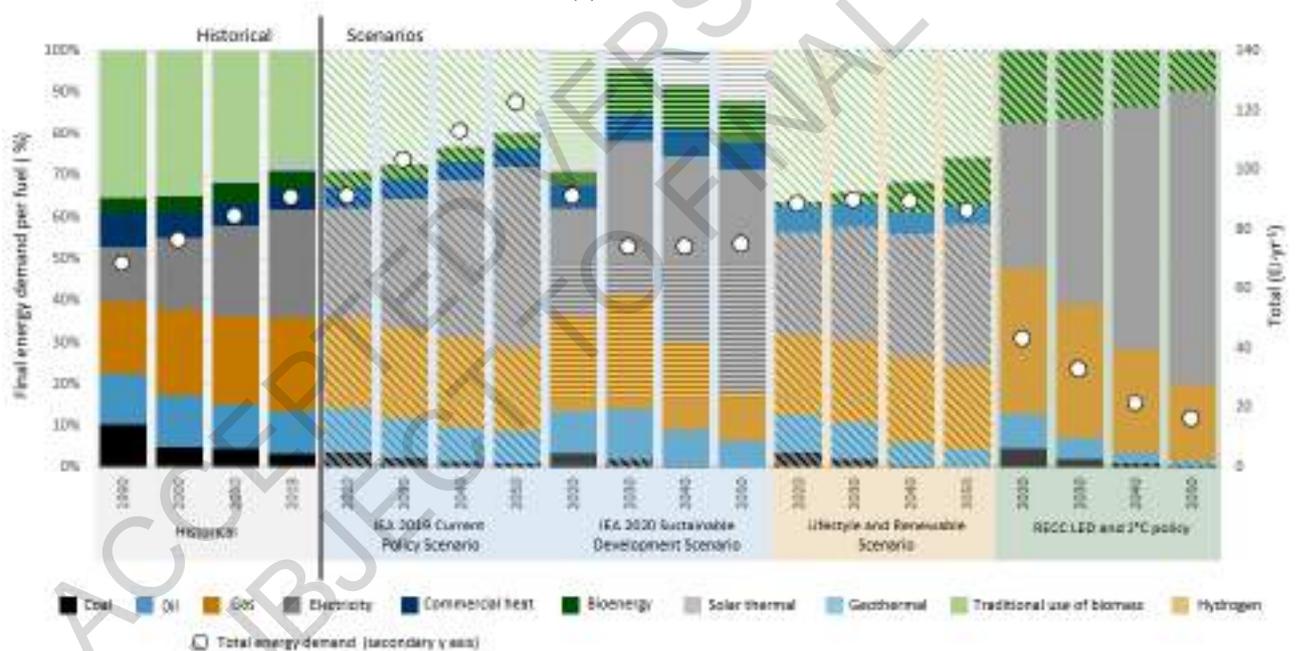

1 economies to a range of 20-40 m² per capita. IEA scenarios assume a growth in the floor area per capita
 2 in all regions with the highest growth in developed countries, up to 72 m² per capita in North America
 3 from 66 m² per capita in 2019. IMAGE-LiRE projects a floor area per capita in Africa at 14 m² per
 4 person. This is lower than the one of 2019, which was at 16 m² per capita (Figure 9.6). Beyond capturing
 5 the sufficiency potential by limiting the growth in the floor area per capita in developed countries while
 6 ensuring decent living standard, the acceptability of the global scenarios by developing countries is
 7 getting attraction in academia (Hickel et al. 2021).

8 **9.3.3 Energy demand trends**

9 Global final energy demand from buildings reached 128.8 EJ in 2019, equivalent to 31% of global final
 10 energy demand. The same year, residential buildings consumed 70% out of global final energy demand
 11 from buildings. Over the period 1990-2019, global final energy demand from buildings grew by 38%,
 12 with 54% increase in non-residential buildings and 32% increase in residential ones. At regional level,
 13 the highest increase of final energy demand occurred in Middle East and Africa in residential buildings
 14 and in all developing Asia in non-residential ones. By 2050, global final energy demand from buildings
 15 is projected to be at 86 EJ in IEA NZE, 111 EJ in IEA SDS and 138 EJ in IMAGE-LiRE. RECC-LED
 16 projects the lowest global final energy demand, at 15.7 EJ by 2050, but this refers to water heating,
 17 space heating and cooling in residential buildings only (Figure 9.7a).

Figure 9.7 Final energy demand per fuel: historical based on IEA data and future emissions based on two IEA scenarios (sustainable development, and net zero emissions), IMAGE Lifestyle-Resource Efficiency and Climate Change-Low Energy Demand scenario (RECC-LED). RECC-LED data include only space heating and cooling and water heating in residential buildings. The IEA current policies scenario is included as a baseline scenario (IEA current policies scenario)

9 Over the period 1990-2019, the use of coal decreased at a global level by 59% in residential buildings
10 and 52% in non-residential ones. Solar thermal experienced the highest increase, followed by
11 geothermal and electricity. However, by 2019, solar thermal and geothermal contributed by only 1%
12 each to global final energy demand, while electricity contributed by 51% in non-residential buildings
13 and 26% in residential ones. The same year, gas contributed by 26% to non-residential final energy
14 demand and 22% to residential final energy demand, which makes gas the second energy carrier used
15 in buildings after electricity. Over the period 1990-2019, the use of gas grew by 75% in residential
16 buildings and by 46% in non-residential ones. By 2050, RECC-LED projects electricity to contribute
17 by 71% to final energy demand in residential buildings, against 62% in IEA-NZE and 59% in IMAGE-
18 LiRE. IEA-NZE is the only scenario to project less than 1% of gas use by 2050 in residential buildings
19 while the contribution of electricity to energy demand of non-residential buildings is above 60% in all
20 scenarios. At regional level, the use of coal in buildings is projected to disappear while the use of
21 electricity is projected to be above 50% in all regions by 2050 (Figure 9.7b).

22 Hydrogen emerged in the policy debate as an important energy carrier for the decarbonisation of the
23 energy system. In the case of the building sector, depending on how hydrogen is sourced (see Box 12.3
24 in Chapter 12), converting gas grids to hydrogen might be an appealing option to decarbonise heat
25 without putting additional stress on the electricity grids. However, according to (Elements energy Ltd
26 2018; Broad et al. 2020; Frazer-Nash Consultancy 2018; Gerhardt et al. 2020) (Strbac et al. 2018) the
27 delivered cost of heat from hydrogen would be much higher than the cost of delivering heat from heat

1 pumps, which could also be used for cooling. Repurposing gas grids for pure hydrogen networks will
2 also require system modifications such as replacement of piping and replacement of gas boilers and
3 cooking appliances, a factor cost to be considered when developing hydrogen roadmaps for buildings.
4 There are also safety and performance concerns with domestic hydrogen appliances (Frazer-Nash
5 Consultancy 2018). Over the period 1990-2019, hydrogen was not used in the building sector and
6 scenarios assessed show a very modest role for hydrogen in buildings by 2050 (Figure 9.7).

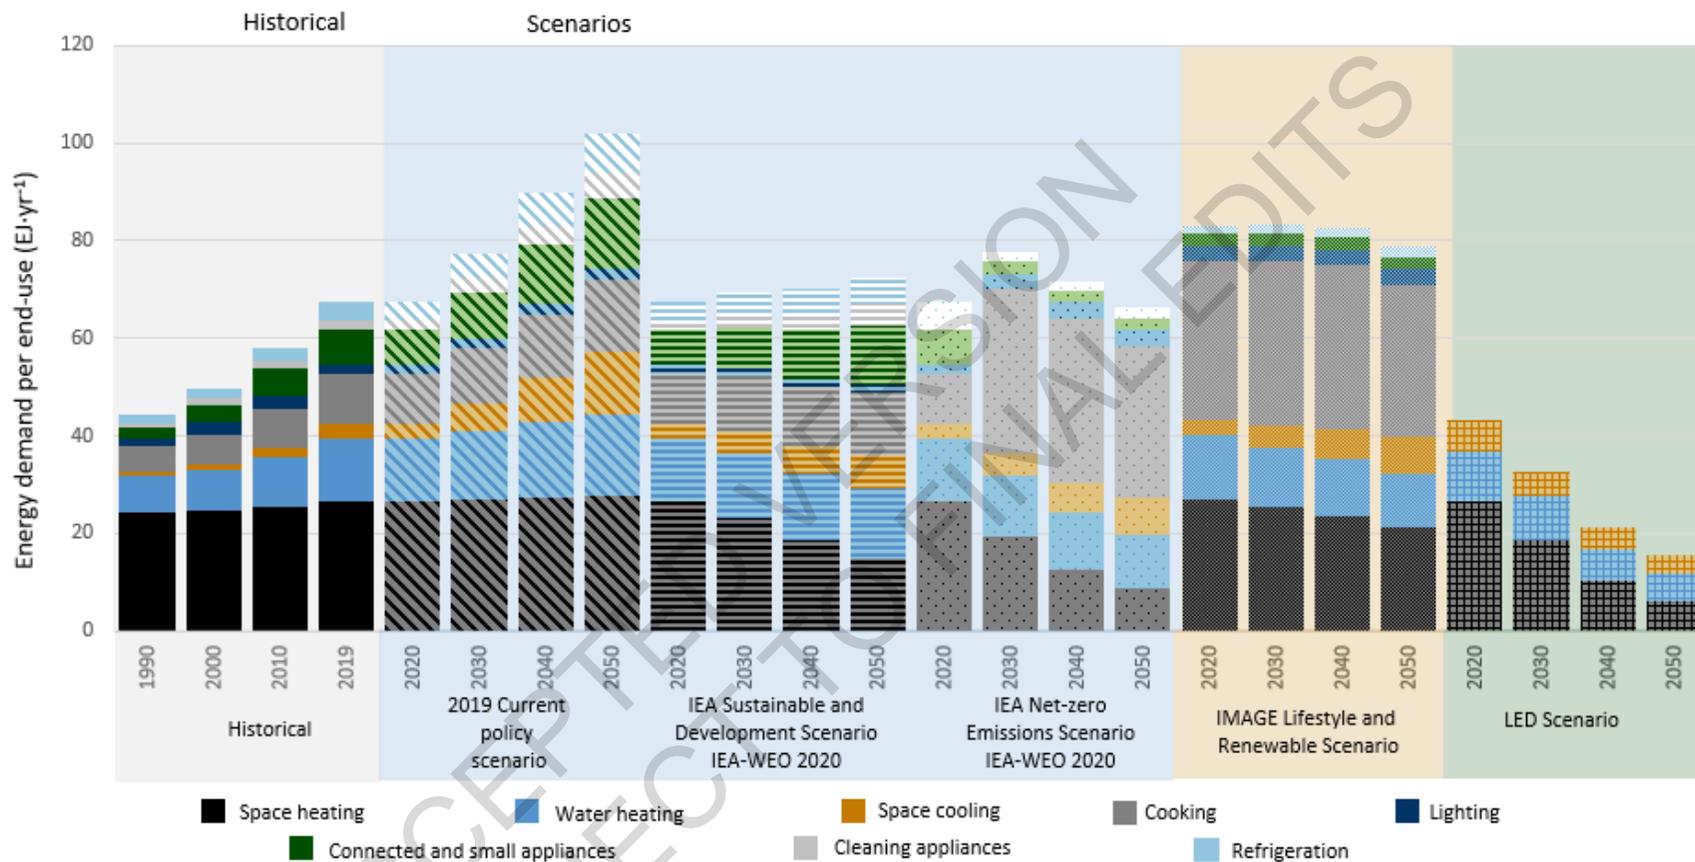

7 In developed countries, biomass is used for generating heat and power leading to reduction of indirect
8 emissions from buildings (Ortwein 2016)(IEA et al. 2020a). However, according to (IEA 2019b) despite
9 the mitigation potential of biomass, if the wood is available locally, its use remains low in developed
10 countries. Biomass is also used for efficient cook stoves and for heating using modern appliances such
11 as pellet-fed central heating boilers. In developing countries, traditional use of biomass is characterised
12 by low efficiency of combustion (due to low temperatures) leading to high levels of pollutants and CO
13 output, as well as low efficiency of heat transfer. The traditional use of biomass is associated with public
14 health risks such as pre mature deaths related to inhaling fumes from cooking (Dixon et al. 2015; Van
15 de Ven et al. 2019; Taylor et al. 2020; IEA 2019b). According to (Hanna et al. 2016) policies failed in
16 improving the use of biomass. Over the period 1990-2019, the traditional use of biomass decreased by
17 1% and all scenarios assessed do not project any traditional use of biomass by 2050. Biomass is also
18 used for the construction of buildings, leading to low embodied emissions compared to concrete
19 (Pauliuk et al. 2021; Hart and Pomponi 2020; Heeren et al. 2015a)

20 Over the period 1990-2019, space heating was the dominant end-use in residential buildings at a global
21 level, followed by water heating, cooking, and connected and small appliances (Figure 9.8a). However,
22 energy demand from connected and small appliances experienced the highest increase, 280%, followed
23 by cooking, 89%, cooling, 75%, water heating, 73% and space heating, around 10%. Space heating
24 energy demand is projected to decline over the period 2020-2050 in all scenarios assessed. RECC-LED
25 projects the highest decrease, 77%, of space heating energy demand, against 68% decrease in the IEA
26 NZE. IMAGE-LiRE projects the lowest decrease of heating energy demand, 21%. To the contrary, all
27 scenarios confirm cooling as a strong emerging trend (Box 9.3) and project an increase of cooling
28 energy demand. IMAGE-LiRE projects the highest increase, 143% against 45% in the IEA-NZE while
29 RECC-LED projects the lowest increase of cooling energy demand, 32%.

30

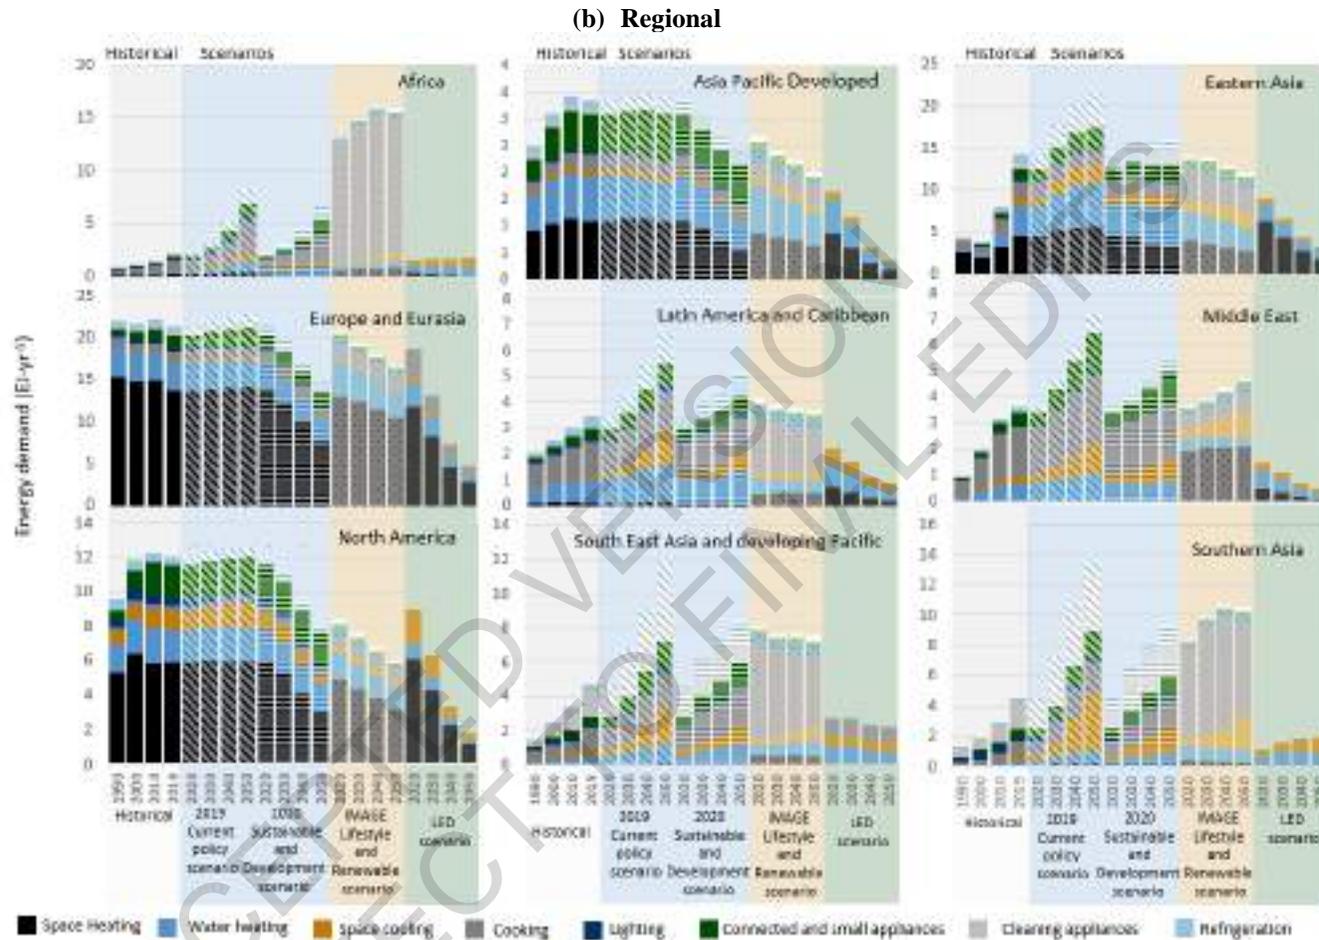

1
2

(a) Global

3

1

2
3
4
5

Figure 9.8 Energy per end use: historical based on IEA data and future emissions based on two IEA scenarios (sustainable development, and net zero emissions), IMAGE Lifestyle-Renewable scenario and Resource Efficiency and Climate Change-Low Energy Demand scenario (RECC-LED). RECC-LED data include only space heating and cooling and water heating. The IEA current policies scenario is included as a baseline scenario (IEA current policies scenario)

1 There are great differences in the contribution of each end-use to the regional energy demand (Figure
2 9.8b). In 2019, more than 50% of residential energy demand in Europe and Eurasia was used for space
3 heating while there was no demand for space heating in Middle East, reflecting differences in climatic
4 conditions. To the contrary, the share of energy demand from cooking out of total represented 53% in
5 the Middle East against 5% in Europe-Eurasia reflecting societal organisations. The highest
6 contribution of energy demand from connected and small appliances to the regional energy demand was
7 observed in 2019 in the Asia Pacific developed, 24%, followed by the region of Southern Asia,
8 Southeast Asia and Developing Pacific, with 17%. Energy demand from cooling was at 9% out of total
9 energy demand of Southern Asia, Southeast Asia and Developing Pacific and at 8% in both Middle East
10 and North America while it was at 1% in Europe in 2019.

11 The increased cooling demand can be partly explained by the increased ownership of room air-
12 conditioners per dwellings in all regions driven by increased wealth and the increased ambient
13 temperatures due to global warming (Cayla et al. 2011) (Liddle and Huntington 2021) (Box 9.3). The
14 highest increase, 32%, in ownership of room air-conditioners was observed in Southern Asia and
15 Southeast Asia and developing Pacific while Europe, Latin America and Caribbean countries, Eastern
16 Asia and Africa experienced an increase of 21% in households' ownership of room air-conditioners.
17 The lowest increases in room air-conditioners ownership were observed in the Middle East and North
18 America with 1% and 8% each as these two markets are almost saturated. All scenarios assessed project
19 an increase of ownership of cooling appliances in all regions over the period 2020-2050.

20 Energy demand from connected and small appliances was, at a global level, above 7 EJ in 2019 (Figure
21 9.8a). However, it is likely that global energy demand from connected and small appliances is much
22 higher as reported data do not include all the connected and small appliances used by households and
23 does not capture energy demand from data centres (Box 9.3). Over the period 1990-2019, the highest
24 increase of energy demand from connected and small appliances, 4740%, was observed in Eastern Asia,
25 followed by Southern Asia, 1358% while the lowest increase, 99%, occurred in Asia Pacific developed
26 countries. The increase of energy demand from connected and small appliances is driven by the
27 ownership increase of such appliances all over the world. The highest increase in ownership of
28 connected appliances, 403%, was observed in Eastern Asia and the lowest increase in ownership of
29 connected appliances was observed in North America, 94%. Future energy demand is expected to occur
30 in the developing world given the projected rate of penetration of household appliances and devices
31 (Wolfram et al. 2012). However, (Grubler et al. 2018) projects a lower energy demand from connected
32 and small appliances by assuming an increase of shared appliances and multiple appliances and
33 equipment will be integrated into units delivering multiple services.

34

35 **START BOX 9.3 HERE**

36 **Box 9.3 Emerging energy demand trends in residential buildings**

37 Literature assessed points to three major energy demand trends:

38 ***Cooling energy demand***

39 In a warming world (IPCC 2021) with a growing population and expanding middle-class, the demand
40 for cooling is likely to increase leading to increased emissions if cooling solutions implemented are
41 carbon intensive (Kian Jon et al. 2021; Dreyfus et al. 2020b; Santamouris 2016; Sustainable Energy for
42 All 2018; United Nations Environment Programme (UNEP) International Energy Agency (IEA) 2020).
43 Sufficiency measures such as building design and forms, which allow balancing the size of openings,
44 the volume, the wall and window area, the thermal properties, shading, and orientation are all non-cost
45 solutions, which should be considered first to reduce cooling demand. Air conditioning systems using
46 halocarbons are the most common solutions used to cool buildings. Up to 4 billion cooling appliances
47 are already installed and this could increase to up 14 billion by 2050 (Peters 2018; Dreyfus et al. 2020b).
48 Energy efficiency of air conditioning systems is of a paramount importance to ensuring that the
49 increased demand for cooling will be satisfied without contributing to global warming through

1 halocarbon emissions (Shah et al. 2019, 2015; Campbell 2018; United Nations Environment
2 Programme (UNEP) International Energy Agency (IEA) 2020). The installation of highly efficient
3 technological solutions with low Global Warming Potential (GWP), as part of the implementation of
4 the Kigali amendment to the Montreal Protocol, is the second step towards reducing GHG emissions
5 from cooling. Developing renewable energy solutions integrated to buildings is another track to follow
6 to reduce GHG emissions from cooling.

7 *Electricity energy demand*

8 Building electricity demand was slightly above 43 EJ in 2019, which is equivalent to more than 18% of
9 global electricity demand. Over the period 1990-2019, electricity demand increased by 161%. The
10 increase of global electricity demand is driven by the combination of rising incomes, income
11 distribution and the S-curve of ownership rates (Wolfram et al. 2012; Gertler et al. 2016). Electricity is
12 used in buildings for plug-in appliances i.e., refrigerators, cleaning appliances, connected and small
13 appliances, and lighting. An important emerging trend in electricity demand is the use of electricity for
14 thermal energy services (cooking, water, and space heating). The increased penetration of heat pumps
15 is the main driver of the use of electricity for heating. Heat pumps used either individually or in
16 conjunction with heat networks can provide heating in cold days and cooling in hot ones. (Lowe et al.
17 2020) suggests electricity is expected to become an important energy vector to decarbonise heating.
18 However, the use of heat pumps will increase halocarbon emissions (United Nations Environment
19 Programme (UNEP) International Energy Agency (IEA) 2020). (Bloess et al. 2018; Barnes and
20 Bhagavathy 2020; Connolly 2017) argue for electrification of heat as a cost-effective decarbonisation
21 measure, if electricity is supplied by renewable energy sources (Ruhnau et al. 2020). The electrification
22 of the heat supplied to buildings is likely to lead to an additional electricity demand and consequently
23 additional investment in new power plants. (Thomaßen et al. 2021) identifies flexibility as a key enabler
24 of larger heat electrification shares. Importantly, heat pumps work at their highest efficiency level in
25 highly efficient buildings and their market uptake is likely to require incentives due to their high up-
26 front cost (Hannon 2015; Heinen et al. 2017).

27 *Digitalisation energy demand*

28 Energy demand from digitalisation occurs in datacentres, which are dedicated buildings or part of
29 buildings for accommodating large amount of information technologies equipment such as servers, data
30 storage and communication devices, and network devices. Data-centres are responsible for about 2% of
31 global electricity consumption (Diguët and Lopez 2019; Avgerinou et al. 2017). Energy demand from
32 datacentres arises from the densely packed configuration of information technologies, which is up to
33 100 times higher than a standard office accommodation (Chu and Wang 2019). Chillers combined with
34 air handling units are usually used to provide cooling in datacentres. Given the high cooling demand of
35 datacentres, some additional cooling strategies, such as free cooling, liquid cooling, low-grade waste
36 heat recovery, absorption cooling, etc., have been adopted. In addition, heat recovery can provide useful
37 heat for industrial and building applications. More recently, datacentres are being investigated as a
38 potential resource for demand response and load balancing (Zheng et al. 2020; Koronen et al. 2020).
39 Supplying datacentres with renewable energy sources is increasing (Cook et al. 2014) and is expected
40 to continue to increase (Kooimey et al. 2011). Estimates of energy demand from digitalisation
41 (connected and small appliances, data centres, and data networks) combined vary from 5% to 12% of
42 global electricity use (Ferreboeuf 2019; Gelenbe and Caseau 2015; Malmmodin and Lundén 2018; Diguët
43 and Lopez 2019). According to (Ferreboeuf 2019) the annual increase of energy demand from
44 digitalisation could be limited to 1.5% against the current 4% if sufficiency measures are adopted along
45 the value chain.

46 Digitalisation occurs also at the construction stage. (European Union 2019; Witthoeft and Kosta 2017)
47 identified seven digital technologies already in use in the building sector. These technologies include
48 (i) Building Information Modelling/Management (BIM), (ii) additive manufacturing, also known as 3D
49 printing, (iii) robots, (iv) drones, (v) 3D scanning, (vi) sensors, and (vii) Internet of Things (IoT). BIM
50 supports decision making in the early design stage and allows assessing a variety of design options and
51 their embodied emissions (Röck et al. 2018; Basbagill et al. 2013). 3D printing reduces material waste
52 and the duration of the construction phase as well as labour accidents (Dixit 2019). Coupling 3D printing

1 and robots allows for increasing productivity through fully automated prefabricated buildings. Drones
2 allow for a better monitoring and inspection of construction projects through real-time comparison
3 between planned and implemented solutions. Coupling drones with 3D scanning allows predicting
4 building heights and energy consumption (Streltsov et al. 2020). Sensors offer a continuous data
5 collection and monitoring of end-use services (i.e., heating, cooling, and lighting), thus allowing for
6 preventive maintenance while providing more comfort to end-users. Coupling sensors with IoT, which
7 connects to the internet household appliances and devices such as thermostats, enable demand-response,
8 and flexibility to reduce peak loads (IEA 2017; Lyons 2019). Overall, connected appliances offer a
9 variety of opportunities for end-users to optimise their energy demand by improving the responsiveness
10 of energy services (Nakicenovic et al. 2019; [IEA] - International Energy Agency 2017) through the
11 use of digital goods and services (Wilson et al., 2020) including peer-to-peer electricity trading
12 (Morstyn et al. 2018).

13 **END BOX 9.3 HERE**

15 **9.4 Mitigation technological options and strategies towards zero carbon** 16 **buildings**

17 Literature in this topic is extensive, but unfortunately, most studies and reviews do not relate themselves
18 to climate change mitigation, therefore there is a clear gap in reporting the mitigation potential of the
19 different technologies (Cabeza et al. 2020). It should be highlighted that when assessing the literature,
20 it is clear that a lot of new research is focussed on the improvement of control systems, including the
21 use of artificial intelligence or internet of things (IoT).

22 This section is organised as follow. First, the key points from AR5 and special reports are summarized,
23 following with a summary of the technological developments since AR5, specially focussing on
24 residential buildings.

25 **9.4.1 Key points from AR5 and special reports**

26 AR5 Chapter 9 on Buildings (Ürge-Vorsatz et al. 2014) presents mitigation technology options and
27 practices to achieve large reductions in building energy use as well as a synthesis of documented
28 examples of large reductions in energy use achieved in real, new, and retrofitted buildings in a variety
29 of different climates and examples of costs at building level. A key point highlighted is the fact that the
30 conventional process of designing and constructing buildings and its systems is largely linear, losing
31 opportunities for the optimization of whole buildings. Several technologies are listed as being able to
32 achieve significant performance improvements and cost potentials (daylighting and electric lighting,
33 household appliances, insulation materials, heat pumps, indirect evaporative cooling, advances in
34 digital building automation and control systems, and smart meters and grids to implement renewable
35 electricity sources).

36 **9.4.2 Embodied energy and embodied carbon**

37 **9.4.2.1 Embodied energy and embodied carbon in building materials**

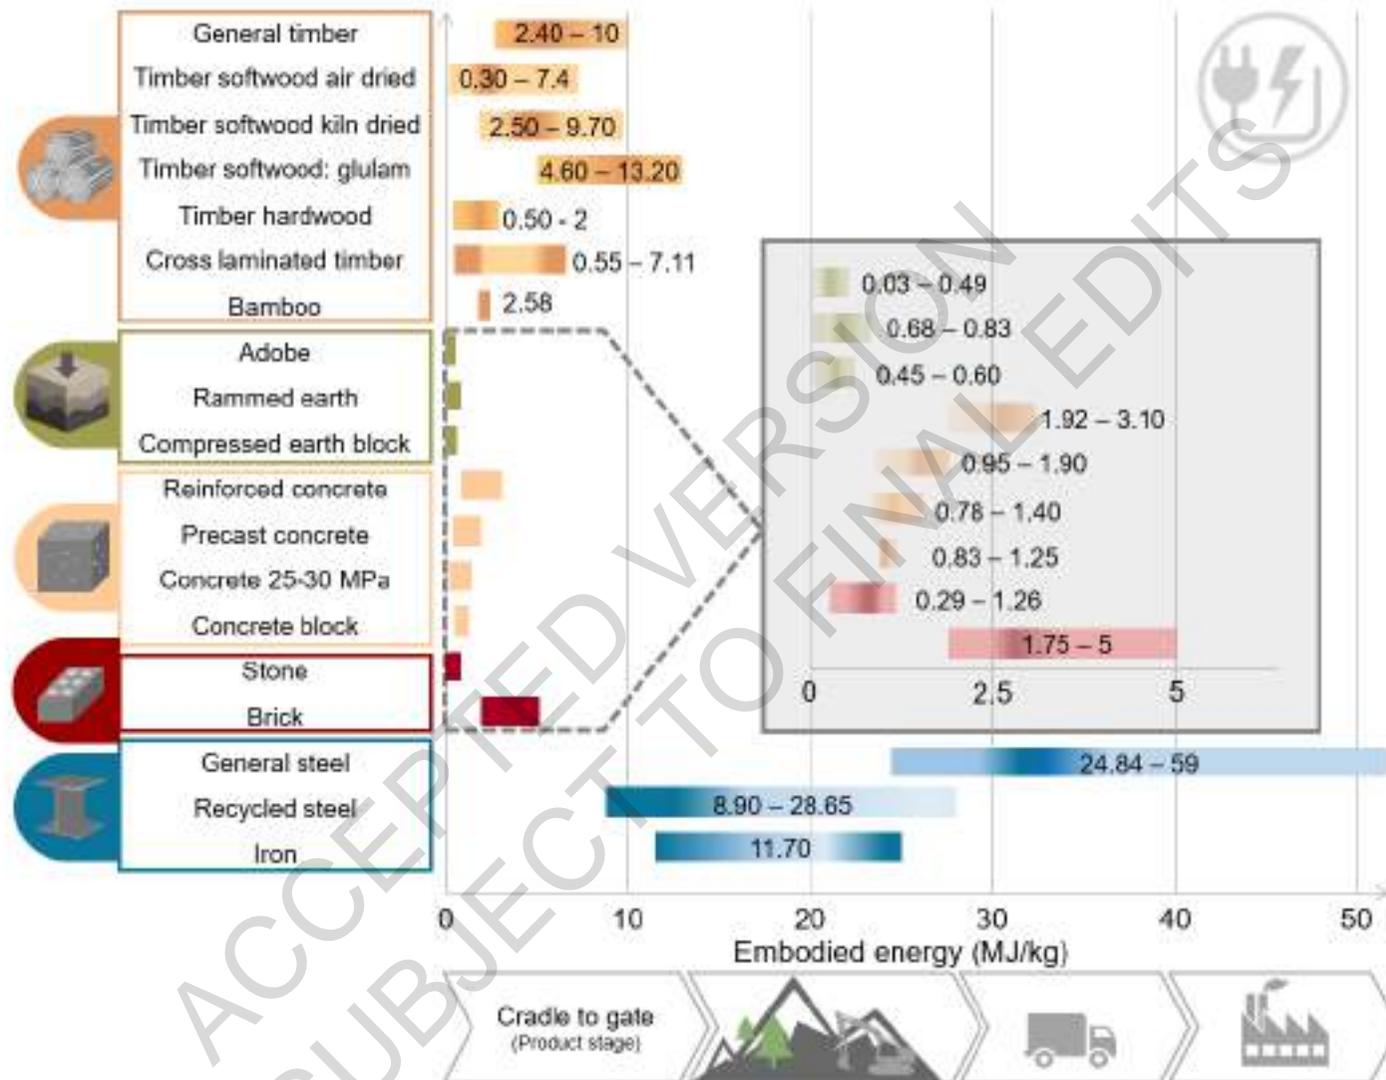

38 As building energy demand is decreased the importance of embodied energy and embodied carbon in
39 building materials increases (Ürge-Vorsatz et al. 2020). Buildings are recognised as built following five
40 building frames: concrete, wood, masonry, steel, and composite frames (International Energy Agency
41 2019a); but other building frames should be considered to include worldwide building construction
42 practice, such as rammed earth and bamboo in vernacular design (Cabeza et al. 2021).

43 The most prominent materials used following these frames classifications are the following. Concrete,
44 a man-made material, is the most widely used building material. Wood has been used for many centuries
45 for the construction of buildings and other structures in the built environment; and it remains as an
46 important construction material today. Steel is the strongest building material; it is mainly used in
47 industrial facilities and in buildings with big glass envelopes. Masonry is a heterogeneous material using
48 bricks, blocks, and others, including the traditional stone. Composite structures are those involving

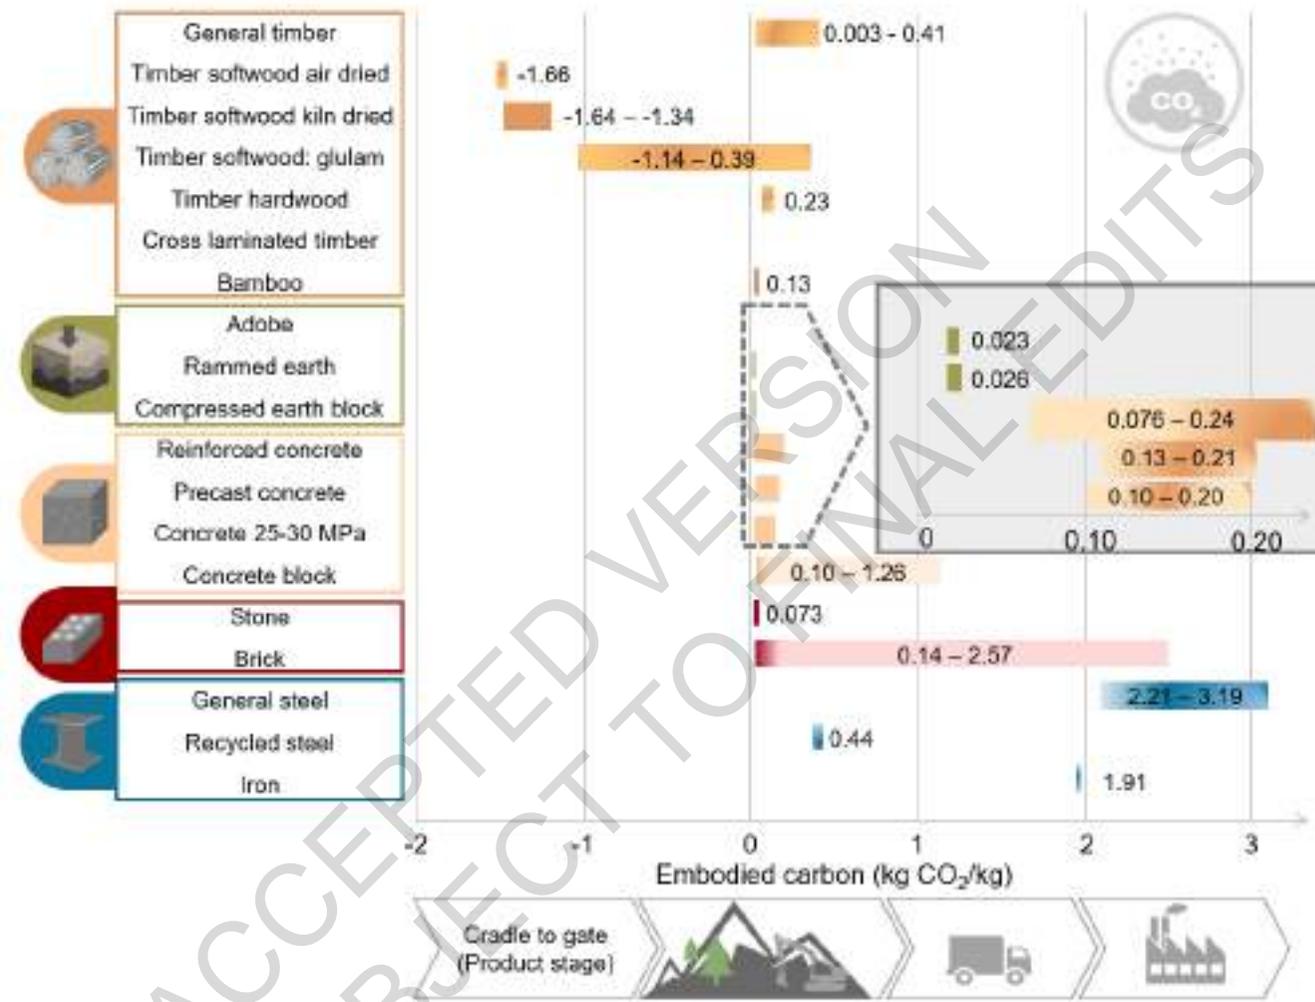

1 multiple dissimilar materials. Bamboo is a traditional building material throughout the world tropical
2 and sub-tropical regions. Rammed earth can be considered to be included in masonry construction, but
3 it is a structure very much used in developing countries and it is finding new interest in developed ones
4 (Cabeza et al. 2021).

5 The literature evaluating the embodied energy in building materials is extensive, but that considering
6 embodied carbon is much more scarce (Cabeza et al. 2021). Recently this evaluation is done using the
7 methodology life cycle assessment (LCA), but since the boundaries used in those studies are different,
8 varying for example, in the consideration of cradle to grave, cradle to gate, or cradle to cradle, the
9 comparison is very difficult (Moncaster et al. 2019). A summary of the embodied energy and embodied
10 carbon cradle to gate coefficients reported in the literature are found in Figure 9.9 (Alcorn and Wood
11 1998; Birgisdottir et al. 2017; Cabeza et al. 2013; De Wolf et al. 2016; Symons 2011; Moncaster and
12 Song 2012; Omrany et al. 2020; Pomponi and Moncaster 2016, 2018; Crawford and Treolar 2010;
13 Vukotic et al. 2010; Cabeza et al. 2021). Steel represents the materials with higher embodied energy,
14 32-35 MJ·kg⁻¹; embodied energy in masonry is higher than in concrete and earth materials, but
15 surprisingly, some type of wood have more embodied energy than expected; there are dispersion values
16 in the literature depending of the ma. On the other hand, earth materials and wood have the lowest
17 embodied carbon, with less than 0.01 kg CO₂ per kg of material (Cabeza et al. 2021). The concept of
18 buildings as carbon sinks raise from the idea that wood stores considerable quantities of carbon with a
19 relatively small ratio of carbon emissions to material volume and concrete has substantial embodied
20 carbon emissions with minimal carbon storage capacity (Churkina et al. 2020; Sanjuán et al. 2019).

Figure 9.9 Building materials (a) embodied energy and (b) embodied carbon (Cabeza et al. 2021).

1 9.4.2.2 Embodied emissions

2 Embodied emissions from production of materials are an important component of building sector
 3 emissions, and their share is likely to increase as emissions from building energy demand decrease
 4 (Röck et al. 2020). Embodied emissions trajectories can be lowered by limiting the amount of new floor
 5 area required (Berrill and Hertwich 2021; Fishman et al. 2021), and reducing the quantity and GHG
 6 intensity of materials through material efficiency measures such as lightweighting and improved
 7 building design, material substitution to lower-carbon alternatives, higher fabrication yields and scrap
 8 recovery during material production, and re-use or lifetime extension of building components (Allwood
 9 et al. 2011; Pamenter and Myers 2021; Churkina et al. 2020; Heeren et al. 2015b; Pauliuk et al. 2021;
 10 Hertwich et al. 2019). Reducing the GHG intensity of energy supply to material production activities
 11 also has a large influence on reducing overall embodied emissions. Figure 9.10 shows projections of
 12 embodied emissions to 2050 from residential buildings in a baseline scenario (SSP2 Baseline) and a
 13 scenario incorporating multiple material efficiency measures and a much faster decarbonization of
 14 energy supply (LED and 2°C policy) (Pauliuk et al. 2021). Embodied emissions are projected to be 32%
 15 lower in 2050 than 2020 in a baseline scenario, primarily due to a lower growth rate of building floor
 16 area per population. This is because the global population growth rate slows over the coming decades,
 17 leading to less demand for new floor area relative to total population. Further baseline reductions in
 18 embodied emissions between 2020 and 2050 derive from improvements in material production and a
 19 gradual decline in GHG intensity of energy supply. In a LED + 2°C policy scenario, 2050 embodied
 20 emissions are 86% lower than the Baseline. This reduction of 2050 emissions comes from contributions
 21 of comparable magnitude from three sources; slower floor area growth leading to less floor area of new
 22 construction per capita (sufficiency), reductions in the mass of materials required for each unit of newly
 23 built floor area (material efficiency), and reduction in the GHG intensity of material production, from
 24 material substitution to lower carbon materials, and faster transition of energy supply.

25 The attribution of changes in embodied emissions to changes in the drivers of population, sufficiency,
 26 material efficiency, and GHG intensity of material production is calculated using additive log-mean
 27 divisia index decomposition analysis (Ang and Zhang 2000). The decomposition of emissions into four
 28 driving factors is shown in Eq. 9.3, where m_{NC}^2 refers to floor area of new construction, kg_{Mat} refers to
 29 mass of materials used for new construction, and kg_{CO2e} refers to embodied GHG emissions in CO_{2e}.
 30 The allocation of changes in emissions between two cases k and $k-1$ to changes in a single driving factor
 31 D is shown in Eq. 9.4. For instance, to calculate changes in emissions due to population growth, D will
 32 take on the value of population in the two cases being compared. The superscript k stands for the time
 33 period and scenario of the emissions, e.g., SSP2 Baseline scenario in 2050. When decomposing
 34 emissions between two cases k and $k-1$, either the time period or the scenario stays constant. The
 35 decomposition is done for every region at the highest regional resolution available, and aggregation
 36 (e.g., to global level) is then done by summing over regions. For changes in emissions within a scenario
 37 over time (e.g., SSP Baseline emissions in 2020 and 2050), the decomposition is made for every decade,
 38 and the total 2020-2050 decomposition is then produced by summing decompositions of changes in
 39 emissions each decade.

40 Equation 9.3

$$41 \quad GHG_{emb}^k = Pop \times \frac{m_{NC}^2}{Pop} \times \frac{kg_{Mat}}{m_{NC}^2} \times \frac{kg_{CO2e}}{kg_{Mat}} = Pop \times Suff \times Eff \times Ren$$

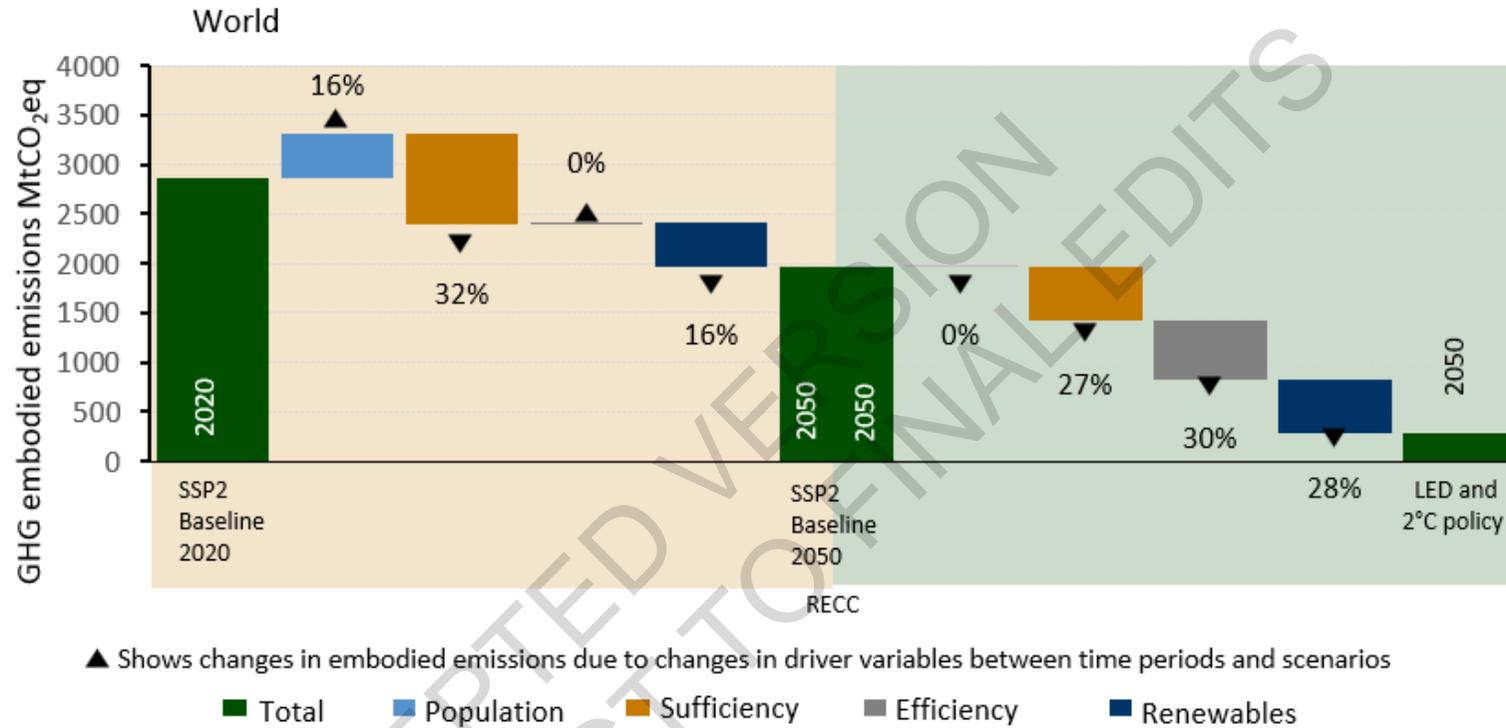

42 Equation 9.4

$$43 \quad \Delta GHG_{emb,D}^{k,k-1} = \frac{GHG_{emb}^k - GHG_{emb}^{k-1}}{\ln(GHG_{emb}^k) - \ln(GHG_{emb}^{k-1})} \times \ln\left(\frac{D^k}{D^{k-1}}\right)$$

2 **Figure 9.10** Decompositions of changes in residential embodied emissions projected by baseline scenarios for 2020-2050, and differences between scenarios in 2050
 3 using two scenarios from the RECC model. (a) Global resolution, and (b) for nine world regions. Emissions are decomposed based on changes in driver variables of
 4 population, sufficiency (floor area of new construction per capita), material efficiency (material production per floor area), and renewables (GHG emissions per
 5 unit material production). ‘Renewables’ is a summary term describing changes in GHG intensity of energy supply. Emission projections to 2050, and differences
 6 between scenarios in 2050, demonstrate mitigation potentials from the dimensions of the SER framework realised in each model scenario.

1 9.4.3 Technological developments since AR5

2 9.4.3.1 Overview of technological developments

3 There are many technologies that can reduce energy use in buildings (Finnegan et al. 2018; Kockat et
 4 al. 2018a), and those have been extensively investigated. Other technologies that can contribute to
 5 achieving carbon zero buildings are less present in the literature. Common technologies available to
 6 achieve zero energy buildings were summarized in (Cabeza and Chàfer 2020) and are presented in
 7 Tables SM9.1 to SM9.3 in detail, where Figure 9.11 shows a summary.

9 **Figure 9.11 Energy savings potential of technology strategies for climate change mitigation in buildings.**

 20 2019; Langevin et al. 2019; Cabeza and Chàfer 2020)

1 Other opportunities exist, such as building light-weighting or more efficient material production, use
2 and disposal (Hertwich et al. 2020), fast-growing biomass sources such as hemp, straw or flax as
3 insulation in renovation processes (Pittau et al. 2019), bamboo-based construction systems as an
4 alternative to conventional high-impact systems in tropical and subtropical climates (Zea Escamilla et
5 al. 2018). Earth architecture is still limited to a niche (Morel and Charef 2019). See also Cross-Chapter
6 Box 9 in Chapter 13 for carbon dioxide removal and its role in mitigation strategies.

7 **9.4.3.2 Appliances and lighting**

8 Electrical appliances have a significant contribution to household electricity consumption (Pothitou et
9 al. 2017). Ownership of appliances, the use of appliances, and the power demand of the appliances are
10 key contributors to domestic electricity consumption (Jones et al. 2015). The drivers in energy use of
11 appliances are the appliance type (e.g., refrigerators), number of households, number of appliances per
12 household, and energy used by each appliance (Cabeza et al. 2014)(Chu and Bowman 2006;
13 Spiliotopoulos 2019). At the same time, household energy-related behaviours are also a driver of energy
14 use of appliances (Khosla et al. 2019) (see Section 9.5). Although new technologies such as IoT linked
15 to the appliances increase flexibility to reduce peak loads and reduce energy demand (Berkeley et al.
16 2020), trends show that appliances account for an increasing amount of building energy consumption
17 (Figure 9.8). Appliances used in developed countries consume electricity and not fuels (fossil or
18 renewable), which often have a relatively high carbon footprint. The rapid increase in appliance
19 ownership (Cabeza et al. 2018b) can affect the electricity grid. Moreover, energy intensity improvement
20 in appliances such as refrigerators, washing machines, TVs, and computers has counteracted the
21 substantial increase in ownership and use since the year 2000 (International Energy Agency 2019b).

22 But appliances also are a significant opportunity for energy efficiency improvement. Research on
23 energy efficiency for different appliances worldwide showed that this research focused in different time
24 frames in different countries (Figure 9.12). This figure presents the number of occurrences of a term
25 (the name of a studied appliance) appearing per year and per country, according to the references
26 obtained from a Scopus search. The figure shows that most research carried out was after 2010. And
27 again, this figure shows that research is mostly carried out for refrigerators and for brown appliances
28 such as smart phones. Moreover, the research carried out worldwide is not only devoted to technological
29 aspects, but also to behavioural aspects and quality of service (such as digital television or smart
30 phones).

1
2

Figure 9.12 Energy efficiency in appliances research. Year and number of occurrences of different appliances in each studied country/territory.

1

2 Lighting energy accounts for around 19% of global electricity consumption (Attia et al. 2017; Enongene
3 et al. 2017; Baloch et al. 2018). Many studies have reported the correlation between the decrease in
4 energy consumption and the improvement of the energy efficiency of lighting appliances (Table 9.1).
5 Today, the new standards recommend the phase out of incandescent light bulbs, linear fluorescent
6 lamps, and halogen lamps and their substitution by more efficient technologies such as compact
7 fluorescent lighting (CFL) and light-emitting diodes (LEDs) (Figure 9.8). Due to the complexity of
8 these systems, simulation tools are used for the design and study of such systems, which can be
9 summarized in Baloch et al. 2018 (Baloch et al. 2018).

10 Single-phase induction motors are extensively used in residential appliances and other building low-
11 power applications. Conventional motors work with fixed speed regime directly fed from the grid,
12 giving unsatisfactory performance (low efficiency, poor power factor, and poor torque pulsation).
13 Variable speed control techniques improve the performance of such motors (Jannati et al. 2017).

14

16

17 Within the control strategies to improve energy efficiency in appliances, energy monitoring for energy
18 management has been extensively researched. Abubakar et al. 2017 (Abubakar et al. 2017) present a
19 review of those methods. The paper distinguishes between intrusive load monitoring (ILM), with
20 distributed sensing, and non-intrusive load monitoring (NILM), based on a single point sensing.

21

22

1

2 **9.4.4 Case studies**

3 **9.4.4.1 Warehouses**

4 Warehouses are major contributors to the rise of greenhouse gas emissions in supply chains (Bartolini
5 et al. 2019). The expanding e-commerce sector and the growing demand for mass customization have
6 even led to an increasing need for warehouse space and buildings, particularly for serving the
7 uninterrupted customer demand in the business-to-consumer market. Although warehouses are not
8 specifically designed to provide their inhabitants with comfort because they are mainly unoccupied, the
9 impact of their activities in the global GHG emissions is remarkable. Warehousing activities contribute
10 roughly 11% of the total GHG emissions generated by the logistics sector across the world. Following
11 this global trend, increasing attention to green and sustainable warehousing processes has led to many
12 new research results regarding management concepts, technologies, and equipment to reduce
13 warehouses carbon footprint, i.e., the total emissions of GHG in carbon equivalents directly caused by
14 warehouses activities.

15 **9.4.4.2 Historical and heritage buildings**

16 Historical buildings, defined as those built before 1945, are usually low-performance buildings by
17 definition from the space heating point of view and represent almost 30–40% of the whole building
18 stock in European countries (Cabeza et al. 2018a). Historical buildings often contribute to townscape
19 character, they create the urban spaces that are enjoyed by residents and attract tourist visitors. They
20 may be protected by law from alteration not only limited to their visual appearance preservation, but
21 also concerning materials and construction techniques to be integrated into original architectures. On
22 the other hand, a heritage building is a historical building which, for their immense value, is subject to
23 legal preservation. The integration of renewable energy systems in such buildings is more challenging
24 than in other buildings. The review carried out by (Cabeza et al. 2018a) different case studies are
25 presented and discussed, where heat pumps, solar energy and geothermal energy systems are integrated
26 in such buildings, after energy efficiency is considered.

27 **9.4.4.3 Positive energy or energy plus buildings**

28 The integration of energy generation on-site means further contribution of buildings towards
29 decarbonisation (Ürge-Vorsatz et al. 2020). Integration of renewables in buildings should always come
30 after maximising the reduction in the demand for energy services through sufficiency measures and
31 maximising efficiency improvement to reduce energy consumption, but the inclusion of energy
32 generation would mean a step forward to distributed energy systems with high contribution from
33 buildings, becoming prosumers (Sánchez Ramos et al. 2019). Decrease price of technologies such as
34 PV and the integration of energy storage (de Gracia and Cabeza 2015) are essential to achieve this
35 objective. Other technologies that could be used are photovoltaic/thermal (Sultan and Ervina Efzan
36 2018), solar/biomass hybrid systems (Zhang et al. 2020b), solar thermoelectric (Sarbu and Dorca 2018),
37 solar powered sorption systems for cooling (Shirazi et al. 2018), and on-site renewables with battery
38 storage (Liu et al. 2021).

39 **9.4.4.4 District energy networks**

40 District heating networks have evolved from systems where heat was produced by coal or waste and
41 storage was in the form of steam, to much higher energy efficiency networks with water or glycol as
42 the energy carrier and fuelled by a wide range of renewable and low carbon fuels. Common low carbon
43 fuels for district energy systems include biomass, other renewables (i.e., geothermal, PV, and large solar
44 thermal), industry surplus heat or power-to-heat concepts, and heat storage including seasonal heat
45 storage (Lund et al. 2018). District energy infrastructure opens opportunities for integration of several
46 heat and power sources and is 'future proof' in the sense that the energy source can easily be converted
47 or upgraded in the future, with heat distributed through the existing district energy network. Latest
48 developments include the inclusion of smart control and AI (Revesz et al. 2020), and low temperature

1 thermal energy districts. Authors show carbon emissions reduction up to 80% compared to the use of
2 gas boilers.

3

4 **9.4.5 Low- and net zero energy buildings – exemplary buildings**

5 Nearly zero energy (NZE) buildings or low-energy buildings are possible in all world relevant climate
6 zones (Mata et al. 2020b; Ürge-Vorsatz et al. 2020) (Figure 9.13). Moreover, they are possible both for
7 new and retrofitted buildings. Different envelope design and technologies are needed, depending on the
8 climate and the building shape and orientation. For example, using the Passive House standard an annual
9 heating and cooling energy demand decrease between 75% and 95% compared to conventional values
10 can be achieved. Table 9.2 lists several exemplary low- and NZE-buildings with some of their feature.

11

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

2 **9.5 Non-technological and behavioural mitigation options and strategies**

3 Non-technological (NT) measures are key for low-carbon buildings, but still attract less attention than
4 technological measures (Ruparathna et al. 2016; Vence and Pereira 2019; Cabeza et al. 2020; Creutzig
5 et al. 2016; Mundaca et al. 2019; Mata et al. 2021b)(Creutzig et al. 2018). The section is set out to
6 understand, over the buildings lifecycle, NT determinants of buildings' energy demand and emissions
7 (Section 9.5.1); to present NT climate mitigation actions (Section 9.5.2); then, to understand how to get
8 these actions implemented (Section 9.5.3). The latter is a starting point in the design of policies (Section
9 9.9).

10 **9.5.1 Non-technological determinants of energy demand and carbon emissions**

11 Buildings climate impact includes CO₂ emissions from operational energy use, carbon footprint, PM_{2.5}
12 concentrations and embodied carbon, and is unequivocally driven by GDP, income, population,
13 buildings floor area, energy price, climate, behaviour, and social and physical environment (Wolske et
14 al. 2020; Mata et al. 2021d).

15 **9.5.1.1 Climate and physical environment**

16 Outdoor temperature, Heating and Cooling Degree Days, sunshine hours, rainfall, humidity and wind
17 are highly determinant of energy demand (Harold et al. 2015; Rosenberg 2014; Lindberg et al. 2019;
18 Risch and Salmon 2017)(Tol et al. 2012). Density, compacity, and spatial effects define the surrounding
19 environment and urban microclimate. Urban residents usually have a relatively affluent lifestyle, but
20 use less energy for heating (Huang 2015; Niu et al. 2012; Rafiee et al. 2019; Ayoub 2019; Oh and Kim
21 2019). Urbanization is discussed in Chapter 8.

22 Climate variability and extreme events may drastically increase peak and annual energy consumption
23 (Mashhoodi et al. 2019; Cui et al. 2017; Hong et al. 2013). Climate change effects on future demand
24 and emissions, are discussed in Section 9.7, and effects of temperature on health and productivity, in
25 Section 9.8.

26 **9.5.1.2 Characteristics of the building**

27 Building typology and floor area (or e.g. number of bedrooms or lot size) are correlated to energy
28 demand (Fosas et al. 2018; Morganti et al. 2019; Manzano-Agugliaro et al. 2015; Moura et al. 2015;
29 Berrill et al. 2021). Affluence is embedded in these variables as higher-income households have larger
30 homes and lots. Residential consumption increases with the number of occupants but consumption per
31 capita decreases proportionally to it (Serrano et al. 2017). Construction or renovation year has a negative
32 correlation as recently built buildings must comply with increasingly strict standards (Brounen et al.
33 2012; Kavousian et al. 2015; Österbring et al. 2016). Only for electricity consumption no significant
34 correlation is observed to building age (Kavousian et al. 2013). Material choices, bioclimatic and
35 circular design discussed in Section 9.4.2.

36 **9.5.1.3 Socio-demographic factors**

37 Income is positively correlated to energy demand (Singh et al. 2017; Bissiri et al. 2019; Sreekanth et al.
38 2011; Couture et al. 2012; Yu 2017; Moura et al. 2015; Mata et al. 2021b; Cayla et al. 2011). High-
39 income households tend to use more efficient appliances and are likely to be more educated and
40 environmentally sensitive, but their higher living standards require more energy (Hidalgo et al. 2018;
41 Harold et al. 2015). Low-income households are in higher risk of fuel poverty (Section 9.8).

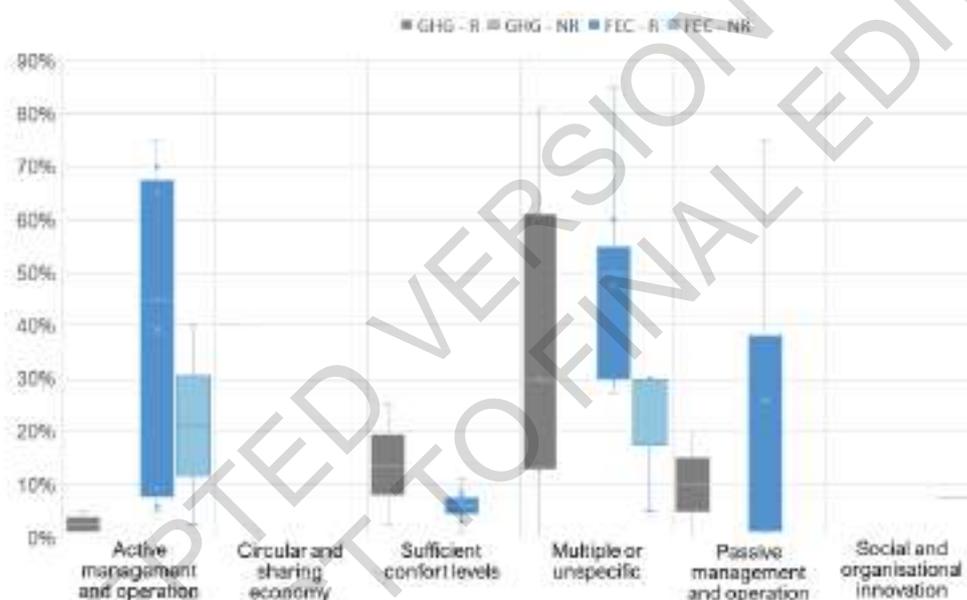

42 Mixed effects are found for household size, age, gender, ethnicity, education levels and tenancy status
43 (Engvall et al. 2014; Arawomo 2019; Lévy and Belaïd 2018; Hansen 2016; Rafiee et al. 2019). Single-
44 parent and elderly households consume more gas and electricity, and gender has no significant effect
45 (Harold et al. 2015; Brounen et al. 2012; Huang 2015). Similarly, larger families use less electricity per
46 capita (Bedir et al. 2013; Kavousian et al. 2013). Heating expenditure tends to be higher for owners
47 than for renters, despite the formers tendency to have more efficient appliances (Gillingham et al. 2012;
48 Davis, 2012; Kavousian et al. 2015).

1 9.5.1.4 Behaviour

2 Occupants presence and movement, interactions with the building, comfort-driven adaptations and
 3 cultural practices determine energy consumption (Li et al. 2019; Khosla et al. 2019; D'Oca et al. 2018;
 4 Hong et al. 2017; O'Brien et al. 2020; Yan et al. 2017). Households consume more on weekends and
 5 public holidays, and households with employed occupants consume less than self-employed occupants,
 6 probably because some of the latter jobs are in-house (Harold et al. 2015; Hidalgo et al. 2018).
 7 Understanding and accurate modelling of occupant behaviour is crucial to reduce the gap between
 8 design and energy performance (Gunay et al. 2013; Yan et al. 2017), especially for more efficient
 9 buildings, which rely on passive design features, human-centred technologies, and occupant
 10 engagement (Grove-Smith et al. 2018; Pitts 2017).

11 9.5.2 Insights from non-technological and behavioural interventions

12 A range of NT actions can substantially reduce buildings energy demand and emissions (Figure 9.14;
 13 see Supplementary Material SM9.2 for details). The subsections below present insights on the variations
 14 depending on the solution, subsector, and region.

15
 16 **Figure 9.14 Energy saving and GHG mitigation potentials for categories of NT interventions for**
 17 **Residential (R) and Non-Residential (NR) buildings, from studies with worldwide coverage.**

18 Sources: (Ruparathna et al. 2016b; Khosrowpour et al. 2016; Kaminska 2019; Creutzig et al. 2016; Wilson et al.
 19 2020b; Derungs et al. 2019; Levesque et al. 2019a; Bierwirth and Thomas 2019b; Roussac and Bright 2012;
 20 Ohueri et al. 2018; Bavaresco et al. 2020; Ahl et al. 2019; Van Den Wymelenberg 2012; Cantzler et al. 2020;
 21 Ivanova and Büchs 2020b; Harris et al. 2021a; van Sluisveld et al. 2016; Rupp et al. 2015; Grover 2019).

22 9.5.2.1 Passive and active design, management, and operation

23 Bioclimatic design and passive strategies for natural heating, cooling and lighting, can greatly reduce
 24 buildings' climate impact, and avoid cooling in developing countries (Bienvenido-Huertas et al. 2021,
 25 2020; Amirifard et al. 2019). Design can provide additional small savings, e.g., by placing refrigerator
 26 away from the oven, radiators or windows (Christidou et al. 2014). Passive management refers to
 27 adjustments in human behaviour such as adapted clothing, allocation of activities in the rooms of the
 28 building to minimize the energy use (Rafsanjani et al. 2015; Klein et al. 2012) or manual operation of
 29 the building envelope (Rijal et al. 2012; Volochovic et al. 2012). Quantitative modelling of such

1 measures is most common for non-residential buildings, in which adaptive behaviours are affected by
2 the office space distribution and interior design, amount of occupants, visual comfort, outdoor view,
3 and ease to use control mechanisms (Talele et al. 2018; O'Brien and Gunay 2014). Socio demographic
4 factors, personal characteristics and contextual factors also influence occupant behaviour and their
5 interactions with buildings (D'Oca et al. 2018b; Hong et al. 2020).

6 Active management refers to human control of building energy systems. Efficient lighting practices can
7 effectively reduce summer peak demand (Dixon et al. 2015; Taniguchi et al. 2016). On the contrary,
8 the application of the Daylight-Saving Time in the US increases up to 7% lighting consumption (Rakha
9 et al. 2018). Efficient cooking practices for cooking, appliance use (e.g. avoid stand-by regime, select
10 eco-mode), or for hot water can save up to 25% (Teng et al. 2012; Berezan et al. 2013; Hsiao et al.
11 2014; Abrahamse and Steg 2013; Peschiera and Taylor 2012; Dixon et al. 2015; Reichert et al. 2016).
12 High behavioural control is so far proven difficult to achieve (Ayoub et al. 2014) (Sköld et al. 2018).
13 Automated controls and technical measures to trigger occupant operations are addressed in Section 9.4.

14 **9.5.2.2 Limited demands for services**

15 Adjustment in the set-point temperature in winter and summer results in savings between 5% and 25%
16 (Ayoub et al. 2014)(Christidou et al. 2014; Sun and Hong 2017; Taniguchi et al. 2016). As introduced
17 in 9.3, a series of recent works study a cap on the living area (Mata et al. 2021a) or an increase in
18 household size (Berrill et al. 2021). These studies are promising but of limited complexity in terms of
19 rebounds, interactions with other measures, and business models, thus require further investigation.
20 Professional assistance and training on these issues is limited (Maxwell et al. 2018).

21 Willingness to adopt is found for certain measures (full load to laundry appliances, lid on while cooking,
22 turning lights off, defer electricity usage and HVAC systems, adjust set-point temperature by 1°C) but
23 not for others (appliances on standby, using more clothes, avoid leaving the TV on while doing other
24 things, defer ovens, ironing or heating systems, adjust set-point temperature by 3°C, move to a low
25 energy house or smaller apartment) (Brown et al. 2013; Sköld et al. 2018; Yohanis 2012; Li et al. 2017).
26 A positive synergy with digitalization and smart home appliances is identified, driven by a combination
27 of comfort requirements and economic interest, confirmed by a willingness to defer electricity usage in
28 exchange for cost savings (Ferreira et al. 2018; Mata et al. 2020c).

29 **9.5.2.3 Flexibility of demand and comfort requirements**

30 In a flexible behaviour, the desired level of service is the same, but it can be shifted over time, typically
31 allowing automated control, for the benefit of the electricity or district heating networks. There are
32 substantial economic, technical, and behavioural benefits from implementing flexibility measures
33 (Mata et al. 2020c), with unknown social impacts.

34 With demand side measures (DSM), such as shifting demand a few hours, peak net demand can be
35 reduced up to 10-20% (Stötzer et al. 2015), a similar potential is available for short-term load shifting
36 during evening hours (Aryandoust and Lilliestam 2017). Although different household types show
37 different consumption patterns and thus an individual availability of DSM capacity during the day (
38 Fischer et al. 2017), there is limited (Shivakumar et al. 2018) or inexistent (Nilsson et al. 2017; Drysdale
39 et al. 2015) information of consumers response to Time of Use pricing, specifically among those living
40 in apartments (Bartusch and Alvehag 2014). Behavioural benefits are identified in terms of increased
41 level of energy awareness of the users (Rehm et al. 2018), measured deliberate attempts of the
42 consumers to reduce and/or shift their electricity usage (Bradley et al. 2016). Real-time control and
43 behavioural change influence 40% of the electricity use during operational life of non-residential
44 buildings (Kamilaris et al. 2014).

45 **9.5.2.4 Circular and sharing economy (CSE)**

46 Non technological CSE solutions, based on the Regenerate, Share, Optimize, Loop, Virtualize,
47 Exchange (ReSOLVE) framework (CE100 2016; ARUP 2018) include sharing, virtualizing and

1 exchanging. These are less studied than circular materials, with notably less investigation of existing
2 buildings and sharing solutions (Pomponi and Moncaster 2017; Høiby and Sand 2018; Kyrö 2020;
3 European Commission 2020).

4 The sharing economy generates an increased utilization rate of products or systems by enabling or
5 offering shared use, access or ownership of products and assets that have a low ownership or use rate.
6 Measures include conditioned spaces (accommodation, facility rooms, offices) as well as tools and
7 transfer of ownership (i.e., second-hand or donation) (Rademaekers et al. 2017; Harris et al. 2021;
8 Mercado 2018; Hertwich et al. 2020; Cantzler et al. 2020; Mata et al. 2021c). The evidence on the link
9 between user behaviour and net environmental impacts of sharing options is still limited (Laurenti et al.
10 2019; Mata et al. 2020a; Harris et al. 2021b) and even begins to be questioned, due to rebounds that
11 partially or fully offset the benefits (Agrawal and Bellos 2017; Zink and Geyer 2017). E.g., the costs
12 savings from reduced ownership can be allocated to activities with a higher carbon intensity, or result
13 in increased mobility. Both reduced ownership and other circular consumption habits show no influence
14 on material footprint, other than mildly positive influence in low-income households (Junnila et al.
15 2018; Ottelin et al. 2020).

16 **9.5.2.5 Value-chain, social and institutional innovations**

17 Cooperative efforts are necessary to improve buildings energy efficiency (Masuda and Claridge 2014;
18 Kamilaris et al. 2014; Ruparathna et al. 2016). For instance, inter-disciplinary understanding of
19 organizational culture, occupant behaviour, and technology adoption is required to set up
20 occupancy/operation best practises (Janda 2014). Similarly, close collaboration of all actors along the
21 value chain can reduce by 50% emissions from concrete use (Habert et al. 2020); such collaboration
22 can be enhanced in a construction project by transforming the project organisation and delivery contract
23 to reduce costs and environmental impact (Hall and Bonanomi 2021). Building commissioning helps to
24 reduce energy consumption by streamlining the systems, but benefits may not persistent. Energy
25 communities are discussed later in the chapter.

26 NT challenges include training and software costs (tailored learning programs, learning-by-doing,
27 human capital mobilization), client and market demand (service specification, design and provision;
28 market and financial analysis) and legal issues (volatile energy prices, meeting regulation); and
29 partnership, governance and commercialization. These challenges are identified for Building
30 Information Modelling (Rahman and Ayer 2019; Oduyemi et al. 2017), PV industry (Triana et al. 2018),
31 Smart Living (Solaimani et al. 2015) or circular economy (Vence and Pereira 2019).

32 **9.5.3 Adoption of climate mitigation solutions– reasons and willingness**

33 Mixed effects are found for technical issues, attitudes, and values (Table 9.3). In spite of proven positive
34 environmental attitudes and willingness to adopt mitigation solutions, these are outweighed by financial
35 aspects all over the world (Mata et al. 2021b). Adopters in developed countries are more sensitive
36 towards financial issues and comfort disruptions; whereas in other world regions techno-economic
37 concerns prevail. Private consumers seem ready to support stronger governmental action, whereas non-
38 private interventions are hindered by constraints in budgets and profits, institutional barriers and
39 complexities (Curtis et al. 2017; Zuhair et al. 2017; Tsoka et al. 2018; Kim et al. 2019).

40 A variety of interventions targeted to heterogeneous consumer groups and decision makers is needed to
41 fulfil their diverse needs (Zhang et al. 2012; Liang et al. 2017; Soland et al. 2018; Marshall et al. 2015;
42 Haines and Mitchell 2014; Gram-Hanssen 2014; Friege et al. 2016; Hache et al. 2017; Ketchman et al.
43 2018). Policy reviews for specific market segments and empirical studies investigating investment
44 decisions would benefit from a multidisciplinary approach to energy consumption patterns and market
45 maturity (Boyd 2016; Marzano et al. 2018; Heiskanen and Matschoss 2017; Baumhof et al. 2018;
46 Wilson et al. 2018).

1 **Table 9.3 Reasons for adoption of climate mitigation solutions. The sign represents if the effect is positive**
 2 **(+) or negative (-), and the number of signs represents confidence level (++, many references; +, few**
 3 **references) (Mata et al. 2021a)**

		Climate mitigation solutions for buildings							
		Building envelope	Efficient technical systems	On-site renewable energy	Behaviour	Performance standards	Low-carbon materials	Digitalization and flexibility	Circular and sharing econ.

1

2 **9.5.3.1 Building envelope**

3 In North America and Europe, personal attitudes, values, and existing information and support are the
4 most and equally important reasons for improving the building envelope. Consumers have some
5 economic concerns and little technical concerns, the later related to the performance and maintenance
6 of the installed solutions (Mata et al, 2021c). In other world regions or per climate zone the literature is
7 limited.

8 Motivations are often triggered by urgent comfort or replacement needs. Maintaining the aesthetic value
9 may as well hinder the installation of insulation if no technical solutions are easily available (Haines
10 and Mitchell 2014; Bright et al. 2019). Local professionals and practitioners can both encourage
11 (Ozarisoy and Altan 2017; Friege 2016) and discourage the installation of insulation, according to their
12 knowledge and training (Maxwell et al. 2018; Curtis et al. 2017; Zuhaib et al. 2017; Tsoka et al. 2018).
13 If energy renovations of the buildings envelopes are not normative, cooperative ownership may be a
14 barrier in apartment buildings (Miezis et al. 2016). Similarly, product information and labelling may be
15 helpful or overwhelming (Ozarisoy and Altan 2017; Lilley et al. 2017; Bright et al. 2019). Decisions
16 are correlated to governmental support (Tam et al. 2016; Swantje et al. 2015) and peer information
17 (Friege et al. 2016; Friege 2016).

18 The intervention is required to be cost efficient, although value could be placed in the amount of energy
19 saved (Mortensen et al. 2016; Howarth and Roberts 2018; Kim et al. 2019; Lilley et al. 2017) or the
20 short payback period (Miezis et al. 2016). Subsidies have a positive effect (Swan et al. 2017).

21 **9.5.3.2 Adoption of efficient HVAC systems and appliances**

22 Mixed willingness is found to adopt efficient technologies. While developed countries are positive
23 towards building envelope technologies, appliances such as A-rated equipment or condensing boilers
24 are negatively perceived (Yohanis 2012). In contrast, adopters in Asia are positive towards energy
25 saving appliances (Liao et al. 2020; Spandagos et al. 2020).

26 Comfort, economic and ecological aspects, as well as information influence the purchase of a heating
27 system (Decker and Menrad 2015; Claudy et al. 2011). Information and support from different
28 stakeholders are the most relevant aspects in different geographical contexts (Tumbaz and Moğulkoç
29 2018; Hernandez-Roman et al. 2017; Curtis et al. 2018; Bright et al. 2019; Chu and Wang 2019).

30 Among high-income countries, economy aspects have positive effects, specially reductions in energy
31 bills and financial incentives or subsidies (Mortensen et al. 2016; Clancy et al. 2017; Christidou et al.
32 2014; Chun and Jiang 2013; Ketchman et al. 2018). Having complementary technologies already in
33 place also has positively affects adoption (Zografakis et al. 2012; Clancy et al. 2017), but performance
34 and maintenance concerns appear as barriers (Qiu et al. 2014). The solutions are positively perceived
35 as high-technology innovative, to enhance status, and are supported by peers and own-environmental
36 values (Ketchman et al. 2018; Mortensen et al. 2016; Heiskanen and Matschoss 2017).

37 **9.5.3.3 Installation of renewable energy sources (RES)**

38 Although consumers are willing to install distributed RES worldwide, and information has successfully
39 supported their roll out, economic and governmental support is still necessary for their full deployment.
40 Technical issues remain for either very novel technologies or for the integration of RES in the energy
41 system (Mata et al. 2021c; Üрге-Vorsatz et al. 2020). Capacities are to be built by coordinated actions
42 by all stakeholders (Musonye et al. 2020). To this aim, energy communities and demonstrative
43 interventions at local scale are key to address technical, financial, regulatory and structural barriers and
44 document long-term benefits (von Wirth et al. 2018; Shafique M Luo J 2020, Fouladvand et al. 2020).

1 Regarding solar technologies, heterogeneous decisions are formed by sociodemographic, economic and
2 technical predictors interwoven with a variety of behavioural traits (Alipour M Salim RA Sahin, O
3 2020; Khan 2020). Studies on PV adoption confirm place-specific (various spatial and peer effects),
4 multi-scalar cultural dynamics (Schaffer and Brun 2015; Bollinger and Gillingham 2012; Graziano and
5 Gillingham 2015). Environmental concern and technophilia drive the earliest PV adopters, while later
6 adopters value economic gains (Hampton and Eckermann 2013; Jager-Waldau et al. 2018; Abreu et al.
7 2019; Palm 2020). Previous experience with similar solutions increases adoption (Bach et al. 2020; K
8 2018; QURAIISHI and AHMED 2019; Reindl and Palm 2020).

9 **9.5.3.4 Low-carbon materials**

10 Studies on low-carbon materials tend to focus on wood-based building systems and prefabricated
11 housing construction, mostly in high-income countries, as many sustainable managed forestries and
12 factories for prefabricated housing concentrated in such regions (Mata et al, 2021c). This uneven
13 promotion of wood can lead to its overconsumption (Pomponi et al. 2020).

14 Although the solutions are not yet implemented at scale, examples include, the adoption of low carbon
15 cement in Cuba motivated by the possibility of supplying the raising demand with low initial investment
16 costs (Cancio Díaz et al. 2017) or adoption of bamboo based social houses in Philippines motivated by
17 local job creation and Typhoon resistance (Zea Escamilla et al. 2016). More generally, low investment
18 costs and high level decision-making, e.g. political will and environmental values of society, increase
19 the adoption rate of low-carbon materials (Steinhardt and Manley 2016; Lien and Lolli 2019; Hertwich
20 et al. 2020). In contrast, observed barriers include lobbying by traditional materials industries, short-
21 term political decision making (Tozer 2019) and concerns over technical performance, risk of damage,
22 and limited alternatives available (Thomas et al. 2014).

23 **9.5.3.5 Digitalization and demand-supply flexibility**

24 Demand-supply flexibility measures are experimentally being adopted in North America, Europe, and
25 Asia-Pacific Developed regions. Changes in the current regulatory framework would facilitate
26 participation based on trust and transparent communication (Wolsink 2012; Nyborg and Røpke 2013;
27 Mata et al. 2020b). However, consumers expect governments and energy utilities to steer the transition
28 (Seidl et al. 2019).

29 Economic challenges are observed, as unclear business models, disadvantageous market models and
30 high costs of advanced smart metering. Technical challenges include constraints for HPs and seasonality
31 of space heating demands. Social challenges relate to lack of awareness of real-time price information
32 and inadequate technical understanding. Consumers lack acceptance towards comfort changes (noise,
33 overnight heating) and increased automation (Sweetnam et al. 2019; Bradley et al. 2016; Drysdale et
34 al. 2015). Risks identified include higher peaks and congestions in low price-hours, difficulties in
35 designing electricity tariffs because of conflicts with CO₂ intensity, and potential instability in the entire
36 electricity system caused by tariffs coupling to wholesale electricity pricing.

37 Emerging market players are changing customer utility relationships, as the grid is challenged with
38 intermittent loads and integration needs for ICTs, interfering with consumers requirements of autonomy
39 and privacy (Parag and Sovacool 2016; Wolsink 2012). Although most private PV owners would make
40 their storage system available as balancing load for the grid operator, the acquisition of new batteries
41 by a majority of consumers requires incentives (Gähns et al. 2015). For distributed energy hubs, social
42 acceptance depends on the amount of local benefits in economic, environmental or social terms
43 (Kalkbrenner and Roosen 2015), and increases around demonstration projects (von Wirth et al. 2018).

44 **9.5.3.6 Circular and sharing economy**

45 The circular and sharing economy begins to be perceived as organizational and technologically
46 innovative, with the potential to provide superior customer value, response to societal trends and

1 positive marketing (Mercado 2018; Cantzler et al. 2020; L.K et al. 2020). Although technical and
2 regulatory challenges remain, there are key difficulties around the demonstration of a business case for
3 both consumers and the supply chain (Pomponi and Moncaster 2017; Hart et al. 2019).

4 Government support is needed an initiator but also to reinforce building retrofit targets, promote more
5 stringent energy and material standards for new constructions, and protect consumer interests
6 (Hongping 2017; Fischer and Pascucci 2017; Patwa et al. 2020). Taxes clearly incentivize waste
7 reduction and recycling (Ajayi et al. 2015; Rachel and Travis 2011; Volk et al. 2019). In developing
8 countries, broader, international, market boundaries can allow for a more attractive business model
9 (Mohit et al. 2020). Participative and new ownership models can favour the adoption of prefabricated
10 buildings (Steinhardt and Manley 2016). Needs for improvements are observed, in terms of design for
11 flexibility and deconstruction, procurement and prefabrication and off-site construction, standardization
12 and dimensional coordination, with differences among solutions (Ajayi et al. 2017)(Schiller et al,
13 2015,2017; Osmani, 2012; Lu and Yuan, 2013; Cossu and Williams, 2015; Bakshan et al 2017; Coehlo
14 et al 2013).

15 Although training is a basic requirement, attitude, past experience, and social pressure can also be highly
16 relevant, as illustrated for waste management in a survey to construction site workers (Amal et al. 2017).
17 Traditional community practices of reuse of building elements are observed to be replaced by a culture
18 of waste (Hongping 2017; Ajayi et al. 2015).

19 20 **9.6 Global and regional mitigation potentials and costs**

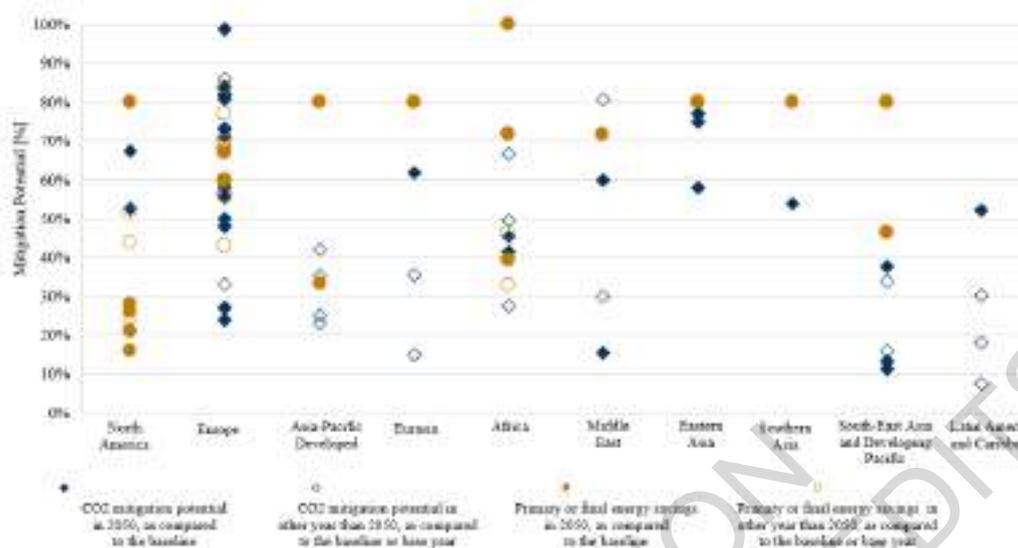

21 **9.6.1 Review of literature calculating potentials for different world countries**

22 Section 9.4 provides an update on technological options and practices, which allow constructing and
23 retrofitting individual buildings to produce very low emissions during their operation phase. Since AR5,
24 the world has seen a growing number of such buildings in all populated continents, and a growing
25 amount of literature calculates the mitigation potential for different countries if such technologies and
26 practices penetrate at scale. Figure 9.15 synthesizes the results of sixty-seven bottom-up studies, which
27 rely on the bottom-up technology-reach approach and assess the potential of such technologies and
28 practices, aggregated to stock of corresponding products and/or buildings at national level.

29 The studies presented in Figure 9.15 rely on all, the combination, or either of the following mitigation
30 strategies: the construction of new high energy-performance buildings taking the advantage of building
31 design, forms, and passive construction methods; the thermal efficiency improvement of building
32 envelopes of the existing stock; the installation of advanced HVAC systems, equipment and appliances;
33 the exchange of lights, appliances, and office equipment, including ICT, water heating, and cooking
34 with their efficient options; demand side management, most often controlling comfort requirements and
35 demand-side flexibility and digitalization; as well as onsite production and use of renewable energy.
36 Nearly all studies, which assess the technological potential assume such usage of space heating, cooling,
37 water heating, and lighting that does not exceed health, living, and working standards, thus realizing at
38 least a part of the non-technological potential, as presented in Figure 9.14. The results presented in
39 Figure 9.15 relate to measures applied within the boundaries of the building sector, including the
40 reduction in direct and indirect emissions. The results exclude the impact of decarbonisation measures
41 applied within the boundaries of the energy supply sector, i.e., the decarbonisation of grid electricity
42 and district heat.

43 The analysis of Figure 9.15 illustrates that there is a large body of literature attesting to mitigation
44 potential in the countries of Europe and North America of up to 55-85% and in Asia-Pacific Developed
45 of up to 45% in 2050, as compared to their sector baseline emissions, even though they sometimes
46 decline. For developing countries, the literature estimates the potential of up to 40-80% in 2050, as

1 compared to their sharply growing baselines. The interpretation of these estimates should be cautious
 2 because the studies rely on assumptions with uncertainties and feasibility constrains (see Sections 9.6.4,
 3 Figure 9.20 and Table SM9.6).

4

 12 Union (Roscini et al. 2020; Brugger et al. 2021; Duscha et al. 2019), Germany (Markewitz et al. 2015; Bürger
 13 et al. 2019; Ostermeyer et al. 2019b), Greece (Mirasgedis et al. 2017), Italy (Calise et al. 2021; Filippi Oberegger
 14 et al. 2020), Lithuania (Toleikyte et al. 2018), Montenegro (Novikova et al. 2018c), Netherlands (Ostermeyer et
 15 al. 2018a), Norway (Sandberg et al. 2021), Serbia (Novikova et al. 2018a), Switzerland (Iten et al. 2017;
 16 Streicher et al. 2017), Poland (Ostermeyer et al. 2019a), the United Kingdom (Ostermeyer, Y.; Camarasa, C.;
 17 Naegeli, C.; Saraf, S.; Jakob, M.; Hamilton, I. Catenazzi 2018a); Eurasia: Armenia, Georgia (Timilsina et al.
 18 2016); the Russian Federation (Bashmakov 2017; Zhang et al. 2020a); Asia-Pacific Developed: Australia
 19 (Butler et al. 2020; Energetics 2016; Zhang et al. 2020a), Japan (Zhang et al. 2020a; Momonoki et al. 2017;
 20 Wakiyama and Kuramochi 2017; Sugiyama et al. 2020; Minami et al. 2019); Africa: Egypt (Pedzi Makumbe,
 21 Manuela Mot, Marwa Moustafa Khalil 2017; Calise et al. 2021), Morocco (Merini et al. 2020), Nigeria (Dioha
 22 et al. 2019; Kwag et al. 2019; Onyenokporo and Ochedi 2019), Rwanda (Colenbrander et al. 2019), South
 23 Africa (Department of Environmental Affairs 2014), Uganda (de la Rue du Can et al. 2018), Algeria, Egypt,
 24 Libya, Morocco, Sudan, Tunisia (Krarti 2019); Middle East - Qatar (Krarti et al. 2017; Kamal et al. 2019),
 25 Saudi Arabia (Khan et al. 2017; Alaidroos and Krarti 2015), Bahrain, Iraq, Jordan, Kuwait, Lebanon, Oman,
 26 Qatar, Saudi Arabia, State of Palestine, Syrian Arab Republic, United Arab Emirates, Yemen (Krarti 2019);
 27 Eastern Asia - China (Tan et al. 2018; Xing et al. 2021; Zhou et al. 2018; Zhang et al. 2020); Southern Asia:
 28 India (de la Rue du Can et al. 2019; Yu et al. 2018; Zhang et al. 2020); South-East Asia and Developing Pacific:
 29 Indonesia (Kusumadewi and Limmeechokchai 2015, 2017), Thailand (Kusumadewi and Limmeechokchai 2015,
 30 2017; Chaichaloempreecha et al. 2017), Viet Nam (ADB 2017), respective countries from the Asia-Pacific
 31 Economic Cooperation (APEC) (Zhang et al. 2020a); Latin America and Caribbean: Brazil (de Melo and de
 32 Martino Jannuzzi 2015; González-Mahecha et al. 2019), Colombia (Prada-hernández et al. 2015), Mexico
 33 (Grande-acosta and Islas-samperio 2020; Rosas-Flores and Rosas-Flores 2020).

34 The novelty since AR5 is emerging bottom-up literature, which attempts to account for potential at
 35 national and global level from applying the sufficiency approach (see Box 9.1 in Section 9.1 and
 36 decomposition analysis in Section 9.3.2). In spite of the reducing energy use per unit of floor area at

1 an average rate of 1.3% per year, the growth of floor area at an average rate of 3% per year causes rising
 2 energy demand and GHG emissions because each new square meter must be served with thermal
 3 comfort and/or other amenities (International Energy Agency 2017; Ellsworth-Krebs 2020). Nearly all
 4 studies reviewed in Figure 9.15 assume the further growth of floor area per capita until 2050, with many
 5 studies of developing countries targeting today per capita floor area as in Europe.

6 Table 9.4 reviews the bottom-up literature, which quantifies the potential from reorganization of human
 7 activities, efficient design, planning, and use of building space, higher density of building and settlement
 8 inhabitancy, redefining and downsizing goods and equipment, limiting their use to health, living, and
 9 working standards, and their sharing, recognizing the number of square meters and devices as a
 10 determinant of GHG emissions that could be impacted via policies and measures. Nearly all national or
 11 regional studies originate from Europe and North America recognizing challenges, developed countries
 12 face toward decarbonisation. Thus, (Goldstein et al. 2020) suggested prioritizing the reduction in floor
 13 space of wealthier population and more efficient space planning because grid decarbonisation is not
 14 enough to meet the U.S. target by 2050 whereas affluent suburbs may have 15 times higher emission
 15 footprints than nearby neighbourhoods. (Cabrera Serrenho et al. 2019) argue that reducing the UK floor
 16 area is a low cost mitigation option given a low building replacement rate and unreasonably high retrofit
 17 costs of existing buildings. (Lorek and Spangenberg 2019) discusses the opportunity of reducing
 18 building emissions in Germany fitting better the structure of the dwelling stock to the declined average
 19 household size, as most dwellings have 3–4 rooms while most households have only one person.

20 Whereas these studies suggest sufficiency as an important option for developed countries, global studies
 21 argue that it is also important for the developing world. This is because it provides the means to address
 22 inequality, poverty reduction and social inclusion, ensuring the provision of acceptable living standards
 23 for the entire global population given the planetary boundaries. As Figure 9.6 illustrates, the largest
 24 share of current construction occurs in developing countries, while these countries follow a similar
 25 demographic track of declining household sizes versus increasing dwelling areas. This trajectory
 26 translates into the importance of their awareness of the likely similar forthcoming challenges, and the
 27 need in early efficient planning of infrastructure and buildings with a focus on space usage and density.

28
 29 **Table 9.4 Potential GHG emission reduction in the building sector offered by the introduction of**
 30 **sufficiency as a main or additional measure, as reported by bottom-up (or hybrid) literature**

Region	Reference	Scenario and its result	Sufficiency for floor space
Globe	(Grubler et al. 2018)	The Low Energy Demand Scenario halves the final energy demand of buildings by 2050, as compared the WEO Current Policy (International Energy Agency 2019c) by modelling the changes in quantity, types, and energy intensity of services.	The scenario assumed a reduction in the residential and non-residential building floor area to 29 and 11 m ² ·cap ⁻¹ respectively.
Globe	(Millward-Hopkins et al. 2020)	With the changes in structural and technological intensity, the Decent Living Energy scenario achieved the decent living standard for all whilst reducing the final energy consumption of buildings by factor three, as compared to the WEO Current Policy Scenario (International Energy Agency 2019c).	The scenario assumed a reduction in floor area to 15 m ² ·cap ⁻¹ across the world.
Globe	(Levesque et al. 2019)	Realizing both the technological and sufficiency potential, the Low Demand Scenario and the Very Low Demand Scenario calculated a reduction in global building energy demand by 32% and 45% in 2050, as compared to the business-as-usual baseline.	The Low Scenario limited the residential and non-residential floor area to 70 and 23 m ² ·cap ⁻¹ ; the Very Low Scenario - to 45 and 15 m ² ·cap ⁻¹ .
EU	(Bierwirth and Thomas 2019b)	For the EU residential sector, the authors calculated potential energy savings of 17% and 29% from setting the per capita floor area limits.	A reduction of the residential floor area to 30 m ² ·cap ⁻¹ and 35 m ² ·cap ⁻¹ ., respectively.
EU	(Roscini et al. 2020)	With help of technological and non-technological measures, the Responsible Policy Scenario for the EU buildings allows achieving the emission reduction by 60% in 2030, as compared to 2015.	The scenario assumed 6% decrease in the residential per capita floor area (to max. 44.8 m ² ·cap ⁻¹).
Canada, UK,	(Hertwich et al. 2020)	The potential reduction in GHG emissions from the production of building materials is 56%-58% in 2050, as compared to these	Via the efficient use of living space, the scenario assumed its 20%

France, Italy, Japan, USA, Germany		baseline emissions. The reduction in heating and cooling energy demand is 9%-10% in 2050, as compared to its baseline.	reduction, as compared to its baseline development
UK	(Cabrera Serrenho et al. 2019)	The scenario found that the sufficiency measures allowed mitigating 30% of baseline emissions of the English building sector in 2050, without other additional measures.	The scenario assumed a 10% reduction in the current floor area per capita by 2050.
USA	(Goldstein et al. 2020)	The scenario calculated 16% GHG mitigation potential in 2050, as compared to the baseline, on the top of two other scenarios assuming building retrofits and grid decarbonization already delivering a 42% emission reduction.	The scenario assumed a 10% reduction in per capita floor area and higher penetration of onsite renewable energy.
Switzerland	(Roca-Puigròs et al. 2020)	The Green Lifestyle scenario allows achieving 48% energy savings by 2050, as compared to the baseline, due to sufficiency in the floor area among other measures.	The scenario assumed a reduction in residential floor area. from 47 to 41 m ² -cap ⁻¹ .
France	(Negawatt 2017)	The Negawatt scenario assumes that sufficiency behaviour becomes a mainstream across all sectors. In 2050, the final energy savings are 21% and 28% for the residential and tertiary sectors respectively, as compared to their baselines.	The scenario assumes a limit of the residential floor at 42 m ² -cap ⁻¹ due to apartment sharing and compact urban planning.
France	(Virage-Energie Nord-Pas-de-Calais. 2016)	The authors assessed sufficiency opportunities across all sectors for the Nord-Pas-de-Calais Region of France. Depending on the level of implementation, sufficiency could reduce the energy consumption of residential and tertiary buildings by 13-30% in 2050, as compared to the baseline.	The scenario assumed sharing spaces, downsizing spaces and sharing equipment from a 'soft' to 'radical' degree.

1

2 9.6.2 Assessment of the potentials at regional and global level

3 This section presents an aggregation of bottom-up potential estimates for different countries into
4 regional and then global figures for 2050, based on literature presented in Section 9.6.1. First, national
5 potential estimates reported as a share of baseline emissions in 2050 were aggregated into regional
6 potential estimates. Second, the latter were multiplied with regional baseline emissions to calculate the
7 regional potential in absolute numbers. Third, the global potential in absolute numbers was calculated
8 as a sum of regional absolute potentials. When several bottom-studies were identified for a region, either
9 a rounded average or a rounded median figure was taken, giving the preference to the one that was
10 closest to the potential estimates of countries with very large contribution to regional baseline emissions
11 in 2050 (i.e., to China in Eastern Asia). Furthermore, we preferred studies, which assessed the whole or
12 a large share of sector emissions and considered a comprehensive set of measures. The regional baseline
13 emissions, refer the WEO Current Policy Scenario (International Energy Agency 2019c). The sector
14 mitigation potential reported in Chapter 12 for the year 2030 was estimated in the same manner.

15 Figure 9.16 presents the mitigation potential in the building sector for the world and each region in
16 2050, estimated as a result of this aggregation exercise. The potentials presented in the figure are
17 different from those reported in Section 9.3.3, where they are estimated by IEA and IMAGE hybrid
18 model. The figure provides two breakdowns of the potential, into the reduction of direct and indirect
19 emissions as well as into the reduction of emissions from introducing sufficiency, energy efficiency,
20 and renewable energy measures. The potential estimates rely on the incremental stepwise approach,
21 assembling the measures according to the SER framework (see Box 9.1) and correcting the amount of
22 the potential at each step for the interaction of measures. The sequence of energy efficiency and
23 renewable energy measures follow the conclusion of the IPCC Global warming of 1.5°C Report (Rogelj
24 et al. 2018) that lower energy demand allows more choice of low-carbon energy supply options, and
25 therefore such sequencing is more beneficial and cost-effective.

26 Figure 9.16 argues that it is possible to mitigate 8.2 GtCO₂ or 61% of global building emissions in 2050,
27 as compared to their baseline. At least 1.4 GtCO₂ or 10% of baseline emissions could be avoided
28 introducing the sufficiency approaches. Further 5.6 GtCO₂ or 42% of baseline emissions could be
29 mitigated with the help of energy efficiency technologies and practices. Finally, at least 1.1 GtCO₂ or
30 9% of baseline emissions could be reduced through the production and use of onsite renewable energy.

1 Out of the total potential, the largest share of 5.4 GtCO₂ will be available in developing countries; these
 2 countries will be able to reduce 59% of their baseline emissions. Developed countries will be able to
 3 mitigate 2.7 GtCO₂ or 65% of their baseline emissions. Only few potential studies, often with only few
 4 mitigation options assessed, were available for the countries of South-East Asia and Developing Pacific,
 5 Africa, and Latin America and Caribbean; therefore, the potential estimates represent low estimates,
 6 and the real potentials are likely be higher.

7

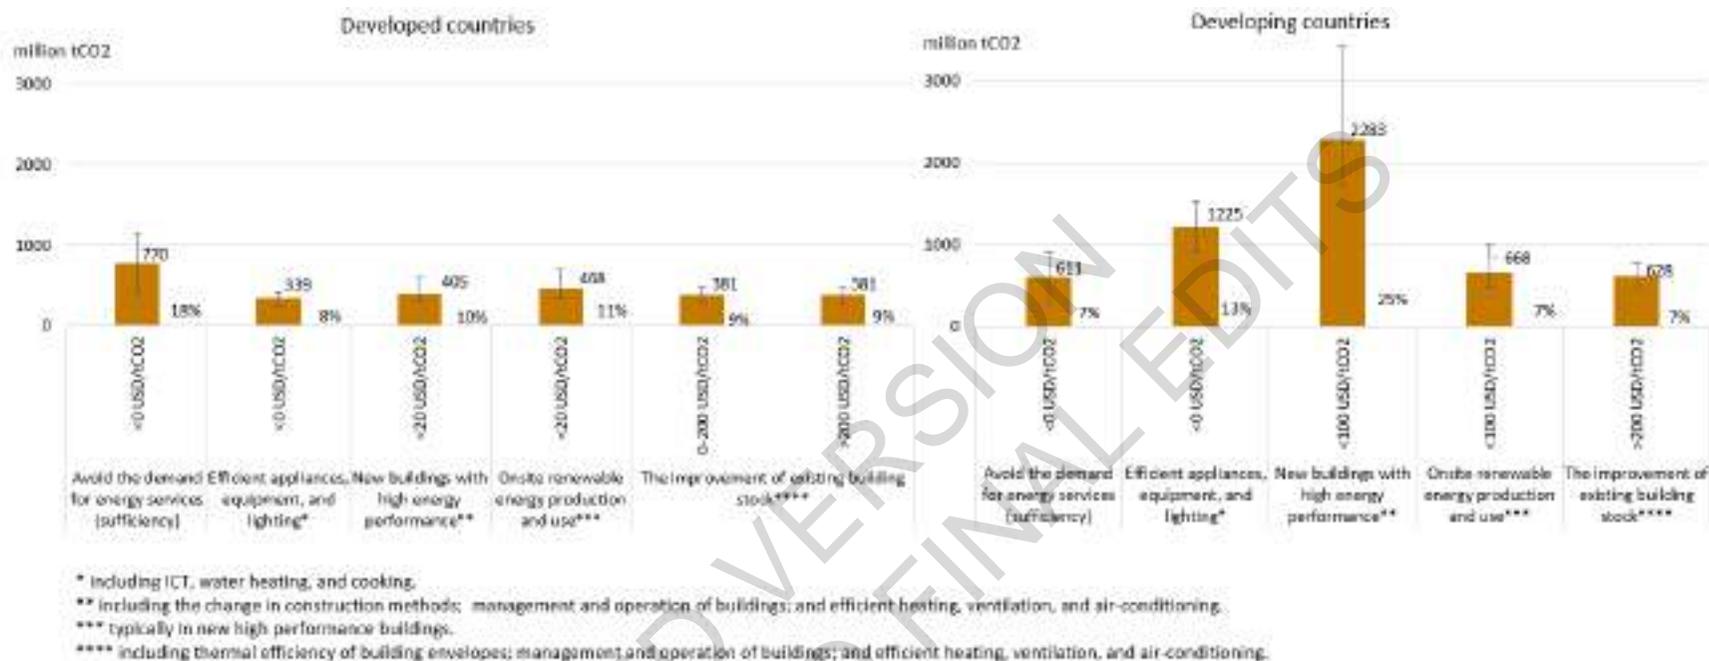

1 **Note:** the baseline refers to the WEO Current Policy Scenario (International Energy Agency 2019c). It may differ from other chapters.

2 **Figure 9.16 Global and regional estimates of GHG emissions in the building sector in 2020 and 2050, and**
3 **their potential reduction in 2050 broken down by measure (sufficiency / energy efficiency / renewable**
4 **energy) and by emission source (direct / indirect)**

5 **9.6.3 Assessment of the potential costs**

6 The novelty since AR5 is that a growing number of bottom-up studies considers the measures as an
7 integrated package recognising their technological complementarity and interdependence, rather than
8 the linear process of designing and constructing buildings and their systems, or incremental
9 improvements of individual building components and energy-using devices during building retrofits,
10 losing opportunities for the optimisation of whole buildings. Therefore, integrated measures rather than
11 the individual measures are considered for the estimates of costs and potentials. Figure 9.17 presents
12 the indicative breakdown of the potential reported in Figure 9.16 by measure and cost, to the extent that
13 it was possible to disaggregate and align to common characteristics. Whereas the breakdown per
14 measure was solely based on the literature reviewed in Section 9.6.1, the cost estimates additionally
15 relied on the literature presented in this section, Figure 9.20, and Table SM9.6. The literature reviewed
16 reports fragmented and sometimes contradicting cost-effectiveness information. Despite a large number
17 of exemplary buildings achieving very high performance in all parts of the world, there is a lack of
18 mainstream literature or official studies assessing the costs of these buildings at scale (Lovins 2018;
19 Ürge-Vorsatz et al. 2020).

20 Figure 9.17 indicates that a very large share of the potential in developed countries could be realized
21 through the introduction of sufficiency measures (at least 18% of their baseline emissions). Literature
22 identifies many opportunities, which may help operationalize it. These are reorganization of human
23 activities, teleworking, coworking, more efficient space design, planning and use, higher density of
24 building and settlement inhabitancy, flexible space, housing swaps, shared homes and facilities, space
25 and room renting, and others (Bierwirth and Thomas 2019a; Ivanova and Büchs 2020; Ellsworth-Krebs
26 2020). Whereas literature does not provide a robust cost assessment of the sufficiency potential, it
27 indicates that these measures are likely to be at no or very little cost (Cabrera Serrenho et al. 2019).

1
 2 **Notes:** 1. The baseline refers to the WEO Current Policy Scenario (International Energy Agency 2019c). It may differ from other chapters. 2. The figure merged the results of Eurasia into those of developed countries.

3 **Figure 9.17 Indicative breakdown of GHG emission reduction potential of the buildings sector in developed and developing countries into measure and costs in**
 4 **2050, in absolute figures with uncertainty ranges and as a share of their baseline emissions**

1 The exchange of lights, appliances, and office equipment, including ICT, water heating, and cooking
2 technologies could reduce more than 8% and 13% of the total sector baseline emissions in developed
3 and developing countries respectively, typically at negative cost (González-Mahecha et al. 2019;
4 Grande-Acosta and Islas-Samperio 2020; de Melo and de Martino Jannuzzi 2015; Prada-hernández et
5 al. 2015; Subramanyam et al. 2017a,b; Department of Environmental Affairs 2014). This cost-
6 effectiveness is however often reduced by a larger size of appliances and advanced features, which
7 offset a share of positive economic effects (Molenbroek et al. 2015).

8 Advanced HVAC technologies backed-up with demand side management, and onsite integrated
9 renewables backed-up with demand-side flexibility and digitalization measures are typically a part of
10 the retrofit or construction strategy. Among HVAC technologies, heat pumps are very often modelled
11 to become a central heating and cooling technology supplied with renewable electricity. The estimates
12 of HVAC cost-effectiveness, including heat pumps, varies in modelling results from very cost-effective
13 to medium (Hirvonen et al. 2020; Akander et al. 2017; Prada-hernández et al. 2015; Department of
14 Environmental Affairs 2014). Among demand side management, demand-side flexibility and
15 digitalization options, various sensors, controls, and energy consumption feedback devices have
16 typically negative costs, whereas advanced smart management systems as well as thermal and electric
17 storages linked to fluctuating renewables are not yet cost-effective (Uchman 2021; Duman et al. 2021;
18 Nguyen et al. 2015; Huang et al. 2019; Sharda et al. 2021; Rashid et al. 2021; Prada-hernández et al.
19 2015). Several developed countries achieved to make onsite renewable energy production and use
20 profitable for at least a part of the building stock (Fina et al. 2020; Vimpari and Junnila 2019; Akander
21 et al. 2017; Horváth et al. 2016), but this is not yet the case for developing countries (Cruz et al. 2020;
22 Grande-acosta and Islas-samperio 2020; Kwag et al. 2019). Due to characteristics and parameters of
23 different building types, accommodating the cost-optimal renewables at large scale is especially
24 difficult in non-residential buildings and in urban areas, as compared to residential buildings and rural
25 areas (Fina et al. 2020; Horváth et al. 2016).

26 Literature agrees that new advanced buildings, using design, form, and passive building construction
27 equipped with demand side measures, and advanced HVAC technologies can reduce the sector total
28 baseline emissions in developed and developing countries by at least 10% and 25% in 2050,
29 respectively, and renewable energy technologies backed-up with demand-side flexibility and
30 digitalization measures typically installed in new buildings could further reduce these emissions by at
31 least 11% and 7% (see also Cross-Chapter Box 12 in Chapter 16). The literature however provides
32 different and sometimes conflicting information of their cost-effectiveness. (Esser et al. 2019) reported
33 that by 2016, the perceived share of buildings similar or close to nZEB in the new construction was just
34 above 20% across the EU. In this region, additional investment costs were no higher than 15%, as
35 reported for Germany, Italy, Denmark, and Slovenia (Erhorn-Kluttig et al. 2019). Still the European
36 market experiences challenges which relate to capacity and readiness, as revealed by (Architects'
37 Council of Europe (ACE) 2019) recording a decline in the share of architects who are designing
38 buildings to nZEB standards to more than 50% of their time, from 14% in 2016 to 11% in 2018. In
39 contrast, the APEC countries reported additional investment costs of 67% on average (Xu and Zhang
40 2017) that makes them a key barrier to the nZEB penetration in developing countries as of today (Feng
41 et al. 2019). This calls for additional R&D policies and financial incentives to reduce the nZEB costs
42 (Xu and Zhang 2017; Kwag et al. 2019).

43 Thermal efficiency retrofits of existing envelopes followed up by the exchange of HVAC backed up
44 with demand side measures could reduce the sector total baseline emissions in developed and
45 developing countries by at least 18% and 7% respectively in 2050. There have been many individual
46 examples of deep building retrofits, which incremental costs are not significantly higher than those of
47 shallow retrofits. However, literature tends to agree that cost-effective or low cost deep retrofits are not
48 universally applicable for all cases, especially in historic urban areas, indicating a large share of the

1 potential in the high-cost category (Mata et al. 2019; Semprini et al. 2017; Paduos and Corrado 2017;
2 Subramanyam et al. 2017b; Department of Environmental Affairs 2014; Streicher et al. 2017; Akander
3 et al. 2017). Achieving deep retrofits assumes additional measures on the top of business-as-usual
4 retrofits, therefore high rate of deep retrofits at acceptable costs are not possible in case of low business-
5 as-usual rates (Streicher et al. 2020).

6 For a few studies, which conducted an assessment of the sector transformation aiming at emission
7 reduction of 50–80% in 2050 versus their baseline, the incremental investment need over the modelling
8 period is estimated at 0.4–3.3% of the country annual GDP of the scenario first year (Kotzur et al. 2020;
9 Novikova et al. 2018c; Bashmakov 2017; Markewitz et al. 2015). These estimates represent strictly the
10 incremental share of capital expenditure and sometimes installation costs. Therefore, these figures are
11 not comparable with investment tracked against the regional or national sustainable finance taxonomies,
12 as recently developed in the EU (European Parliament and the Council 2020), Russia (Government of
13 Russian Federation 2021), South Africa (National Treasury of Republic of South Africa 2021), and
14 others, or the growing literature on calculating the recent finance flows (Macquarie et al. 2020; Hainaut
15 et al. 2021; Novikova et al. 2019; Valentova et al. 2019; Kamenders et al. 2019), because they are
16 measured against other methodologies, which are not comparable with the methodologies used to derive
17 the incremental costs by integrated assessment models and bottom-up studies. Therefore, the gap
18 between the investment need and recent investment flows is likely to be higher, than often reported.

19 **9.6.4 Determinants of the potentials and costs**

20 That fact that the largest share of the global floor area is still to be built offers a large potential for
21 emission reduction that is however only feasible if ambitious building energy codes will be applied to
22 this new stock (see Section 9.9.3 on building codes). The highest demand for additional floor area will
23 occur in developing countries; the building replacement is also the highest in developing countries
24 because their building lifetime could be as short as 30 years (Lixuan et al. 2016; Alaidroos and Krarti
25 2015). Whereas as of 2018, 73 countries had already had building codes or were developing them, only
26 41 had mandatory residential codes and 51 had mandatory non-residential codes (Global Alliance for
27 Buildings and Construction 2019). Therefore, the feasibility of capturing this potential is a subject to
28 greater coverage, adoption, and strength of building codes.

29 Low rates of building retrofits are the major feasibility constrain of building decarbonization in
30 developed countries. Long building lifetime and their slow replacement caused a lock-in of low energy
31 performance in old buildings of developed countries, especially in urban areas. A few studies of
32 developing countries, mostly medium and high-income, also considered building retrofits (Yu et al.
33 2018b; Zhou et al. 2018; Krarti 2019; Kamal et al. 2019; Prada-hernández et al. 2015). The studies in
34 developed countries tend to rely on either of the strategies: very “deep” envelope retrofits followed by
35 the exchange of HVAC with various advanced alternatives (Novikova et al. 2018c,b; Csoknyai et al.
36 2016; Filippi Oberegger et al. 2020; Duscha et al. 2019) or more shallow retrofits followed by switching
37 to low-carbon district heating or by the exchange of current HVAC with heat pumps linked to onsite
38 renewables backed up energy storages (Kotzur et al. 2020; Hirvonen et al. 2020; Yeh et al. 2016). The
39 factors, which impact the feasibility of these strategies therefore are the building retrofit rates and
40 replacement rates of building systems. To achieve the building stock decarbonization by 2050, most
41 studies reviewed in Figure 9.16 assume “deep” retrofit rates between 2.5% and 5%, and even 10% per
42 annum. (Esser et al. 2019) reported that the annual renovation rate in EU28 is around 0.2%, with
43 relatively small variation across individual EU member states. (Sandberg et al. 2016) simulated retrofit
44 rates in eleven European countries and concluded that only minor future increases in the renovation
45 rates of 0.6–1.6% could be expected. Therefore, without strong policies supporting these renovations,
46 the feasibility to achieve such high “deep” retrofit rates is low.

47 Among key factors affecting the costs-effectiveness of achieving high-performance buildings remain
48 low energy prices in many countries worldwide (Alaidroos and Krarti 2015; Akander et al. 2017) and

1 high discount rates reflecting low access to capital and high barriers. (Copiello et al. 2017) found that
2 the discount rate affects the economic results of retrofits four times higher than the energy price, and
3 therefore the reduction in upfront costs and working out barriers are the feasibility enablers.

4 The good news is that literature expects a significant cost reduction for many technologies, which are
5 relevant for the construction of high energy-performance buildings and deep retrofits. Applying a
6 technology learning curve to the data available for Europe and reviewing dozens of studies available,
7 (Köhler et al. 2018) estimated the cost reduction potential of biomass boilers, heat pumps, ventilation,
8 air-conditioning, thermal storages, electricity storages, solar PVs and solar thermal systems of 14%,
9 20%, 46–52%, 29%, 29%, 65%, 57%, and 43% respectively in 2050; no significant cost reduction
10 potential was found however for established and wide-spread insulation technologies. More investment
11 into RDD to reduce the technology costs and more financial incentives to encourage uptake of the
12 technologies would allow moving along this learning curve.

13 Furthermore, some literature argues that the key to cost-effectiveness is not necessarily a reduction in
14 costs of technologies, but a know-how and skills of their choosing, combining, sequencing, and timing
15 to take the most benefits of their interdependence, complementarity, and synergy as illustrated by many
16 examples (Lovins 2018; Ürge-Vorsatz et al. 2020). However, the scenarios reviewed lack such
17 approaches in their cost assessments. Few indicative examples of cost reduction at scale were provided
18 though not by the scenario literature, but case studies of the application of One-Stop Shop (OSS)
19 approach at scale (see Section 9.9.4). In 2013, the Dutch Energiesprong network brokered a deal
20 between Dutch building contractors and housing associations to reduce the average retrofit costs from
21 EUR 130,000 down to 65,000 for 111,000 homes with building prefabrication systems and project
22 delivery models while targeting energy savings of 45–80% (Ürge-Vorsatz et al. 2020); out of which
23 10,000 retrofits have been realized by 2020. The French Observatory of Low Energy Buildings reported
24 to achieve the cost-effective deep renovations of 818 dwellings and 27 detached houses in France setting
25 a cap for absolute primary energy consumption to achieve after renovation and a cap for the budget to
26 deliver it; the cost-effectiveness was however calculated with grants and public subsidies (Saheb 2018).

27 Literature emphasizes the critical role of the time between in 2020 and 2030 for the building sector
28 decarbonisation (IEA 2020a; Roscini et al. 2020). To set the sector at the pathway to realize its whole
29 mitigation potential, it is critical to exponentially accelerate the learning of this know-how and skills to
30 reduce the costs and remove feasibility constraints to enable the penetration of advanced technologies
31 at speed that the world has not seen before. The World Energy Outlook (IEA 2020a) portrayed in the
32 Net Zero Emissions by 2050 Scenario (see Box 9.2) the challenges and commitments the sector will
33 have to address by 2030. These include bringing new buildings and existing buildings to near zero, with
34 a half of existing buildings in developed countries and a third of existing buildings in developing
35 countries being retrofitted by 2030. These also mean banning the sale of new fossil fuel-fired boilers,
36 as well as making heat pumps and very efficient appliances standard technologies. The Net Zero
37 Emissions by 2050 Scenario achieves almost fully to decarbonize the sector by 2050, with such
38 commitments reflected neither in the planning and modelling efforts (Section 9.9) nor in policies and
39 commitments (Section 9.9) of most world countries, with the countries of South-East Asia and
40 Developing Pacific, Southern Asia, Africa, and Latin America and Caribbean having the least research.

41 As discussed in Section 9.6.1, the alternative and low-cost opportunity to reduce the sector emissions
42 in the countries with high floor area per capita and the low stock turnover is offered by the introduction
43 of the sufficiency approach. Section 9.9.3.1 discusses a range of policy instruments, which could
44 support the realization of the sufficiency potential. As the approach is new, the literature does not yet
45 report experiences of these measures. In the framework of project OptiWohn, the German cities of
46 Göttingen, Köln und Tübingen just started testing the sufficiency approach and policy measures for
47 sufficiency (Stadt Göttingen 2020). Therefore, the feasibility of realizing the sufficiency potential
48 depends on its recognition by the energy and climate policy and the introduction of supporting measures

1 (Samadi et al. 2017; Ellsworth-Krebs 2020; Goldstein et al. 2020). More research is needed to
2 understand which measures will work and which will not.

3 Similar to buildings, the energy consumption and associated emissions of appliances and equipment is
4 driven by the replacement of old appliances and the additional stock due to the increase in penetration
5 and saturation of appliances. The feasibility of appliance stock replacement with efficient options is
6 higher than the feasibility of building stock replacement or retrofit due to their smaller size, shorter
7 lifetime, and cheaper costs (Chu and Bowman 2006; Spiliotopoulos 2019). Some literature argues that
8 once appliances achieve a particular level of efficiency their exchange does not bring benefits from the
9 resource efficiency point of view (Hertwich et al. 2019). Even through the data records a permanent
10 energy efficiency improvement of individual devices (Figure 9.12), their growing offsets energy savings
11 delivered by this improvement. The emerging literature suggests addressing the growing number of
12 energy services and devices as a part of climate and energy policy (Bierwirth and Thomas 2019b).
13 Sections 9.5.2.2 describes measures for limiting demand for these services and Section 9.5.3.6 addresses
14 reducing the number of technologies through their ownership and use patterns. (Grubler et al. 2018)
15 also suggested redefining energy services and aggregating appliances, illustrating the reduction of
16 energy demand by factor 30 to substitute over 15 different end-use devices with one integrated digital
17 platform. More research is needed to understand opportunities to realize this sufficiency potential for
18 appliances, and more research is needed to understand policies which may support these opportunities
19 (Bierwirth and Thomas 2019a).

20 The difference between baselines is among the main reason for difference between the potential
21 estimates in 2030 reported by Chapter 6 on buildings of AR4 (Levine et al. 2017) and the current section
22 of AR6. For developed countries, the sector direct and indirect baseline emissions in AR6 are 43% and
23 28% lower than those in AR4 respectively. For developing countries, the sector direct baseline
24 emissions in AR6 are 47% lower than those in AR4, and the sector indirect baseline emissions are 3%
25 higher than those in AR4. As AR6 is closer to 2030 than AR4 and thus more precise, the likely reason
26 for the difference (besides the fact that some potential was realized) is that AR4 overall overestimated
27 the future baseline emissions, and it underestimated how quickly the fuel switch to electricity from other
28 energy carriers has been happening, especially in developing countries. As illustrated, the baseline is
29 one of determinant of the potential size and hence, all reported estimates shall only be interpreted
30 together with the baseline developments.

31 The potential is a dynamic value, increasing with the technological progress. Most potential studies
32 reviewed in Section 9.6.1 consider today mature commercialised or near to commercialisation
33 technologies with demonstrated characteristics “freezing them” in the potential estimates until the study
34 target year. Until 2050, many of these technologies will further improve, and furthermore new advanced
35 technologies may emerge. Therefore, the potential estimates are likely to be low estimates of the real
36 potential volumes. Furthermore, models apply many other assumptions and they cannot always capture
37 right emerging societal or innovation trends; these trends may also significantly impact the potential
38 size into both directions (Brugger et al. 2021).

39 With the declining amount of emissions during the building operation stage, the share of building
40 embodied emissions in their lifetime emissions will grow, also due to additional building material
41 (Peñaloza et al. 2018; Cabeza et al. 2021). Reviewing 650 life cycle assessment case studies, (Röck et
42 al. 2020) estimated the contribution of embodied emissions to building lifetime emissions up to 45–
43 50% for highly efficient buildings, surpassing 90% in extreme cases.

44 Recently, a significant body of research has been dedicated to studying the impacts of using bio-based
45 solutions (especially timber) for building construction instead of conventional materials, such as
46 concrete and steel, because more carbon is stored in bio-based construction materials than released
47 during their manufacturing. Assuming the aggressive use of timber in mid-rise urban buildings,
48 Churkina et al. (2020) estimated the associated mitigation potential between 0.04-3.7 GtCO₂ per year

1 depending on how fast countries adopt new building practices and floor area per capita. Based on a
2 simplified timber supply-demand model for timber-based new floor area globally by 2050, Pomponi et
3 al. (2020) showed that the global supply of timber can only be 36% of the global demand for it between
4 2020 and 2050; especially much more forest areas will be required in Asian countries, such as China
5 and India and American countries, such as the USA, Mexico, and Argentina. Goswein et al. (2021)
6 conducted a similar detailed analysis for Europe and concluded that current European forest areas and
7 wheat plantations are sufficient to provide timber and straw for the domestic construction sector.

8 The increased use of timber and other bio-based materials in buildings brings not only benefits, but also
9 risks. The increased use of timber can accelerate degradation through poor management and the pressure
10 for deforestation, as already recorded in the Amazon and Siberia forests, and the competition for land
11 and resources (Brancalion et al. 2018; Carrasco et al. 2017; Hart and Pomponi 2020; Pomponi et al.
12 2020). Churkina et al. (2020) emphasized that promoting the use of more timber in buildings requires
13 the parallel strengthening of legislation for sustainable forest management, forest certification
14 instruments, and care for the people and social organizations that live in forests. In tropical and
15 subtropical countries, the use of bamboo and other fibres brings more benefits and less risks than the
16 use of timber (ibid). One of the main barriers associated with the use of bio-based materials in buildings
17 is fire safety, although there is extensive research on this topic (Audebert et al. 2019; Östman et al.
18 2017). This is a particularly important criterion for the design of medium and high-rise buildings, which
19 tend to be the most adequate typologies for denser and more compact cities. Overall, more robust
20 models are needed to assess the interlinkages between the enhanced use of bio-based materials in the
21 building stock and economic and social implications of their larger supply, as well as the associated
22 competition between forest and land-use activities (for food), and ecological aspects. Furthermore, more
23 research is required on how to change forest and building legislation and design a combination of policy
24 instruments for the specific political, economic and cultural county characteristics (Hildebrandt et al.
25 2017). Benefits and risks of enhanced use of wood products in buildings are also discussed in Chapter
26 7, Section 7.4.5.3.

27 28 **9.7 Links to adaptation**

29 Buildings are capital-intensive and long-lasting assets designed to perform under a wide range of
30 climate conditions (Hallegatte 2009; Pyke et al. 2012). Their long life span means that the building
31 stock will be exposed to future climate (de Wilde and Coley 2012; Wan et al. 2012; Hallegatte 2009)
32 and, as such, adaptation measures will be necessary.

33 The impacts of climate change on buildings can affect building structures, building construction,
34 building material properties, indoor climate and building energy use (Andrić et al. 2019). Many of those
35 impacts and their respective adaptation strategies interact with GHG mitigation in different ways.

36 **9.7.1 Climate change impacts and adaptation in buildings**

37 A large body of literature on climate impacts on buildings focuses on the impacts of climate change on
38 heating and cooling needs (de Wilde and Coley 2012; Wan et al. 2012; Andrić et al. 2019). The
39 associated impacts on energy consumption are expected to be higher in hot summer and warm winter
40 climates, where cooling needs are more relevant (Li et al. 2012; Wan et al. 2012; Andrić et al. 2019). If
41 not met, this higher demand for thermal comfort can impact health, sleep quality and work productivity,
42 having disproportionate effects on vulnerable populations and exacerbating energy poverty (Falchetta
43 and Mistry 2021; Biardeau et al. 2020; Sun et al. 2020) (see Section 9.8).

44 Increasing temperatures can lead to higher cooling needs and, therefore, energy consumption (Schaeffer
45 et al. 2012; Clarke et al. 2018; International Energy Agency 2018; Wan et al. 2012; Li et al. 2012;
46 Andrić et al. 2019). Higher temperatures increase the number of days/hours in which cooling is required
47 and as outdoor temperatures increase, the cooling load to maintain the same indoor temperature will be

1 higher (Andrić et al. 2019). These two effects are often measured by cooling degree-days¹ (CDD) and
2 there is a vast literature on studies at the global (Atalla et al. 2018; Mistry 2019; Isaac and van Vuuren
3 2009; Biardeau et al. 2020; Clarke et al. 2018) and regional level (Bezerra et al. 2021; Zhou et al. 2014;
4 Falchetta and Mistry 2021). Other studies use statistical econometric analyses to capture the empirical
5 relationship between climate variables and energy consumption (Auffhammer and Mansur 2014; van
6 Ruijven et al. 2019). A third effect is that higher summer temperatures can incentivize the purchase of
7 space cooling equipment (Auffhammer 2014; De Cian et al. 2019; Biardeau et al. 2020), especially in
8 developing countries (Pavanello et al. 2021).

9 The impacts of increased energy demand for cooling can have systemic repercussions (Ralston Fonseca
10 et al. 2019; Ciscar and Dowling 2014), which in turn can affect the provision of other energy services.
11 Space cooling can be an important determinant of peak demand, especially in periods of extreme heat
12 (International Energy Agency 2018). Warmer climates and higher frequency and intensity of heat waves
13 can lead to higher loads (Dirks et al. 2015; Auffhammer et al. 2017), increasing the risk of grid failure
14 and supply interruptions.

15 Although heating demand in cold climate regions can be expected to decrease with climate change and,
16 to a certain extent, outweigh the increase in cooling demand, the effects on total primary energy
17 requirements are uncertain (Wan et al. 2012; Li et al. 2012). Studies have found that increases in
18 buildings energy expenditures for cooling more than compensate the savings from lower heating
19 demands in most regions (Clarke et al. 2018). In addition, climate change may affect the economic
20 feasibility of district heating systems (Andrić et al. 2019).

21 In cold climates, a warming climate can potentially increase the risk of overheating in high-performance
22 buildings with increased insulation and airtightness to reduce heat losses (Gupta and Gregg 2012). In
23 such situations, the need for active cooling technologies may arise, along with higher energy
24 consumption and GHG emissions (Gupta et al. 2015).

25 Changes in cloud formation can affect global solar irradiation and, therefore, the output of solar
26 photovoltaic panels, possibly affecting on-site renewable energy production (Burnett et al. 2014). The
27 efficiency of solar photovoltaic panels and their electrical components decreases with higher
28 temperatures (Simioni and Schaeffer 2019) (Bahaidarah et al. 2013). However, studies have found that
29 such effect can be relatively small (Totschnig et al. 2017), making solar PV a robust option to adapt to
30 climate change (Shen and Lior 2016; Santos and Lucena 2021) (see Section 9.4).

31 Climate change can also affect the performance, durability and safety of buildings and their elements
32 (facades, structure, etc.) through changes in temperature, humidity, wind, and chloride and CO₂
33 concentrations (Bastidas-Arteaga et al. 2010; Bauer et al. 2018; Rodríguez-Rosales et al. 2021; Chen et
34 al. 2021). Historical buildings and coastal areas tend to be more vulnerable to these changes (Huijbregts
35 et al. 2012; Mosoarca et al. 2019; Cavalagli et al. 2019; Rodríguez-Rosales et al. 2021).

36 Temperature variations affect the building envelope, e.g. with cracks and detachment of coatings (Bauer
37 et al. 2016, 2018). Higher humidity (caused by wind-driven rain, snow or floods) hastens deterioration
38 of bio-based materials such as wood and bamboo (Brambilla and Gasparri 2020), also deteriorating
39 indoor air quality and users health (Grynning et al. 2017; Lee et al. 2020; Huijbregts et al. 2012).

40 Climate change can accelerate the degradation of reinforced concrete structures due to the increase of
41 chloride ingress (Bastidas-Arteaga et al. 2010) and the concentration of CO₂, which increase the
42 corrosion of the embedded steel (Stewart et al. 2012; Peng and Stewart 2016; Chen et al. 2021).

FOOTNOTE¹ CDD can be generally defined as the monthly or annual sum of the difference between an indoor set point temperature and outdoor air temperature whenever the latter is higher than a given threshold temperature (Mistry 2019).

1 Corrosion rates are higher in places with higher humidity and humidity fluctuations (Guo et al. 2019),
2 and degradation could be faster with combined effects of higher temperatures and more frequent and
3 intense precipitations (Bastidas-Arteaga et al. 2010; Chen et al. 2021).

4 Higher frequency and intensity of hurricanes, storm surges and coastal and non-coastal flooding can
5 escalate economic losses to civil infrastructure, especially when associated with population growth and
6 urbanization in hazardous areas (Bjarnadottir et al. 2011; Lee and Ellingwood 2017; Li et al. 2016).
7 Climate change should increase the risk and exposure to damage from flood (de Ruig et al. 2019), sea
8 level rise (Bove et al. 2020; Zanetti et al. 2016; Bosello and De Cian 2014) and more frequent wildfires
9 (Craig et al. 2020; Barkhordarian et al. 2018).

10

11 **9.7.2 Links between mitigation and adaptation in buildings**

12 Adaptation options interacts with mitigation efforts because measures to cope with climate change
13 impacts can increase energy and material consumption, which may lead to higher GHG emissions
14 (Kalvelage et al. 2014; Davide et al. 2019; Sharifi 2020). Energy consumption is required to adapt to
15 climate change. Mitigation measures, in turn, influence the degree of vulnerability of buildings to future
16 climate and, thus, the adaptation required.

17 Studies have assessed the increases in energy demand to meet indoor thermal comfort under future
18 climate (de Wilde and Coley 2012; Li et al. 2012; Andrić et al. 2019; Clarke et al. 2018). Higher cooling
19 needs may induce increases in energy demand (Wan et al. 2012; Li et al. 2012), which could lead to
20 higher emissions, when electricity is fossil-based (International Energy Agency 2018; Biarreau et al.
21 2020), and generate higher loads and stress on power systems (Auffhammer et al. 2017; Dirks et al.
22 2015). In this regard, increasing energy efficiency of space cooling appliances and adopting dynamic
23 cooling setpoint temperatures, can reduce the energy needs for cooling and limit additional emissions
24 and pressures on power systems (Davide et al. 2019; Bezerra et al. 2021) (Bienvenido-Huertas et al.
25 2020) (see Section 9.4, Figure 9.11 and Tables SM9.1 to SM9.3). This can also be achieved with on-
26 site renewable energy production, especially solar PV for which there can be a timely correlation
27 between power supply and cooling demand, improving load matching (Salom et al. 2014; Grove-Smith
28 et al. 2018).

29 Mitigation alternatives through passive approaches may increase resilience to climate change impacts
30 on thermal comfort and reduce active cooling needs (González Mahecha et al. 2020; Rosse Caldas et
31 al. 2020; van Hooff et al. 2016; Wan et al. 2012; Andrić et al. 2019). Combining passive measures can
32 help counteracting climate change driven increases in energy consumption for achieving thermal
33 comfort (Huang and Hwang 2016).

34 Studies raise the concern that measures aimed at building envelope may increase the risk of overheating
35 in a warming climate (Dodoo and Gustavsson 2016; Fosas et al. 2018) (see Section 9.4). If this is the
36 case, there may be a conflict between mitigation through energy efficiency building regulations and
37 climate change adaptation (Fosas et al. 2018). However, while overheating may occur as a result of
38 poor insulation design, better insulation may actually reduce overheating when properly projected and
39 the overheating risk can be overcome by clever designs (Fosas et al. 2018).

40 Strengthening building structures to increase resilience and reduce exposure to the risk of extreme
41 events, such as draughts, torrential floods, hurricanes and storms, can be partially achieved by
42 improving building standards and retrofitting existing buildings (Bjarnadottir et al. 2011). However,
43 future climate is not yet considered in parameters of existing building energy codes (Steenbergen et al.
44 2012). While enhancing structural resilience would lead to GHG emissions (Liu and Cui 2018), so
45 would disaster recovery and re-building. This adaptation-mitigation trade-off needs to be further
46 assessed.

1 Since adaptation of the existing building stock may be more expensive and require building retrofit,
2 climate change must be considered in the design of new buildings to ensure performance robustness in
3 both current and future climates, which can have implications for construction costs (de Rubeis et al.
4 2020; Picard et al. 2020; Hallegatte 2009; Pyke et al. 2012; de Wilde and Coley 2012) and emissions
5 (Liu and Cui 2018). Building energy codes and regulations are usually based on cost-effectiveness and
6 historical climate data, which can lead to the poor design of thermal comfort in future climate
7 (Hallegatte 2009; Pyke et al. 2012; de Wilde and Coley 2012) and non-efficient active adaptive
8 measures based on mechanical air conditioning (De Cian et al. 2019) (see Section 9.4, Figure 9.11 and
9 Tables SM9.1 to SM9.3). However, uncertainty about future climate change creates difficulties for
10 projecting parameters for the design of new buildings (Hallegatte 2009; de Wilde and Coley 2012). This
11 can be especially relevant for social housing programs (Rubio-Bellido et al. 2017; González Mahecha
12 et al. 2020; Triana et al. 2018) in developing countries.

13 The impacts on buildings can lead to higher maintenance needs and the consequent embodied
14 environmental impacts related to materials production, transportation and end-of-life, which account
15 for a relevant share of GHG emissions in buildings life cycle (Rasmussen et al. 2018). Climate change
16 induced biodegradation is especially important for bio-based materials such as wood and bamboo
17 (Brambilla and Gasparri 2020) which are important options for reducing emissions imbued in buildings'
18 construction materials (Peñaloza et al. 2016; Churkina et al. 2020; Rosse Caldas et al. 2020).

19 Although there can potentially be conflicts between climate change mitigation and adaptation, these can
20 be dealt with proper planning, actions, and policies. The challenge is to develop multifunctional
21 solutions, technologies and materials that can mitigate GHG emissions while improving buildings
22 adaptive capacity. Solutions and technologies should reduce not only buildings' operational emissions,
23 but also embodied emissions from manufacturing and processing of building materials (Röck et al.
24 2020). For instance, some building materials, such as bio-concrete, can reduce life cycle emissions of
25 buildings and bring benefits in terms of building thermal comfort in tropical and subtropical climates.
26 Also, energy efficiency, sufficiency and on-site renewable energy production can help to increase
27 building resilience to climate change impacts and reduce pressure on the energy system.

28

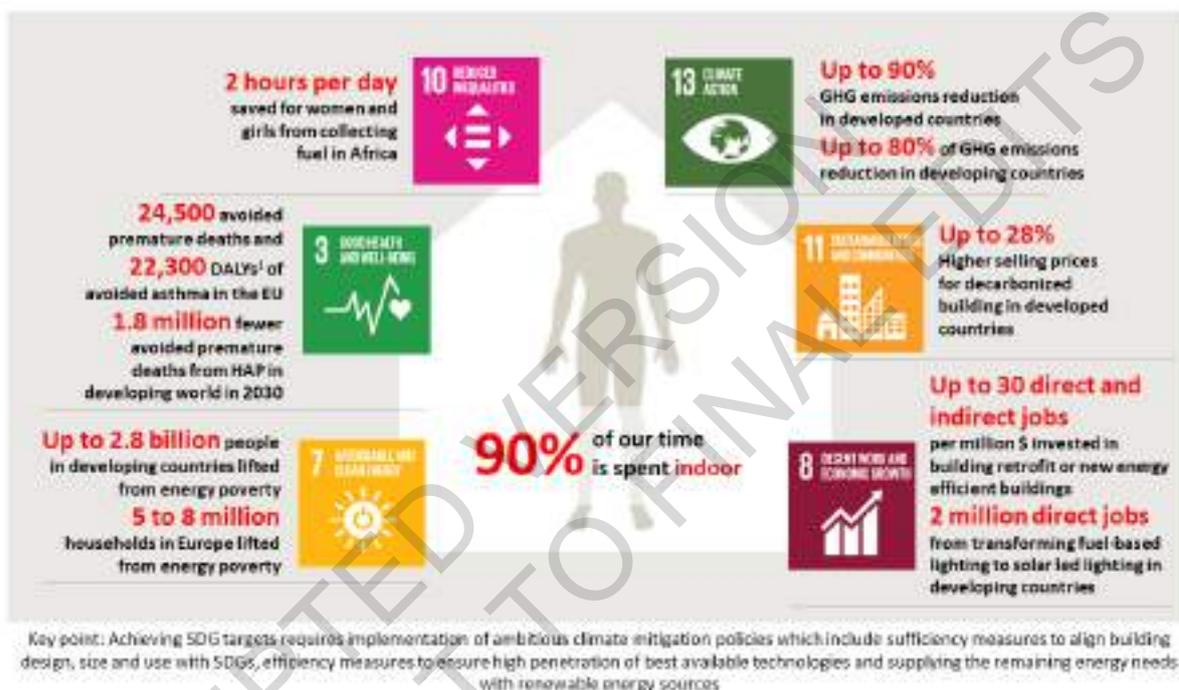

29 **9.8 Links to sustainable development**

30 **9.8.1 Overview of contribution of mitigation options to sustainable development**

31 A growing body of research acknowledges that mitigation actions in buildings may have substantial
32 social and economic value beyond their direct impact of reducing energy consumption and/or GHG
33 emissions (Ürge-Vorsatz et al. 2016; Deng et al. 2017; Reuter et al. 2017; IEA 2014; US EPA 2018;
34 Kamal et al. 2019; Bleyl et al. 2019) (see also Cross-Chapter Box 6 in Chapter 7). In other words, the
35 implementation of these actions in the residential and non-residential sector holds numerous multiple
36 impacts (co-benefits, adverse side-effects, trade-offs, risks, etc.) for the economy, society and end-users,
37 in both developed and developing economies, which can be categorized into the following types (Nikas
38 et al. 2020; Thema et al. 2017; Ferreira et al. 2017; Reuter et al. 2017; IEA 2014; US EPA 2018; Ürge-
39 Vorsatz et al. 2016): (i) health impacts due to better indoor conditions, energy/fuel poverty alleviation,
40 better ambient air quality and reduction of the heat island effect; (ii) environmental benefits such as
41 reduced local air pollution and the associated impact on ecosystems (acidification, eutrophication, etc.)
42 and infrastructures, reduced sewage production, etc.; (iii) improved resource management including
43 water and energy; (iv) impact on social well-being, including changes in disposable income due to
44 decreased energy expenditures and/or distributional costs of new policies, fuel poverty alleviation and
45 improved access to energy sources, rebound effects, increased productive time for women and children,
46 etc.; (v) microeconomic effects (e.g., productivity gains in non-residential buildings, enhanced asset
47 values of green buildings, fostering innovation); (vi) macroeconomic effects, including impact on GDP
48 driven by energy savings and energy availability, creation of new jobs, decreased employment in the
49 fossil energy sector, long-term reductions in energy prices and possible increases in electricity prices in

1 the medium run, possible impacts on public budgets, etc.; and (vii) energy security implications (e.g.,
 2 access to modern energy resources, reduced import dependency, increase of supplier diversity, smaller
 3 reserve requirements, increased sovereignty and resilience).

4 Well-designed and effectively implemented mitigation actions in the sector of buildings have significant
 5 potential for achieving the United Nations (UN) Sustainable Development Goals (SDGs). Specifically,
 6 the multiple impacts of mitigation policies and measures go far beyond the goal of climate action
 7 (SDG13) and contribute to further activating a great variety of other SDGs (Figure 9.18 presents some
 8 indicative examples). Table 9.4 reviews and updates the analysis carried out in the context of the Special
 9 Report on Global Warming of 1.5°C (Roy et al. 2018) demonstrating that the main categories of GHG
 10 emission reduction interventions in buildings, namely the implementation of energy sufficiency and
 11 efficiency improvements as well as improved access and fuel switch to modern low carbon energy,
 12 contribute to achieving 16 out of a total of 17 SDGs.

 5 **Notes:** The strength of interaction between mitigation actions and SDGs is described with a seven-point scale
 6 (Nilsson et al., 2016) Also, the symbol X shows the interactions between co-benefits/risk associated with
 7 mitigation actions and the SDGs. **SDG1:** Sufficiency and efficiency measures result in reduced energy
 8 expenditures and other financial savings that further lead to poverty reduction. Access to modern energy forms
 9 will largely help alleviate poverty in developing countries as the productive time of women and children will
 10 increase, new activities can be developed, etc. The distributional costs of some mitigation policies promoting
 11 energy efficiency and lower carbon energy may reduce the disposable income of the poor. **SDG2:** Energy
 12 sufficiency and efficiency measures result in lower energy bills and avoiding the “heat or eat” dilemma. Improved
 13 cook-stoves provide better food security and reduces the danger of fuel shortages in developing countries; under
 14 real-world conditions these impacts may be limited as the households use these stoves irregularly and
 15 inappropriately. Green roofs can support food production. Improving energy access enhances agricultural
 16 productivity and improves food security; on the other hand, increased bioenergy production may restrict the
 17 available land for food production. **SDG3:** All categories of mitigation action result in health benefits through
 18 better indoor air quality, energy/fuel poverty alleviation, better ambient air quality, and reduction of the heat island
 19 effect. Efficiency measures with inadequate ventilation may lead to the sick building syndrome symptoms. **SDG4:**
 20 Energy efficiency measures result in reduced school absenteeism due to better indoor environmental conditions.
 21 Also, fuel poverty alleviation increases the available space at home for reading. Improved access to electricity and
 22 clean fuels enables people living in poor developing countries to read, while it is also associated with greater
 23 school attendance by children. **SDG5:** Efficient cook-stoves and improved access to electricity and clean fuels in
 24 developing countries will result in substantial time savings for women and children, thus increasing the time for
 25 rest, communication, education and productive activities. **SDG6:** Reduced energy demand due to sufficiency and
 26 efficiency measures as well as an upscaling of RES can lead to reduced water demand for thermal cooling at
 27 energy production facilities. Also, water savings result through improved conditions and lower space of dwellings.
 28 Improved access to electricity is necessary to treat water at homes. In some situations, the switch to bioenergy
 29 could increase water use compared to existing conditions. **SDG7:** All categories of mitigation action result in
 30 energy/fuel poverty alleviation in both developed and developing countries as well as in improving the security
 31 of energy supply. **SDG8:** Positive and negative direct and indirect macroeconomic effects (GDP, employment,
 32 public budgets) associated with lower energy prices due to the reduced energy demand, energy efficiency and
 33 RES investments, improved energy access and fostering innovation. Also, energy efficient buildings with
 34 adequate ventilation, result in productivity gains and improve the competitiveness of the economy. **SDG9:**
 35 Adoption of distributed generation and smart grids helps in infrastructure improvement and expansion. Also, the
 36 development of “green buildings” can foster innovation. Reduced energy demand due to sufficiency and
 37 efficiency measures as well as an upscaling of RES can lead to early retirement of fossil energy infrastructure.
 38 **SDG10:** Efficient cook-stoves as well as improved access to electricity and clean fuels in developing countries
 39 will result in substantial time savings for women and children, thus enhancing education and the development of
 40 productive activities. Sufficiency and efficiency measures lead to lower energy expenditures, thus reducing
 41 income inequalities. The distributional costs of some mitigation policies promoting energy efficiency and lower
 42 carbon energy as well as the need for purchasing more expensive equipment and appliances may reduce the
 43 disposable income of the poor and increase inequalities. **SDG11:** Sufficiency and efficiency measures as well as
 44 fuel switching to RES and improvements in energy access would eliminate major sources (both direct and indirect)
 45 of poor air quality (indoor and outdoor). Helpful if in-situ production of RES combined with charging electric
 46 two, three and four wheelers at home. Buildings with high energy efficiency and/or green features are sold/rented

1 at higher prices than conventional, low energy efficient houses. **SDG12**: Energy sufficiency and efficiency
2 measures as well as deployment of RES result in reduced consumption of natural resources, namely fossil fuels,
3 metal ores, minerals, water, etc. Negative impacts on natural resources could be arisen from increased penetration
4 of new efficient appliances and equipment. **SDG13**: See sections 9.4-9.6. **SDG15**: Efficient cookstoves and
5 improved access to electricity and clean fuels in developing countries will result in halting deforestation. **SDG16**:
6 Building retrofits are associated with lower crime. Improved access to electric lighting can improve safety
7 (particularly for women and children). Institutions that are effective, accountable and transparent are needed at all
8 levels of government for providing energy access and promoting modern renewables as well as boosting
9 sufficiency and efficiency. **SDG17**: The development of zero energy buildings requires among others capacity
10 building, citizen participation as well as monitoring of the achievements.

20 et al. 2016; Rao and Pachauri 2017; Rosenthal et al. 2018; Saheb et al. 2018b,a; Scott et al. 2014; Smith et al.
21 2016; Steenland et al. 2018; Tajani et al. 2018; Teubler et al. 2020; Thomson et al. 2017a; Tonn et al. 2018; Torero
22 2015; Van de Ven et al. 2020; Venugopal et al. 2018; Wierzbicka et al. 2018; Willand et al. 2015a; Winter et al.
23 2015; Zheng et al. 2012; Liu et al. 2015a; Sola et al. 2016; Song et al. 2016; Zhao et al. 2017; Grubler et al. 2018;
24 Thema et al. 2017; Üрге-Vorsatz et al. 2016; Nikas et al. 2020) (Blair et al. 2021; Batchelor et al. 2019; ESMAP
25 et al. 2020; Walters and Midden 2018) (European Commission 2016) (MacNaughton et al. 2018)

26 A review of a relatively limited number of studies made by (Üрге-Vorsatz et al. 2016) and (Payne et al.
27 2015) showed that the size of multiple benefits of mitigation actions in the sector of buildings may
28 range from 22% up to 7,400% of the corresponding energy cost savings. In 7 out of 11 case studies
29 reviewed, the value of the multiple impacts of mitigation actions was equal or greater than the value of
30 energy savings. Even in these studies, several effects have not been measured and consequently the size
31 of multiple benefits of mitigation actions may be even higher. Quantifying and if possible, monetizing,
32 these wider impacts of climate action would facilitate their inclusion in cost-benefit analysis, strengthen
33 the adoption of ambitious emissions reduction targets, and improve coordination across policy areas
34 reducing costs (Thema et al. 2017) (Smith et al. 2016).

35

36 **9.8.2 Climate mitigation actions in buildings and health impacts**

37 **9.8.2.1 Lack of access to clean energy**

38 In 2018, approximately 2.8 billion people worldwide, most of whom live in Asia and Africa, still use
39 polluting fuels, such as fuelwood, charcoal, dried crops, cow dung, etc., in low-efficiency stoves for
40 cooking and heating, generating household air pollution (HAP), which adversely affects the health of
41 the occupants of the dwellings, especially children and women (World Health Organization 2016;
42 Quinn et al. 2018; Rahut et al. 2017; Mehetre et al. 2017; Rosenthal et al. 2018; Das et al. 2018; Xin et
43 al. 2018; Liu et al. 2018) (IEA et al. 2020b). Exposure to HAP from burning these fuels is estimated to
44 have caused 3.8 million deaths from heart diseases, strokes, cancers, acute lower respiratory infections
45 in 2016 (World Health Organization 2018). It is acknowledged that integrated policies are needed to
46 address simultaneously universal energy access, limiting climate change and reducing air pollution
47 (World Health Organization 2016). (Rafaj et al. 2018) showed that a scenario achieving these SDGs in
48 2030 will imply in 2040 two million fewer premature deaths from HAP compared to current levels, and
49 1.5 million fewer premature deaths in relation to a reference scenario, which assumes the continuation
50 of existing and planned policies. The level of incremental investment needed in developing countries
51 to achieve universal access to modern energy was estimated at around USD0.8 trillion cumulatively to
52 2040 in the scenarios examined (Rafaj et al. 2018).

1 At the core of these policies is the promotion of improved cook-stoves and other modern energy-
2 efficient appliances to cook (for the health benefits of improved cook-stoves see for example (García-
3 Frapolli et al. 2010; Aunan et al. 2013) (Jeuland et al. 2018; Malla et al. 2011)), as well as the use of
4 non-solid fuels by poor households in developing countries (Figure 9.19). Most studies agree that the
5 use of non-solid energy options such as LPG, ethanol, biogas, piped natural gas, and electricity is more
6 effective in reducing the health impacts of HAP compared to improved biomass stoves (see for example
7 (Larsen 2016; Rosenthal et al. 2018; Steenland et al. 2018; Goldemberg et al. 2018). On the other hand,
8 climate change mitigation policies (e.g., carbon pricing) may increase the costs of some of these clean
9 fuels (e.g., LPG, electricity), slowing down their penetration in the poor segment of the population and
10 restricting the associated health benefits (Cameron et al. 2016). In this case, appropriate access policies
11 should be designed to efficiently shield poor households from the burden of carbon taxation (Cameron
12 et al. 2016). The evaluation of the improved biomass burning cook-stoves under real-world conditions
13 has shown that they have lower than expected, and in many cases limited, long-run health and
14 environmental impacts, as the households use these stoves irregularly and inappropriately, fail to
15 maintain them, and their usage decline over time (Wathore et al. 2017; Patange et al. 2015; Aung et al.
16 2016; Hanna et al. 2016). In this context, the various improved cook-stoves programs should consider
17 the mid- and long-term needs of maintenance, repair, or replacement to support their sustained use
18 (Schilman et al. 2019; Shankar et al. 2014).

2

1 Electrification of households in rural or remote areas results also to significant health benefits. For
2 example, in El Salvador, rural electrification of households leads to reduced overnight air pollutants
3 concentration by 63% due to the substitution of kerosene as a lighting source, and 34-44% less acute
4 respiratory infections among children under six (Torero 2015). In addition, the connection of the health
5 centres to the grid leads to improvements in the quality of health care provided (Lenz et al. 2017).

6 **9.8.2.2 Energy/fuel poverty, indoor environmental quality and health**

7 Living in fuel poverty, and particularly in cold and damp housing is related to excess winter mortality
8 and increased morbidity rates due to respiratory and cardiovascular diseases, arthritic and rheumatic
9 illnesses, asthma, etc. (Camprubí et al. 2016; Wilson et al. 2016; Lacroix and Chaton 2015; Ormandy
10 and Ezratty 2016; Payne et al. 2015; Thema et al. 2017). In addition, lack of affordable warmth can
11 generate stress related to chronic discomfort and high bills, fear of falling into debt, and a sense of
12 lacking control, which are potential drivers of further negative mental health outcomes, such as
13 depression (Howden-Chapman et al. 2012; Payne et al. 2015; Wilson et al. 2016; Liddell and Guiney
14 2015). Health risks from exposure to cold and inadequate indoor environmental quality may be higher
15 for low-income, energy-poor households, and in particular for those with elderly, young children, and
16 members with existing respiratory illness (Payne et al. 2015; Thomson et al. 2017b; Nunes 2019). High
17 temperatures during summer can also be dangerous for people living in buildings with inadequate
18 thermal insulation and inappropriate ventilation (Sanchez-Guevara et al. 2019; Thomson et al. 2019;
19 Ormandy and Ezratty 2016). Summer fuel poverty (or summer overheating risk) may increase
20 significantly in the coming decades under a warming climate (see also Section 9.7), with the poorest,
21 who cannot afford to install air conditioning, and the elderly (Nunes 2020) being the most vulnerable.

22 Improved energy efficiency in buildings contributes in fuel poverty alleviation and brings health gains
23 through improved indoor temperatures and comfort as well as reduced fuel consumption and associated
24 financial stress (Thomson and Thomas 2015; Curl et al. 2015; Poortinga et al. 2018; Lacroix and Chaton
25 2015; Liddell and Guiney 2015) (Willand et al. 2015). On the other hand, households suffering most
26 from fuel poverty experience more barriers for undertaking building retrofits (Camprubí et al. 2016)
27 (Charlier et al. 2018; Braubach and Ferrand 2013), moderating the potential health gains associated
28 with implemented energy efficiency programs. This can be avoided if implemented policies to tackle
29 fuel poverty target the most socially vulnerable households (Lacroix and Chaton 2015; Camprubí et al.
30 2016). (Mzavanadze 2018a) estimated that in EU-28 accelerated energy efficiency policies, reducing
31 the energy demand in residential sector by 333 TWh in 2030 compared to a reference scenario, coupled
32 with strong social policies targeting the most vulnerable households, could deliver additional co-
33 benefits in the year of 2030 of around 24,500 avoided premature deaths due to indoor cold and around
34 22,300 DALYs of avoided asthma due to indoor dampness. The health benefits of these policies amount
35 to €4.8 billion in 2030. The impacts on inhabitants in developing countries would be much greater than
36 those in EU-28 owing to the much higher prevalence of impoverished household.

37 Apart from thermal comfort, the internal environment of buildings impacts public health through a
38 variety of pathways including inadequate ventilation, poor indoor air quality, chemical contaminants
39 from indoor or outdoor sources, outdoor noise, or poor lighting. The implementation of interventions
40 aiming to improve thermal insulation of buildings combined with inadequate ventilation may increase
41 the risk of mould and moisture problems due to reduced air flow rates, leading to indoor environments
42 that are unhealthy, with the occupants suffering from the sick building syndrome symptoms
43 (Wierzbicka et al. 2018; Cedeño-Laurent et al. 2018) (Willand et al. 2015). On the other hand, if the
44 implementation of energy efficiency interventions or the construction of green buildings is accompanied
45 by adequate ventilation, the indoor environmental conditions are improved through less moisture,
46 mould, pollutant concentrations, and allergens, which result in fewer asthma symptoms, respiratory
47 risks, chronic obstructive pulmonary diseases, heart disease risks, headaches, cancer risks, etc. (Cowell
48 2016; Allen et al. 2015; Doll et al. 2016; Wilson et al. 2016; Thomson and Thomas 2015) (Hamilton et
49 al. 2015; Militello-Hourigan and Miller 2018; Underhill et al. 2018; Cedeño-Laurent et al. 2018). (Fisk
50 2018) showed that increased ventilation rates in residential buildings results in health benefits ranging
51 from 20% to several-fold improvements; however, these benefits do not occur consistently, and
52 ventilation should be combined with other exposure control measures. As adequate ventilation imposes

1 additional costs, the sick building syndrome symptoms are more likely to be seen in low income
2 households (Shrubsole et al. 2016).

3 The health benefits of residents due to mitigation actions in buildings are significant (for a review see
4 (Maidment et al. 2014; Fisk et al. 2020; Thomson and Thomas 2015)), and are higher among low
5 income households and/or vulnerable groups, including children, the elderly and those with pre-existing
6 illnesses (Maidment et al. 2014; IEA 2014; Ortiz et al. 2019). (Tonn et al. 2018) estimated that the
7 health-related benefits attributed to the two weatherization programs implemented in the US in 2008
8 and 2010 exceeds by a factor of 3 the corresponding energy cost savings yield. (IEA 2014) also found
9 that the health benefits attributed to energy efficiency retrofit programs may outweigh their costs by up
10 to a factor of 3. (Ortiz et al. 2019) estimated that the energy retrofit of vulnerable households in Spain
11 requires an investment of around EUR 10.9-12.3 thousands per dwelling and would generate an average
12 saving to the healthcare system of EUR 372 per year and dwelling (due to only better thermal comfort
13 conditions in winter).

14 **9.8.2.3 Outdoor air pollution**

15 According to (World Health Organization 2018) around 4.2 million premature deaths worldwide (in
16 both cities and rural areas) are attributed to outdoor air pollution. Only in China, the premature
17 mortalities attributed to PM_{2.5} and O₃ emissions exceeded 1.1 million in 2010 (Gu et al. 2018).
18 Mitigation actions in residential and non-residential sectors decrease the amount of fossil fuels burnt
19 either directly in buildings (for heating, cooking, etc.) or indirectly for electricity generation and thereby
20 reduce air pollution (e.g., PM, O₃, SO₂, NO_x), improve ambient air quality and generate significant
21 health benefits through avoiding premature deaths, lung cancers, ischemic heart diseases, hospital
22 admissions, asthma exacerbations, respiratory symptoms, etc. (Karlsson et al. 2020; Balaban and
23 Puppim de Oliveira 2017; MacNaughton et al. 2018; Levy et al. 2016). Several studies have monetized
24 the health benefits attributed to reduced outdoor air pollution due to the implementation of mitigation
25 actions in buildings, and their magnitude expressed as a ratio to the value of energy savings resulting
26 from the implemented interventions in each case, are in the range of 0.08 in EU, 0.18 in Germany, 0.26-
27 0.40 in US, 0.34 in Brazil, 0.47 in Mexico, 0.74 in Turkey, 8.28 in China and 11.67 in India (Diaz-
28 Mendez et al. 2018; Joyce et al. 2013; MacNaughton et al. 2018; Levy et al. 2016). In developed
29 economies, the estimated co-benefits are relatively low due to the fact that the planned interventions
30 influence a quite clean energy source mix (Tuomisto et al. 2015; MacNaughton et al. 2018). On the
31 other hand, the health co-benefits in question are substantially higher in countries and regions with
32 greater dependency on coal for electricity generation and higher baseline morbidity and mortality rates
33 (Kheirbek et al. 2014; MacNaughton et al. 2018).

34 **9.8.3 Other environmental benefits of mitigation actions**

35 Apart from the health benefits mentioned above, mitigation actions in the buildings sector are also
36 associated with environmental benefits to ecosystems and crops, by avoiding acidification and
37 eutrophication, biodiversity through green roofs and walls, building environment through reduced
38 corrosion of materials, etc. (Mzavanadze 2018b; Thema et al. 2017) (Knapp et al. 2019; Mayrand and
39 Clergeau 2018), while some negative effects cannot be excluded (Dylewski and Adamczyk 2016).

40 Also, very important are the effects of mitigation actions in buildings on the reduction of consumption
41 of natural resources, namely fossil fuels, metal ores, minerals, etc. These comprise savings from the
42 resulting reduced consumption of fuels, electricity and heat and the lifecycle-wide resource demand for
43 their utilities, as well as potential net savings from the substitution of energy technologies used in
44 buildings (production phase extraction) (Thema et al. 2017) (European Commission 2016). (Teubler et
45 al. 2020) found that the implementation of an energy efficiency scenario in European buildings will
46 result in resource savings (considering only those associated with the generation of final energy
47 products) of 406 kg per MWh lower final energy demand in the residential sector, while the
48 corresponding figure for non-residential buildings was estimated at 706 kg per MWh of reduced energy
49 demand. On the other hand, (Smith et al. 2016) claim that a switch to more efficient appliances could
50 result in negative impacts from increased resource use, which can be mitigated by avoiding premature
51 replacement and maximizing recycling of old appliances.

1 Mitigation actions aiming to reduce the embodied energy of buildings through using local and
2 sustainable building materials can be used to leverage new supply chains (e.g., for forestry products),
3 which in turn bring further environmental and social benefits to local communities (Hashemi et al. 2015;
4 Cheong C and Storey D 2019). Furthermore, improved insulation and the installation of double- or
5 triple-glazed windows result in reduced noise levels. It is worth mentioning that for every 1 dB decrease
6 in excess noise, academic performance in schools and productivity of employees in office buildings
7 increases by 0.7% and 0.3% respectively (Kockat et al. 2018b). (Smith et al. 2016) estimated that in the
8 UK the annual noise benefits associated with energy renovations in residential buildings may reach
9 £400 million in 2030 outweighing the benefits of reduced air pollution.

10 **9.8.4 Social well-being**

11 **9.8.4.1 *Energy/fuel poverty alleviation***

12 In 2018 almost 0.79 billion people in developing countries did not have access to electricity, while
13 approximately 2.8 billion people relied on polluting fuels and technologies for cooking (IEA et al.
14 2020b). Only in sub-Saharan Africa, about 548 million people (i.e., more than 50% of the population)
15 live without electricity. In developed economies, the EU Energy Poverty Observatory estimated that in
16 EU-28 44.5 million people were unable to keep their homes warm in 2016, 41.5 million had arrears on
17 their utility bills the same year, 16.3% of households faced disproportionately high energy expenditure
18 in 2010, and 19.2% of households reported being uncomfortably hot during summer in 2012 (Thomson
19 and Bouzarovski 2018). (Okushima 2016) using the “expenditure approach” estimated that fuel poverty
20 rates in Japan reached 8.4% in 2013. In the US, in 2015, 17 million households (14.4% of the total)
21 received an energy disconnect/delivery stop notice and 25 million households (21.2% of the total) had
22 to forgo food and medicine to pay energy bills (Bednar and Reames 2020).

23 The implementation of well-designed climate mitigation measures in buildings can help to reduce
24 energy/fuel poverty and improve living conditions with significant benefits for health (see Section
25 9.8.2) and well-being (Smith et al. 2016; Payne et al. 2015; Tonn et al. 2018). The social implications
26 of energy poverty alleviation for the people in low- and middle-income developing countries with no
27 access to clean energy fuels are further discussed in Section 9.8.4.2. In other developing countries and
28 in developed economies as well, the implementation of mitigation measures can improve the ability of
29 households to affordably heat/cool a larger area of the home, thus increasing the space available to a
30 family and providing more private and comfortable spaces for several activities like homework (Payne
31 et al. 2015). By reducing energy expenditures and making energy bills more affordable for households,
32 a “heat or eat” dilemma can be avoided resulting in better nutrition and reductions in the number of low
33 birthweight babies (Payne et al. 2015; Tonn et al. 2018). Also, renovated buildings and the resulting
34 better indoor conditions, can enable residents to avoid social isolation, improve social cohesion, lower
35 crime, etc. (Payne et al. 2015). (European Commission 2016) found that under an ambitious recast of
36 Energy Performance Buildings Directive (EPBD), the number of households that may be lifted from
37 fuel poverty across the EU lies between 5.17 and 8.26 million. To capture these benefits, mitigation
38 policies and particularly energy renovation programmes should target the most vulnerable among the
39 energy-poor households, which very often are ignored by the policy makers. In this context, it is
40 recognized that fuel poverty should be analysed as a multidimensional social problem (Mashhoodi et
41 al. 2019; Thomson et al. 2017b) (Charlier and Legendre 2019; Baker et al. 2018), as it is related to
42 energy efficiency, household composition, age and health status of its members, social conditions
43 (single parent families, existence of unemployed and retired people, etc.), energy prices, disposable
44 income, etc. In addition, the geographical dimension can have a significant impact on the levels of fuel
45 poverty and should be taken into account when formulating response policies (Besagni and Borgarello
46 2019; Mashhoodi et al. 2019).

47 **9.8.4.2 *Improved access to energy sources, gender equality and time savings***

48 In most low- and middle-income developing countries women and children (particularly girls) spend a
49 significant amount of their time for gathering fuels for cooking and heating (World Health Organization
50 2016; Rosenthal et al. 2018). For example, in Africa more than 70% of the children living in households
51 that primarily cook with polluting fuels spend at least 15 hours and, in some countries, more than 30
52 hours per week in collecting wood or water, facing significant safety risks and constraints on their

1 available time for education and rest (World Health Organization 2016; Mehetre et al. 2017). Also, in
2 several developing countries (e.g., in most African countries but also in India, in rural areas in Latin
3 America and elsewhere) women spend several hours to collect fuel wood and cook, thus limiting their
4 potential for productive activities for income generation or rest (García-Frapolli et al. 2010; Mehetre
5 et al. 2017; World Health Organization 2016). Expanding access to clean household energy for cooking,
6 heating and lighting will largely help alleviate these burdens (Lewis et al. 2017; World Health
7 Organization 2016; Rosenthal et al. 2018) (Malla et al. 2011). (Jeuland et al. 2018) found that the time
8 savings associated with the adoption of cleaner and more fuel-efficient stoves by low-income
9 households in developing countries are amount to USD 1.3-1.9 per household per month, constituting
10 the 23-43% of the total social benefits attributed to the promotion of clean stoves.

11 Electrification of remote rural areas and other regions that do not have access to electricity enables
12 people living in poor developing countries to read, socialize, and be more productive during the evening,
13 while it is also associated with greater school attendance by children (Torero 2015; Rao et al. 2016;
14 Barnes and Samad 2018). (Chakravorty et al. 2014) found that a grid connection can increase non-
15 agricultural incomes of rural households in India from 9% up to 28.6% (assuming a higher quality of
16 electricity). On the other hand, some studies clearly show that electricity consumption for connected
17 households is extremely low, with limited penetration of electrical appliances (e.g., (Lee et al. 2017;
18 Cameron et al. 2016) and low quality of electricity (Chakravorty et al. 2014). The implementation of
19 appropriate policies to overcome bureaucratic red tape, low reliability, and credit constraints, is
20 necessary for maximizing the social benefits of electrification.

21 **9.8.5 Economic implications of mitigation actions**

22 **9.8.5.1 Buildings-related labour productivity**

23 Low-carbon buildings, and particularly well-designed, operated and maintained high-performance
24 buildings with adequate ventilation, may result in productivity gains and improve the competitiveness
25 of the economy through three different pathways (Bleyle et al. 2019; Thema et al. 2017; Niemelä et al.
26 2017; Mofidi and Akbari 2017; MacNaughton et al. 2015) (European Commission 2016): (i) increasing
27 the amount of active time available for productive work by reducing the absenteeism from work due to
28 illness, the presenteeism (i.e., working with illness or working despite being ill), and the inability to
29 work due to chronic diseases caused by the poor indoor environment; (ii) improving the indoor air
30 quality and thermal comfort of non-residential buildings, which can result in better mental well-being
31 of the employees and increased workforce performance; and (iii) reducing the school absenteeism due
32 to better indoor environmental conditions, which may enhance the future earnings ability of the students
33 and restrict the parents absenteeism due to care-taking of sick children.

34 Productivity gains due to increased amount of active time for work is directly related to acute and
35 chronic health benefits attributed to climate mitigation actions in buildings (see Section 9.8.2.2). The
36 bulk of studies quantifying the impact of energy efficiency on productivity focus on acute health effects.
37 Proper ventilation in buildings is of particular importance and can reduce absenteeism due to sick days
38 by 0.6–1.9 days per person per year (MacNaughton et al. 2015)(Ben-David et al. 2017; Thema et al.
39 2017). In a pan-European study, (Chatterjee and Ürgel-Vorsatz 2018) showed that deep energy retrofits
40 in residential buildings may increase the number of active days by 1.78-5.27 (with an average of 3.09)
41 per year and person who has actually shifted to a deep retrofitted building. Similarly, the interventions
42 in the non-residential buildings result in increased active days between 0.79 and 2.43 (with an average
43 of 1.4) per year and person shifted to deeply retrofitted non-residential buildings.

44 As regards improvements in workforce performance due to improved indoor conditions (i.e., air quality,
45 thermal comfort, etc.), (Kozusznik et al. 2019) conducted a systematic review on whether the
46 implementation of energy efficient interventions in office buildings influence well-being and job
47 performance of employees. Among the 34 studies included in this review, 31 found neutral to positive
48 effects of green buildings on productivity and only 3 studies indicated detrimental outcomes for office
49 occupants in terms of job performance. Particularly longitudinal studies, which observe and compare
50 the office users' reactions over time in conventional and green buildings, show that green buildings
51 have neutral to positive effects on occupants well-being and work performance (Thatcher and Milner
52 2016; Candido et al. 2019; Kozusznik et al. 2019). (Bleyle et al. 2019) estimated that deep energy retrofits

1 in office buildings in Belgium would generate a workforce performance increase of 10.4 to 20.8
2 EUR·m⁻² renovated. In Europe every 1°C reduction in overheating during the summer period increases
3 students learning performance by 2.3% and workers performance in office buildings by 3.6% (Kockat
4 et al. 2018b). Considering the latter indicator, it was estimated that by reducing overheating across
5 Europe, the overall performance of the workers in office buildings can increase by 7-12% (Kockat et
6 al. 2018b).

7 **9.8.5.2 Enhanced asset values of energy efficient buildings**

8 A significant number of studies confirm that homes with high energy efficiency and/or green features
9 are sold at higher prices than conventional, low energy efficient houses. A review of 15 studies from 12
10 different countries showed that energy efficient dwellings have a price premium ranging between 1.5%
11 and 28%, with a median estimated at 7.8%, for the highest energy efficient category examined in each
12 case study compared to reference houses with the same characteristics but lower energy efficiency (the
13 detailed results of this review are presented in Table SM9.55 included in the Supplementary Material).
14 In a given real estate market, the higher the energy efficiency of dwellings compared to conventional
15 housing, the higher their selling prices. However, a number of studies show that this premium is largely
16 realized during resale transactions and is smaller or even negative in some cases immediately after the
17 completion of the construction (Deng and Wu 2014; Yoshida and Sugiura 2015). A relatively lower
18 number of studies (also included in Table SM9.5 of Supplementary Material) show that energy
19 efficiency and green features have also a positive effect on rental prices of dwellings (Cajias et al. 2019;
20 Hyland et al. 2013), but this is weaker compared to sales prices, and in a developing country even
21 negative as green buildings, which incorporate new technologies such as central air conditioning, are
22 associated with higher electricity consumption (Zheng et al. 2012).

23 Regarding non-residential buildings, (European Commission 2016) reviewed a number of studies
24 showing that buildings with high energy efficiency or certified with green certificates present higher
25 sales prices by 5.2-35%, and higher rents by 2.5-11.8%. More recent studies in relation to those included
26 in the review confirm these results (e.g., (Mangialardo et al. 2018; Ott and Hahn 2018)) or project even
27 higher premiums (e.g., (Chegut et al. 2014)) found that green certification in the London office market
28 results in a premium of 19.7% for rents). On the other hand, in Australia, a review study showed mixed
29 evidence regarding price differentials emerged as a function of energy performance of office buildings
30 (Acil Allen Consulting 2015). Other studies have shown that energy efficiency and green certifications
31 have been associated with lower default rates for commercial mortgages (An and Pivo 2020; Wallace
32 et al. 2018; Mathew et al. 2021).

33 More generally, (Giraudet 2020) based on a meta-analysis of several studies, showed that the
34 capitalization of energy efficiency is observed in building sales and rental (even in the absence of energy
35 performance certificates), but the resulting market equilibrium can be considered inefficient as rented
36 dwellings are less energy efficient than owner-occupied ones.

37 **9.8.5.3 Macroeconomic effects**

38 Investments required for the implementation of mitigation actions, create, mainly in the short-run,
39 increase in the economic output and employment in sectors delivering energy efficiency services and
40 products, which are partially counterbalanced by less investments and lower production in other parts
41 of the economy (Thema et al. 2017; US EPA 2018; Yushchenko and Patel 2016) (European
42 Commission 2016) (see also Cross-Working Group Box 1 in Chapter 3). The magnitude of these
43 impacts depends on the structure of the economy, the extent to which energy saving technologies are
44 produced domestically or imported from abroad, but also from the growth cycle of the economy with
45 the benefits being maximized when the related investments are realized in periods of economic
46 recession (Mirasgedis et al. 2014; Thema et al. 2017; Yushchenko and Patel 2016). Particularly in
47 developing countries if the mitigation measures and other interventions to improve energy access
48 (Figure 9.19) are carried out by locals, the impact on economy, employment and social well-being will
49 be substantial (Mills 2016; Lehr et al. 2016). As many of these programs are carried out with foreign
50 assistance funds, it is essential that the funds be spent in-country to the full extent possible, while some
51 portion of these funds would need to be devoted to institution building and especially training. (Mills
52 2016) estimated that a market transformation from inefficient and polluting fuel-based lighting to solar-

1 LED systems to fully serve the 112 million households that currently lack electricity access will create
2 directly 2 million new jobs in these developing countries, while the indirect effects could be even
3 greater. (IEA 2020b) estimated that 9-30 jobs would be generated for every million dollars invested in
4 building retrofits or in construction of new energy efficient buildings (gross direct and indirect
5 employment), with the highest employment intensity rates occurring in developing countries.
6 Correspondingly, 7-16 jobs would be created for every million dollars spent in purchasing highly
7 efficient and connected appliances, while expanding clean cooking through LPG could create 16-75
8 direct local jobs per million dollars invested. Increases in product and employment attributed to energy
9 efficiency investments also affect public budgets by increasing income and business taxation, reducing
10 unemployment benefits, etc. (Thema et al. 2017), thus mitigating the impact on public deficit of
11 subsidizing energy saving measures (Mikulic et al. 2016).

12 Furthermore, energy savings due to the implementation of mitigation actions will result, mainly in the
13 long-run, in increased disposable income for households, which in turn may be spent to buy other goods
14 and services, resulting in economic development, creation of new permanent employment and positive
15 public budget implications (IEA 2014; US EPA 2018; Thema et al. 2017). According to (Anderson et
16 al. 2014), the production of these other goods and services is usually more labour-intensive compared
17 to energy production, resulting in net employment benefits of about 8 jobs per million dollars of
18 consumer bill savings in the US. These effects may again have a positive impact on public budgets.
19 Furthermore, reduced energy consumption on a large scale is likely to have an impact on lower energy
20 prices and hence on reducing the cost of production of various products, improving the productivity of
21 the economy and enhancing security of energy supply (IEA 2014; Thema et al. 2017).

22 **9.8.5.4 Energy security**

23 GHG emission reduction actions in the sector of buildings affect energy systems by: (i) reducing the
24 overall consumption of energy resources, especially fossil fuels; (ii) promoting the electrification of
25 thermal energy uses; and (iii) enhancing distributed generation through the incorporation of RES and
26 other clean and smart technologies in buildings. Increasing sufficiency, energy efficiency and
27 penetration of RES result in improving the primary energy intensity of the economy and reducing
28 dependence on fossil fuels, which for many countries are imported energy resources (Markovska et al.
29 2016; Thema et al. 2017; Boermans et al. 2015). The electrification of thermal energy uses is expected
30 to increase the demand for electricity in buildings, which in most cases can be reversed (at national or
31 regional level) by promoting nearly zero energy new buildings and a deep renovation of the existing
32 building stock (Couder and Verbruggen 2017; Boermans et al. 2015). In addition, highly efficient
33 buildings can keep the desired room temperature stable over a longer period and consequently they have
34 the capability to shift heating and cooling operation in time (Boermans et al. 2015). These result in
35 reduced peak demand, lower system losses and avoided generation and grid infrastructure investments.
36 As a significant proportion of the global population, particularly in rural and remote locations, still lack
37 access to modern energy sources, renewables can be used to power distributed generation or micro-grid
38 systems that enable peer-to-peer energy exchange, constituting a crucial component to improve energy
39 security for rural populations (Leibrand et al. 2019; Kirchhoff and Strunz 2019). For successful
40 development of peer-to-peer micro-grids, financial incentives to asset owners are critical for ensuring
41 their willingness to share their energy resources, while support measures should be adopted to ensure
42 that also non-asset holders can contribute to investments in energy generation and storage equipment
43 and have the ability to sell electricity to others (Kirchhoff and Strunz 2019).

44

45 **9.9 Sectoral barriers and policies**

46 **9.9.1 Barriers, feasibility, and acceptance**

47 Understanding the reasons why cost-effective investment in building energy efficiency are not taking
48 place as expected by rational economic behaviour is critical to design effective policies for decarbonize
49 the buildings (Cattaneo 2019; Cattano et al. 2013). Barriers depend from the actors (owner, tenant,
50 utility, regulators, manufacturers, etc.), their role in energy efficiency project and the market,

1 technology, financial economic, social, legal, institutional, regulatory and policy structures (Reddy
2 1991; Weber 1997; Sorrell et al. 2000; Reddy 2002; Sorrell et al. 2011; Cagno et al. 2012; Bardhan et
3 al., 2014; Bagaini et al. 2020; Vogel et al. 2015; Khosla et al. 2017; Gupta et al. 2017). Barriers
4 identified for the refurbishment of exiting building or construction of new efficient buildings includes:
5 lack of high-performance products, construction methods, monitoring capacity, investment risks,
6 policies intermittency, information gaps, principal agent problems (both tenant and landlord face
7 disincentives to invest in energy efficiency), skills of the installers, lack of a trained and ready
8 workforce, governance arrangements in collectively owned properties and behavioural anomalies. (Do
9 et al. 2020; Dutt 2020; Gillingham and Palmer 2014; Yang et al., 2019; Song et al. 2020; Buessler et al.
10 2017)). A better understanding of behavioural barriers (Frederiks et al. 2015) is essential to design
11 effective policies to decarbonise the building sector. Energy efficiency in buildings faces one additional
12 problem: the sector is highly heterogeneous, with many different building types, sizes and operational
13 uses. Energy efficiency investments do not take place in isolation but in competition with other priorities
14 and as part of a complex, protracted investment process (Cooremans 2011). Therefore, a focus on
15 overcoming barriers is not enough for effective policy. Organisational context is important because the
16 same barrier might have very different organisational effects and require very different policy responses
17 (Mallaburn 2018). Cross-Chapter Box 2 in Chapter 2 presents a summary of methodologies for
18 estimating the macro-level impact of policies on indices of GHG mitigation.

19 Reaching deep decarbonisation levels throughout the life cycle of buildings depend on
20 multidimensional criteria for assessing the feasibility of mitigation measures, including criteria related
21 to geophysical, environmental-ecological, technological, economic, socio-cultural and institutional
22 dimensions. An assessment of 16 feasibility criteria for mitigation measures in the buildings sector
23 indicates whether a specific factor, within broader dimensions, acts as a barrier or helps enabling such
24 mitigation measures (Figure 9.20, Supplementary material Table SM9.6, Annex II.11). Although
25 mitigation measures are aggregated in the assessment of Figure 9.20 and feasibility results can differ
26 for more specific measures, generally speaking, the barriers to mitigation measures in buildings are few,
27 sometimes including technological and socio-cultural challenges. However, many co-benefits could
28 help enable mitigation in the buildings sector. For instance, many measures can have positive effects
29 on the environment, health and well-being, and distributional potential, all of which can boost their
30 feasibility. The feasibility of mitigation measures varies significantly according to socio-economic
31 differences across and within countries.

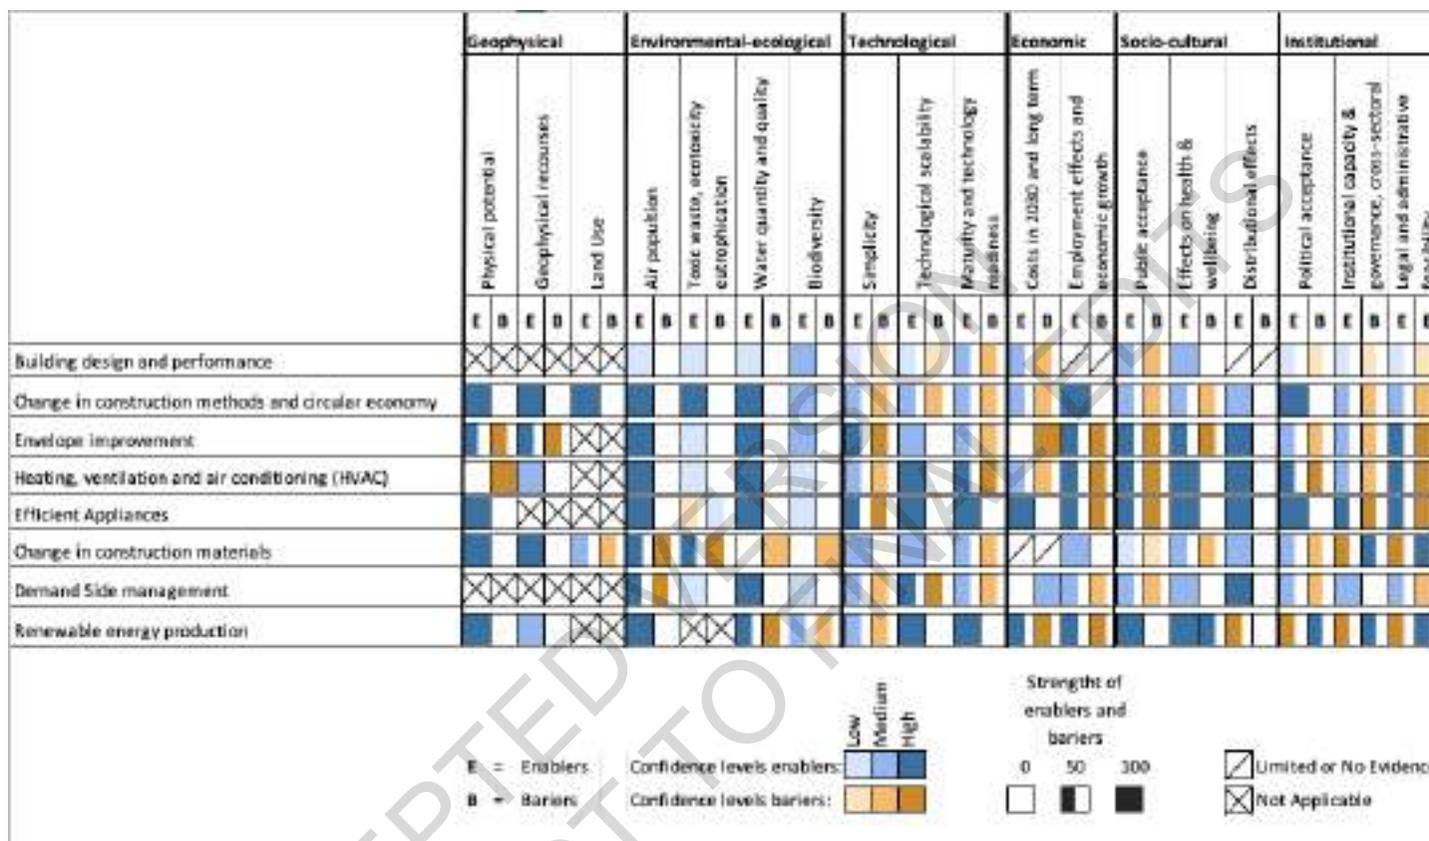

Figure 9.20 Summary of the extent to which different factors would enable or inhibit the deployment of mitigation options in buildings.

Blue bars indicate the extent to which the indicator enables the implementation of the option (E) and orange bars indicate the extent to which an indicator is a barrier (B) to the deployment of the option, relative to the maximum possible barriers and enablers assessed. A X signifies the indicator is not applicable or does not affect the feasibility of the option, while a forward slash / indicates that there is no or limited evidence whether the indicator affects the feasibility of the option. The shading indicates the level of confidence, with darker shading signifying higher levels of confidence. Table SM9.6 provides an overview of the extent to which the feasibility of options may differ across context (e.g., region), time (e.g., 2030 versus 2050), and scale (e.g., small versus large), and includes a line of sight on which the assessment is based. The assessment method is explained in Annex II.11.

1 **9.9.2 Rebound effects**

2 In the buildings sector energy efficiency improvements and promotion of cleaner fuels can lead to all
3 types of rebound effects, while sufficiency measures lead only to indirect and secondary effects (Chitnis
4 et al. 2013). The consideration of the rebound effects as a behavioural economic response of the
5 consumers to cheaper energy services can only partially explain the gap between the expected and actual
6 energy savings (Galvin and Sunikka-Blank 2017). The prebound effect, a term used to describe the
7 situation where there is a significant difference between expected and observed energy consumption of
8 non-refurbished buildings, is usually implicated in high rebound effects upon retrofitting (Teli et al.
9 2016; Cali et al. 2016; Galvin and Sunikka-Blank 2017). The access for all to modern energy services
10 such as heating and cooling is one of the wellbeing objectives governments aim for. However, ensuring
11 this access leads to an increase of energy demand which is considered as a rebound effect by (Berger
12 and Hötl 2019; Poon 2015; Seebauer 2018; Sorrell et al. 2018; Orea et al. 2015; Teli et al. 2016; Chitnis
13 et al. 2013). (Aydin et al. 2017) found that in the Netherlands the rebound effect for the lowest wealth
14 quantile is double compared to the highest wealth quantile. Similar, energy access in developing
15 countries leads to an increase consumption compared to very low baselines which is considered by some
16 authors as rebound (Copiello 2017). On the other hand, in households whose members have a higher
17 level of education and/or strong environmental values, the rebound is lower (Seebauer 2018).

18 Rebound effects in the building sector could be a co-benefit, in cases where the mechanisms involved
19 provide faster access to affordable energy and/or contribute to improved social well-being, or a trade-
20 off, to the extent that the external costs of the increased energy consumption exceed the welfare benefits
21 of the increased energy service consumption (Galvin and Sunikka-Blank 2017; Sorrell et al. 2018)
22 (Chan and Gillingham 2015; Borenstein 2015). In cases where rebound effects are undesirable,
23 appropriate policies could be implemented for their mitigation.

24 There is great variation in estimates of the direct and indirect rebound effects, which stems from the
25 end-uses included in the analysis, differences in definitions and methods used to estimate the rebound
26 effects, the quality of the data utilized, the period of analysis and the geographical area in consideration
27 (Gillingham et al. 2016; International Risk Governance Council 2013; Galvin 2014). Several studies
28 examined in the context of this assessment (see Table SM9.7) showed that direct rebound effects for
29 residential energy consumption, which includes heating, are significant and range between -9% and
30 91%, with a median at 35% in Europe, 0-30% with a median at 20% in the US, and 72-127%, with a
31 median at 89% in China. The direct rebound effects for energy services other than heating may be
32 lower (Chen et al. 2018; Sorrell et al. 2018). The rebound effects may be reduced with the time as the
33 occupants learn how to optimally use the systems installed in energy renovated buildings (Cali et al.
34 2016) and seem to be lower in the case of major renovations leading to nZEB (Corrado et al. 2016).
35 The combined direct and indirect or the indirect only rebound effects were found to range between -2%
36 and 80%, with a median at 12% (see Table SM9.7). In non-residential buildings the rebound effects
37 may be smaller, as the commercial sector is characterized by lower price elasticities of energy demand,
38 while the comfort level in commercial buildings before renovation is likely to be better compared to
39 residential buildings (Qiu 2014).

40 **9.9.3 Policy packages for the decarbonisation of buildings**

41 There is no single energy efficiency policy (Wiese et al. 2018) able to decarbonise the building sector,
42 but a range of policies are needed, often included in a policy package (Kern et al., 2017; Rosenow et al.
43 2017) to enhance robustness against risks and uncertainties in both short and long-term and addressing
44 the different stakeholder perspectives (Forouli et al. 2019; Nikas et al. 2020; Doukas and Nikas 2020).
45 This is due to: the many barriers; the different types of buildings (residential, non-residential, etc.); the
46 different socio-economic groups of the population (social housing, informal settlement, etc.); the
47 country development status; the local climate (cooling and/or heating), ownership structure (tenant or

1 owner), the age of buildings. Effective policy packages include mandatory standards, codes, the
2 provision of information, carbon pricing, financing, and technical assistance for end-users. Important
3 element related to policy packages is whether the policies reinforce each other or diminish the impact
4 of individual policies, due to policy “overcrowding”. Examples are the EU policy package for efficiency
5 in buildings (Rosenow and Bayer 2017; Economidou et al, 2020; BPIE, 2020) and China goal of 10
6 million m² NZEB during the 13th Five-Year Plan, presented in the Supplementary Material (Section
7 SM9.4). See also Cross-Chapter Box 10 in Chapter 14 for integrated policymaking for sector transitions.

8 Revisions in tenant and condominium law are necessary for reducing disincentives between landlord
9 and tenant or between multiple owners, these acts alone cannot incentivise them to uptake an energy
10 efficiency upgrade in a property (Economidou and Serrenho, 2019). A package addressing split
11 incentives include regulatory measures, information measures, labels, individual metering rules and
12 financial models designed to distribute costs and benefits to tenants and owners in a transparent and fair
13 way (Bird and Hernández 2012; Economidou and Bertoldi 2015; Castellazi et al. 2017). A more active
14 engagement of building occupants in energy saving practices, the development of agreements
15 benefitting all involved actors, acknowledgement of real energy consumption and establishment of cost
16 recovery models attached to the property instead of the owner are useful measures to address
17 misalignments between actors.

18 In developed countries policy packages are targeted to increase the number and depth of renovations of
19 existing building, while for developing countries policies focus on new construction, including
20 regulatory measures and incentives, while carbon pricing would be more problematic unless there is a
21 strong recycling of the revenues. Building energy codes and labels could be based on LCA emissions,
22 rather than energy consumption during the use phase of buildings, as it is the case in Switzerland and
23 Finland (Kuittinen and Häkkinen 2020).

24 Policy packages should also combine sufficiency, efficiency, and renewable energy instruments for
25 buildings, for example some national building energy codes already include minimum requirements for
26 the use of renewable energy in buildings.

27 **9.9.3.1 Sufficiency and efficiency policies**

28 Recently the concept of sufficiency complementary to energy efficiency has been introduced in policy
29 making (Saheb 2021; Bertoldi 2020; Hewitt 2018; Brischke et al. 2015; Thomas et al. 2019), see Box
30 9.1. Lorek and Spangenberg (2019b) investigated the limitations of the theories of planned behaviour
31 and social practice and proposed an approach combining both theories resulting in a heuristic
32 sufficiency policy tool. Lorek and Spangenberg (2019b) showed that increased living area per person
33 counteracts efficiency gains in buildings and called for sufficiency policy instruments to efficiency by
34 limit building size. This could be achieved via mandatory and prescriptive measures, e.g., progressive
35 building energy codes (IEA, 2013), or financial penalties in the form of property taxation (e.g., non-
36 linear and progressive taxation), or with mandatory limits on building size per capita. Heindl and
37 Kanschik (2016) suggested that voluntary policies promoting sufficiency and proposed that sufficiency
38 should be "integrated in a more comprehensive normative framework related to welfare and social
39 justice". Alcott highlighted that in sufficiency there is a loss of utility or welfare (Alcott, 2008), Thomas
40 et al. (2019) described some of the possible policies, some based on the sharing economy principles,
41 for examples co-sharing space, public authorities facilitating the exchange house between young and
42 expanding families with elderly people, with reduce need for space. Policies for sufficiency include
43 land-use and urban planning policies. Berril et al, (2021) proposed removing policies, which support
44 supply of larger home typologies, e.g., single-family home or local land-use regulations restricting
45 construction of multifamily buildings. In non-residential building, sufficiency could be implemented
46 through the sharing economy, for example with flexible offices space with hot-desking.

1 Scholars have identified the "energy efficiency gap" (Hirst and Brown 1990; Jaffe and Stavins 1994;
2 Stadelmann 2017; Gillingham and Palmer 2014; Alcott and Greenstone 2012) and policies to overcome
3 it. (Markandya et al. 2015) and Shen et al. (2016) have classified energy efficiency policies in three
4 broad categories: the command and control (e.g. mandatory building energy codes; mandatory
5 appliances standards, etc.); price instruments (e.g. taxes, subsidies, tax deductions, credits, permits and
6 tradable obligations, etc.); and information instruments (e.g. labels, energy audits, smart meters and
7 feed-back, etc.). Based on the EU Energy Efficiency Directive, the MURE and the IEA energy
8 efficiency policy databases (Bertoldi and Mosconi 2020), Bertoldi (2020) proposed six policy
9 categories: regulatory, financial and fiscal; information and awareness; qualification, training and
10 quality assurance; market-based instruments: voluntary action. The categorization of energy efficiency
11 policies used in this chapter is aligned with the taxonomy used in Chapter 13, sub-section 13.5.1
12 (economic or market-based instruments, regulatory instruments, and other policies). However, the
13 classification used here is more granular in order to capture the complexity of end-use energy efficiency
14 and buildings.

15 *1. Regulatory instruments*

16 Building energy codes

17 Several scholars highlighted the key role of mandatory building energy codes and minimum energy
18 performance requirements for buildings (Enker and Morrison 2017). Wang et al. (2019) finds that
19 "Building energy efficiency standards (BEES) are one of the most effective policies to reduce building
20 energy consumption, especially in the case of the rapid urbanization content in China". Ex-post policy
21 evaluation shows that stringent buildings codes reduce energy consumption in buildings and CO₂
22 emissions and are cost-effective (Scott et al. 2015; Aydin and Brounen 2019; (Yu et al. 2017; Yu et al.
23 2018)(Aroonruengsawat 2012; Levinson 2016; Kotchen 2017; Jacobsen and Kotchen 2013).
24 Progressive building energy codes include requirements on efficiency improvement but also on
25 sufficiency and share of renewables (Rosenberg et al., 2017; Clune et al. 2012) and on embodied
26 emissions (Schwarz et al. 2020), for example the 2022 ASHRAE Standard 90.1 includes prescriptive
27 on-site renewable energy requirements for non-residential building. Evans et al. (2017; 2018) calls for
28 strengthen the compliance checks with efficiency requirements or codes when buildings are in operation
29 and highlighted the need for enforcement of building energy codes to achieve the estimate energy and
30 carbon savings recommending actions to improve enforcements, including institutional capacity and
31 adequate resources.

32 Evans et al. (2017; 2018) identified strengthening the compliance checks with codes when buildings
33 are in operation and the need for enforcement of building energy codes in order to achieve the estimate
34 energy and carbon savings, recommending actions to improve enforcements, including institutional
35 capacity and adequate resources. Another important issue to be addressed by policies is the 'Energy
36 Performance Gap' (EPG), i.e., the gap between design and policy intent and actual outcomes.
37 Regulatory and market support regimes are based on predictive models (Cohen and Bordass 2015) with
38 general assumptions about building types, the way they are used and are not covering all energy
39 consumption. In the perspective of moving towards net zero carbon, it is important that policy capture
40 and address the actual in-use performance of buildings (Gupta and Kotopouleas 2018; Gupta et al.
41 2015). Outcome-based codes are increasingly important because overcome some limitations of
42 prescriptive building energy codes, which typically do not regulate all building energy uses or do not
43 regulate measured operational energy use in buildings. Regulating all loads, especially plug and process
44 loads, is important because they account for an increasingly large percentage of total energy use as
45 building envelope and space-conditioning equipment are becoming more efficient (Denniston et al.,
46 2011; Colker, 2012; Enker and Morrison, 2020).

47 Building codes could also foster the usage of wood and timber as a construction in particular for multi-
48 storey buildings and in the long term penalise carbon intensive building materials (Ludwig 2019) with

1 policies based on environmental performance assessment of buildings and the “wood first”
2 principle (Ludwig, 2019; Ramage et al., 2017).

3 Retro-commissioning is a cost-effective process to periodically check the energy performance of
4 existing building and assure energy savings are maintained overtime (Ssembatya et al., 2021)(Kong et
5 al. 2019).

6 In countries with low rate of new construction, it is important to consider mandatory building energy
7 codes for existing buildings, but this may also be relevant for countries with high new construction, as
8 they will have soon a large existing building stock. The EU has requirements already in place when
9 building undergo a major renovation (Economidou et. al, 2020). Countries considering mandatory
10 regulations for existing buildings include Canada, the U.S. (specific cities), China, Singapore. Policies
11 include mandating energy retrofits for low performances existing buildings, when sold or rented. In
12 countries with increasing building stock, in particular in developing countries, policies are more
13 effective when targeting new buildings (Kamal et al. 2019).

14 NZEBs definitions are proposed by (Marszal et al. 2011; Deng and Wu 2014; Zhang and Zhou 2015;
15 Wells et al. 2018; Williams et al. 2016);), covering different geographical areas, developing and
16 developed countries, and both existing buildings and new buildings. In 2019, China issued the national
17 standard Technical Standard for Nearly Zero Energy Building (MoHURD, 2019). California has also
18 adopted a building energy code mandating for NZEBs for new residential buildings in 2020 and 2030
19 for commercial buildings (Feng et al. 2019). Several countries have adopted targets, roadmaps or
20 mandatory building energy codes requiring net zero energy buildings (NZEBs) for some classes of new
21 buildings (Feng et al. 2019).

22 Building Labels and Energy Performance Certificates (EPCs)

23 Buildings labels are an important instrument , with some limitations. Li et al. (2019b) reviewed the EU
24 mandatory Energy Performance Certificates for buildings and proposed several measures to make the
25 EPC more effective in driving the markets towards low consumption buildings. Some authors have
26 indicated that the EPC based on the physical properties of the buildings (asset rating) may be misleading
27 due to occupancy behaviour (Cohen and Bordass 2015) and calculation errors (Crawley et al. 2019).
28 Control authorities can have a large impact on the quality of the label (Mallaburn 2018). Labels can
29 also include information on the GHG embedded in building material or be based on LCA.

30 US EPA Energy Star and NABERS (Gui and Gou, 2020) are building performance labels based on
31 performance, not on modelled energy use. Singapore has mandatory building energy labels, as do many
32 cities in the U.S., while India and Brazil have mandatory labels for public buildings.

33 Mandatory energy performance disclosure and benchmarking of building energy consumption is a
34 powerful policy instrument in particular for non-residential buildings (Trencher et al. 2016) and could
35 be more accurate than energy audits. Gabe (2016) showed that mandatory disclosure is more effective
36 than voluntary disclosure. Some US cities (e.g., New York) have adopted Emissions Performance
37 Standards for buildings, capping CO2 emissions. Accurate statistics related to energy use are very
38 important for reducing GHG in building sector. In 2015, the Republic of Korean established the National
39 Building Energy Integrated Management System, where building data and energy consumption
40 information are collected for policy development and public information.

41 Energy audits

42 Energy audits, help to overcome the information barriers to efficiency investments, in particular
43 buildings owned or occupied by small companies (Kalantzis and Revoltella, 2019). In the EU energy
44 audits are mandatory for large companies under the Energy Efficiency Directive (Nabitz and Hirzel
45 2019), with some EU Member States having a long experience with energy audits, as part of national
46 voluntary agreements with the private sector (Cornelis 2019; Rezessy and Bertoldi 2011). Singapore

1 has adopted mandatory audit for buildings (Shen et al, 2016). In the United States, several cities have
2 adopted energy informational policies in recent years, including mandatory buildings audits (Trencher
3 et al. 2016; Kontokosta et al., 2020). The State of New York has in place a subsidized energy audit for
4 residential building since 2010 (Boucher et al. 2018). It is important to assure the training of auditors
5 and the quality of the audit.

6 Minimum Energy Performance Standards (MEPSs)

7 Mandatory minimum efficiency standards for building technical equipment and appliances (e.g.,
8 HVAC, appliances, ICT, lighting, etc.) is a very common, tested and successful policy in most of the
9 OECD countries (e.g. EU, US, Canada, Australia, etc.) for improving energy efficiency (Wu et al.
10 2019; Scott et al. 2015; Sonnenschein et al. 2019). Brucal and Roberts (2019) showed that efficiency
11 standards reduce product price. McNeil et al. (2019) highlighted how efficiency standards will help
12 developing countries in reducing the power peak demand by a factor of two, thus reducing large
13 investment costs in new generation, transmission, and distribution networks. Mandatory standards have
14 been implemented also other large economies, e.g., Russia, Brazil, India, South Africa, China, Ghana,
15 Kenya, Malaysia (Salleh et al., 2019), with an increase in the uptake also in developing countries, e.g.
16 Ghana, Kenya, Tunisia, etc. In Japan, there is a successful voluntary programme the Top Runner, with
17 similar results of mandatory efficiency standards (Inoue and Matsumoto 2019).

18 Appliance energy labelling

19 Mandatory energy labelling schemes for building technical equipment and appliances are very often
20 implemented together with minimum efficiency standards, with the mandatory standard pushing the
21 market towards higher efficiency and the label pulling the market (Bertoldi, 2019). OECD countries,
22 China and many developing countries (for example Ghana, Kenya, India, South Africa, etc.) (Chunekar
23 2014) (Diawuo et al., 2018; Issock Issock et al., 2018) have adopted mandatory energy labelling. Other
24 labelling schemes are of voluntary nature, e.g. the Energy Star programme in the US (Ohler et al., 2020),
25 which covers many different appliances.

26 Information campaign

27 Provision of information (e.g. public campaigns, targeted technical information, etc.) is a common
28 policy instrument to change end-user behaviour. Many authors agree that the effect of both targeted and
29 general advertisement and campaigns have a short lifetime and the effects tend to decrease over time
30 (Simcock et al. 2014; Diffney et al. 2013; Reiss and White 2008). The meta-analysis carried out by
31 (Delmas et al. 2013) showed that energy audits and personal information were the most effective
32 followed by providing individuals with comparisons with their peers' energy use including "non-
33 monetary, information-based" (Delmas et al. 2013). An effective approach integrates the social norm
34 as the basis for information and awareness measures on energy behaviour (Gifford 2011; Schultz et al.
35 2007). Information is more successful when it inspires and engages people: how people feel about a
36 given situation often has a potent influence on their decisions (Slovic and Peters 2006). The message
37 needs to be carefully selected and kept as simple as possible focusing on the following: entertain,
38 engage, embed and educate (Dewick and Owen 2015).

39 Energy consumption feedback with smart meters, smart billing and dedicated devices and apps is
40 another instrument recently exploited to reduce energy consumption (Zangheri et al. 2019; Karlin et al.
41 2015; Buchanan et al. 2018) very often coupled with contest-based interventions or norm-based
42 interventions (Bergquist et al. 2019). (Hargreaves et al. 2018) proposes five core types of action to
43 reduce energy use: turn it off, use it less, use it more carefully, improve its performance, and replace
44 it/use an alternative. According to (Aydin et al. 2018), technology alone will not be enough to achieve
45 the desired energy savings due to the rebound effect. The lack of interest from household occupants,
46 confusing feedback message and difficulty to relate it to practical intervention, overemphasis on
47 financial savings and the risks of "fallback effects" where energy use returns to previous levels after a

1 short time or rebound effects has been pointed out (Buchanan et al. 2015) as the main reasons for the
2 failing of traditional feedback. (Labanca and Bertoldi 2018) highlight the current limitations of policies
3 for energy conservation and suggests complementary policy approach based on social practices
4 theories.

5 *2. Market-based instruments*

6 Carbon allowances

7 A number of authors (Wadud and Chintakayala 2019; Fan et al. 2016; Raux et al. 2015; Marek et al.
8 2018; Li et al. 2015, 2018; Fawcett and Parag 2017) have investigated personal carbon allowances
9 introduced previously (Fleming 1997; Bristow et al. 2010; Fawcett 2010; Starkey 2012; Raux and
10 Marlot 2005; Ayres 1995). Although there is not yet any practical implementation of this policy, it
11 offers an alternative to carbon taxes, although there are some practical issues to be solved before it could
12 be rolled out. Recently the city of Lahti in Finland has introduced a personal carbon allowance in the
13 transport sector (Kuokkanen et al. 2020). Under this policy instrument governments sets allocates (free
14 allocation, but allowances could also be auctioned) allowances to cover the carbon emission for one
15 year, associated with energy consumption. Trade of allowances between people can be organised.
16 Personal carbon allowances can also foster renewable energies (energy consumption without carbon
17 emissions) both in the grid and in buildings (e.g., solar thermal). Personal carbon allowances can make
18 the carbon price more explicit to consumers, allowing them to know from the market value of each
19 allowance (e.g., 1 kg of CO₂). This policy instrument will shift the responsibility to the individual. Some
20 categories may have limited ability to change their carbon budget or to be engaged by this policy
21 instruments. In addition, in common with many other environmental policies the distributional effects
22 have to be assessed carefully as this policy instrument may favour well off people able to purchase
23 additional carbon allowances or install technologies that reduce their carbon emissions (Burgess 2016;
24 Wang et al. 2017).

25 The concept of carbon allowances or carbon budget can also be applied to buildings, by assigning a
26 yearly CO₂ emissions budget to each building. This policy would be a less complex than personal
27 allowances as buildings have metered or billed energy sources (e.g., gas, electricity, delivered heat,
28 heating oil, etc.). The scheme stimulates investments in energy efficiency and on-site renewable
29 energies and energy savings resulting from behaviour by buildings occupant. For commercial buildings,
30 similar schemes were implemented in the UK CRC Energy Efficiency Scheme (closed in 2019) or the
31 Tokyo Metropolitan Carbon and Trade Scheme (Nishida and Hua 2011)(Bertoldi et al. 2013a). The
32 Republic of Korea implemented since 2015 an Emission Trading Scheme, covering buildings (Park and
33 Hong 2014; Narassimhan et al. 2018; Lee and Yu 2017). More recently under the New York Climate
34 Mobilization Act enacted in 2019 New York City Local Law 97 established "Carbon Allowances" for
35 large buildings (Spiegel-Feld, 2019; Lee, 2020).

36 Public money can be used to reward and give incentives to energy saved, as a result of technology
37 implementation, and/or as a result of energy conservation and sufficiency (Eyre 2013; Bertoldi et al.
38 2013b; Prasanna et al. 2018). This can be seen as a core feature of the Energy Savings Feed-in Tariff
39 (ES-FiT). The ES-FiT is a performance-based subsidy, whereby actions undertaken by end-users – e.g.,
40 investments in energy efficiency technology measures – are awarded based on the real energy savings
41 achieved.

42 Utilities Programmes, Energy Efficiency Resource Standard and Energy Efficiency Obligations

43 Ratepayers funded efficiency programmes, energy efficiency obligations, energy efficiency resource
44 standards and white certificates have been introduced in some EU Member States, in several US States,
45 Australia, South Korea and Brazil (Bertoldi et al. 2013a; Aldrich and Koerner 2018; Wirl 2015; Choi
46 et al. 2018a; Palmer et al. 2013; Brennan and Palmer 2013; Rosenow and Bayer 2017; Fawcett and
47 Darby 2018; Fawcett et al. 2019; Giraudet and Finon, 2015; Goldman et al, 2020; Nadel, 2019; Slinger

1 and Colburn, 2019). This policy instrument helps in improving energy efficiency in buildings, but there
2 is no evidence that it can foster deep renovations of existing buildings. Recently this policy instrument
3 has been investigated in some non-OECD countries such as Turkey, where white certificates could
4 deliver energy savings with some limitations (Duzgun and Komurgoz 2014) and UAE, as a useful
5 instrument to foster energy efficiency in buildings (Friedrich and Afshari 2015). Another similar market
6 based instrument is the energy saving auction mechanism implemented in some US States, Switzerland,
7 and in Germany (Thomas and Rosenow 2020; Langreder et al. 2019; Rosenow et al. 2019). Energy
8 efficiency projects participate in auctions for energy savings based on the cost of the energy saved and
9 receive a financial incentive, if successful.

10 Energy or carbon taxes

11 Energy and/or carbon taxes are a climate policy, which can help in reducing energy consumption (Sen
12 and Vollebergh 2018) and manage the rebound effect (Peng et al. 2019; Font Vivanco et al. 2016;
13 Freire-González 2020; Bertoldi 2020). The carbon tax has been adopted mainly in OECD countries and
14 in particular in EU Member States (Hájek et al. 2019; Bertoldi 2020; Sen and Vollebergh 2018). There
15 is high agreement that carbon taxes can be effective in reducing CO₂ emissions (Andersson 2017; IPCC
16 2018; Hájek et al. 2019). It is hard to define the optimum level of taxation in order to achieve the desired
17 level of energy consumption or CO₂ emission reduction (Weisbach et al. 2009). As for other energy
18 efficiency policy distributional effect and equity considerations have to be carefully considered and
19 mitigated (Borozan 2019). High energy prices tend to reduce the energy consumption particularly in
20 less affluent households, and thus attention is needed in order to avoid unintended effects such as energy
21 poverty. Bourgeois et al. (2021) showed that using carbon tax revenue to finance energy efficiency
22 investment reduces fuel poverty and increases cost-effectiveness. (Giraudet et al. 2021) assessed the
23 cost-effectiveness of various energy efficiency policies in France, concluding that a carbon tax is the
24 most effective. In particular, revenues could be invested in frontline services that can provide a range
25 of support - including advising householders on how to improve their homes. Hence, the introduction
26 of a carbon tax can be neutral or even positive to the economy, as investments in clean technologies
27 generate additional revenues. In addition, in the long term, a carbon/energy tax could gradually replace
28 the tax on labour reducing labour cost (e.g., the example of the German Eco-tax), thus helping to create
29 additional jobs in the economy. In literature, this is known as double dividend (Murtagh et al. 2013)
30 (Freire-González and Ho 2019). Urban economic researches (Rafaj et al. 2018; Creutzig 2014; Borck
31 and Brueckner 2018) have highlighted that higher carbon price would translate in incentives for citizens
32 to live closer to the city centre, which often means less floor space, less commuting distance and thus
33 reduced emissions. Xiang and Lawley (2019) indicated that the carbon tax in British Columbia
34 substantially reduced residential natural gas consumption. Saelim (2019) showed that simulated carbon
35 tax on residential consumption in Thailand will have a low impact on welfare and it will be slightly
36 progressive. Lin and Li (2011) indicate that a carbon tax could reduce the energy consumption and
37 boost the uptake of energy efficiency and renewable energies, while at the same time may impact social
38 welfare and the competitiveness of industry. Solaymani (2017) showed that in Malaysia a tax with
39 revenue recycling increases in the welfare of rural and urban households. Van Heerden et al. (2016)
40 explored economic and environmental effects of the CO₂ tax in South Africa highlighting the negative
41 impact on GDP. This negative impact of the carbon tax on GDP is however greatly reduced by the
42 manner in which the tax revenue is recycled. National circumstances shall be taken into consideration
43 in introducing energy taxes, considering the local taxation and energy prices context with regard to
44 sustainable development, justice and equity.

45 A policy, which can have similar impact to a carbon tax and is the energy price/subsidy reform, which
46 also involves raising energy prices. Energy price/subsidy reform reduces energy consumption and
47 greenhouse gas emissions and encourages investment in energy efficiency (Aldubyan and Gasim, 2021;
48 Coady et al., 2018). In a similar manner, government revenues from subsidies reforms can be used to

1 mitigate the distributional impact on vulnerable population groups, including direct cash transfer
2 programmes (Schaffitzel, et al. 2020; Rentschler and Brazilian, 2017).

3 Taxes could also be used to penalise inefficient behaviour and favour the adoption of efficient behaviour
4 and technologies. Taxes are used in some jurisdictions to promote energy efficient appliances with
5 lower VAT. Similarly, the annual building/property tax (and also the purchase tax) could be based on
6 the CO₂ emissions of the buildings, rather than on the value of the building. Tax credits are also an
7 important subsidy for the renovation of buildings in France (Giraudet, 2020), Italy (Alberini and
8 Bigano, 2015) and other countries.

9 **9.9.4 Financing mechanisms and business models for reducing energy demand**

10 Grants and subsidies are traditional financing instruments used by governments when optimal levels of
11 investments cannot be fully supported by the market alone. They can partly help overcoming the upfront
12 cost barrier as they directly fill an immediate financial gap and thus enable a temporary shift in the
13 market (Newell et al. 2019). These forms of support are usually part of policy mixes including further
14 fiscal and financial instruments such as feed-in tariffs and tax breaks (Polzin et al. 2019). Potential
15 issues with subsidies are the limited availability of public financing, the stop and go due to annual
16 budget and the competition with commercial financing.

17 Loans provide liquidity and direct access to capital important in deep renovation projects (Rosenow et
18 al. 2014). There is empirical evidence (Giraudet et al. 2021), that banks make large profits on personal
19 loans for renovation purposes. International financing institutions (IFIs) and national governments
20 provided subsidies in public-private partnerships so that financial institutions can offer customers loans
21 with attractive terms (Olmos et al. 2012). Loan guarantees are effective in reducing intervention
22 borrowing costs (Soumaré and Lai 2016). Combination of grants and subsidised loans financed by IFIs
23 could be an effective instrument together with guarantees. An important role in financing energy
24 efficiency can be played by green banks, which are publicly capitalized entities set up to facilitate
25 private investment in low-carbon, including energy efficiency (Linh and Anh, 2017; Tu and Yen, 2015;
26 Khan, 2018; Bahl, 2012) . Green banks have been established at the national level (e.g., UK, Poland)
27 and in the US at state and city level.

28 Wholesaling of EE of loans and utilities programmes, are other important financing instruments.
29 Another financing mechanism for building efficiency upgrades, mainly implemented so far in the US,
30 is efficiency-as-a-service under an energy services agreement (ESA), where the building owners or
31 tenant pay to the efficiency service provider a charge based on realized energy savings without any
32 upfront cost (Kim et al., 2012; Bertoldi, 2020). ESA providers give performance guarantees assuming
33 the risk that expected savings would occur (Bertoldi, 2020).

34 Energy Performance Contracting (EPC) is an agreement between a building owner and Energy Services
35 Company (ESCO) for energy efficiency improvements. EPC is a common financing vehicle for large
36 buildings and it is well developed in several markets (Nurchayanto et al, 2020; Stuart et. al, 2018;
37 Carvallo et al, 2015; Ruan et al., 2018; Zheng et al., 2021; Bertoldi and Boza Kiss, 2017). Quality
38 standards are a part of the EPC (Augustins et al. 2018) . Guarantees can facilitate the provision of
39 affordable and sufficient financing for ESCOs (Bullier and Milin 2013). The ESCO guarantees a certain
40 level of energy savings and it shields the client from performance risk. The loan goes on the client's
41 balance sheet and the ESCO assumes full project performance risk (Deng et al. 2015). One of the
42 limitations is on the depth of the energy renovation in existing buildings. According to (Giraudet et al.
43 2018), EPC is effective at reducing information problems between contractors and investors.

44 Energy efficient mortgages are mortgages that credits a home energy efficiency by offering preferential
45 mortgage terms to extend existing mortgages to finance efficiency improvements. There are two types
46 of energy mortgages: (i) the Energy Efficient Mortgages (EEMs), and (ii) the Energy Improvement

1 Mortgages (EIMs), both can help in overcoming the main barriers to retrofit policies (Miu et al. 2018).
2 The success depends on the improved energy efficiency with a positive impact on property value and
3 on the reduction of energy bills and the income increase in the household. In the EU, the EeMAP
4 Initiative aims to create a standardised energy efficient mortgage template (Bertoldi et al. 2021).

5 On-bill financing is a mechanism that reduces first-cost barriers by linking repayment of energy
6 efficiency investments to the utility bill and thereby allowing customers to pay back part or all costs of
7 energy efficiency investments over time (Brown 2009). On-bill finance programmes can be categorised
8 into: (i) on-bill loans (assignment of the obligation to the property) and (ii) on-bill tariffs (payment off
9 in case of ownership transfer) (Eadson et al. 2013). On-bill finance programmes can be more effective
10 when set up as a service rather than a loan. (Mundaca and Klocke, 2018).

11 Property Assessed Clean Energy (PACE) is a means of financing energy renovations and renewable
12 energy through the use of specific bonds offered by municipal governments to investors (Mills 2016).
13 Municipalities use the funds raised to loan money towards energy renovations in buildings. The loans
14 are repaid over the assigned long term (15-20 years) via an annual assessment on their property tax bill
15 (Kirkpatrick and Benneer 2014). This model has been subject to consumer protection concerns.
16 Residential PACE programmes in California have been shown to increase PV deployment in
17 jurisdictions that adopt these programs (Ameli et al., 2017; Kirkpatrick and Benneer 2014). In US
18 commercial buildings, PACE volumes and programs, however, continue to grow (Lee, 2020).

19 Revolving funds allow reducing investment requirements and enhancing energy efficiency investment
20 impacts by recovering and reinvesting the savings generated (Setyawan 2014). Revolving fund could
21 make retrofit cost-neutral in the long term and could also dramatically increase low carbon investments,
22 including in developing countries (Gouldson et al. 2015).

23 Carbon finance, started under the Kyoto Protocol with the flexible mechanisms and further enhanced
24 under the Paris Agreement (Michaelowa et al. 2019), is an activity based on “carbon emission rights”
25 and its derivatives (Liu et al. 2015a). Carbon finance can promote low-cost emission reductions (Zhou
26 and Li 2019). Under Emission Trading Schemes or other carbon pricing mechanisms, auctioning carbon
27 allowances creates a new revenue stream. Revenues from auctioning could be used to finance energy
28 efficiency projects in buildings with grants, zero interest loans or guarantees (Wiese et al., 2020).

29 Crowdfunding is a new and rapidly growing form of financial intermediation that channels funds from
30 investors to borrowers (individuals or companies) or users of equity capital (companies) without
31 involving traditional financial organizations such as banks (Miller and Carriveau 2018). Typically, it
32 involves internet-based platforms that link savers directly with borrowers (European Union 2015). It
33 can play a significant role at the start of a renewable and sustainable energy projects (Dilger et al. 2017).

34 The One-Stop Shop (OSS) service providers for buildings energy renovations are organizations,
35 consortia, projects, independent experts or advisors that usually cover the whole or large part of the
36 customer renovation journey from information, technical assistance, structuring and provision of
37 financial support, to the monitoring of savings (Mahapatra et al. 2019; Bertoldi 2021b). OSSs are
38 transparent and accessible advisory tools from the client perspective and new, innovative business
39 models from the supplier perspective (Boza-Kiss and Bertoldi 2018).

40 **9.9.5 Policies mechanisms for financing for on-site renewable energy generation**

41 On-site renewable energy generation is a key component for the building sector decarbonisation,
42 complementing sufficiency and efficiency. Renewable energies (RES) technologies still face barriers
43 due to the upfront investment costs, despite the declining price of some technologies, long pay-back
44 period, unpredictable energy production, policy incertitude, architectural (in particular for built-in PV)
45 and landscape considerations, technical regulations for access to the grid, and future electricity costs
46 (Mah et al. 2018; Agathokleous and Kalogirou 2020).

1 Several policy instruments for RES have been identified by scholars (Azhgaliyeva et al. 2018; Pitelis
2 et al. 2020; Fouquet 2013): direct investments; feed-in tariffs; grants and subsidies; loans, taxes;
3 (tradable) green certificates or renewable/clean energy portfolio standards; information and education;
4 strategic planning; codes and standards; building codes; priority grid access; research, development and
5 deployment; and voluntary approaches. There are specific policies for renewable heating and cooling.
6 (Connor et al. 2013). In 2011, the UK introduced the Renewable Heat Incentive (RHI) support scheme
7 (Balta-Ozkan et al. 2015; Connor et al. 2015). The RHI guarantee a fixed payment per unit of heat
8 generated by a renewable heat technology for a specific contract duration (Yılmaz Balaman et al. 2019).

9 The most common implemented policy instruments are the feed-in tariffs (FiTs) and the Renewable/
10 Energy Portfolio Standards (RPSs) (Alizada 2018; Xin-gang et al. 2017a; Bergquist et al., 2020), with
11 FiTs more suited for small scale generation. More than 60 countries and regions worldwide have
12 implemented one of the two policies (Sun and Nie 2015). FiT is a price policy guaranteeing the purchase
13 of energy generation at a specific fixed price for a fixed period (Xin-gang et al. 2020; Barbosa et al.
14 2018). RPS is a quantitative policy, which impose mandatory quota of RES generation to power
15 generators (Xin-gang et al. 2020) .

16 A flat rate feed-in tariff (FiT) is a well-tested incentive adopted in many jurisdictions to encourage end-
17 users to generate electricity from RES using rooftop and on-site PV systems (Pacudan 2018). More
18 recently, there has been an increasing interest for dynamic FiTs taking into account electricity costs,
19 hosting capacity, ambient temperature, and time of day (Hayat et al. 2019). Since 2014, EU Member
20 States have been obligated to move from FiT to feed-in premium (FiTP) (Hortay and Rozner 2019);
21 where a FiTP consist in a premium of top of the electricity market price. Lecuyer and Quirion (2019)
22 argued that under uncertainty over electricity prices and renewable production costs a flat FiT results
23 in higher welfare than a FiTP. One of the main concerns with FiT systems is the increasing cost of
24 policies maintenance (Pereira da Silva et al. 2019; Roberts et al. 2019a; Zhang et al. 2018). In Germany,
25 the financial costs, passed on to consumers in the form a levy on the electricity price have increased
26 substantially in recent years (Winter and Schlesewsky 2019) resulting in opposition to the FiT in
27 particular by non-solar customers. A particular set up of the FiT encourage self-consumption through
28 net metering and net billing, which has a lower financial impact on electricity ratepayers compared with
29 traditional FiTs (Roberts et al. 2019b; Vence and Pereira 2019; Pacudan 2018).

30 In some countries, e.g. Australia (Duong et al. 2019), South Korea (Choi et al. 2018a), China (Yi et al.
31 2019), there was a transition from subsidies under the FiT to market-based mechanisms, such as RPSs
32 and tendering. Compared with FiT, RPS (or Renewable Obligations) reduce the subsidy costs (Zhang
33 et al. 2018). A number of scholars (Xin-gang et al. 2017; Li et al. 2019a; Liu et al. 2018a) have
34 highlighted the RPSs effectiveness in promoting the development of renewable energy. Other authors
35 (Requate 2015; An et al. 2015) have presented possible negative impacts of RPSs.

36 Both FiT and RPS can support the development of RES. Scholars compared the effectiveness of RPSs
37 and FiTs with mix results and different opinions, with some scholars indicating the advantages of RPS
38 (Ciarreta et al. 2017, 2014; Xin-gang et al. 2017), while Nicolini and Tavoni (2017) showed that in Italy
39 FiTs are outperforming RPSs and Tradable Green Certificates (TGCs). García-Álvarez et al. (2018)
40 carried out an empirical assessment of FiTs and RPSs for PV systems energy in EU over the period
41 2000–2014 concluding that that FiTs have a significant positive impact on installed PV capacity. This
42 is due to the small size of many rooftop installations and the difficulties in participating in trading
43 schemes for residential end users. Similar conclusions were reached by (Dijkgraaf et al. 2018) assessing
44 30 OECD countries and concluding that there is a “positive effect of the presence of a FiT on the
45 development of a country's added yearly capacity of PV”. Other scholars (Couture and Gagnon 2010;
46 Lewis and Wiser 2007; Lipp 2007; Cory et al. 2009) concluded that FiT can create a stable investment
47 framework and long-term policy certainty and it is better than RPS for industrial development and job
48 creation. Ouyang and Lin (2014) highlighted that RPS has a better implementation effect than FiT in

1 China, where FiT required very large subsidy. Ford et al. (2007) showed that TGC is a market-based
2 mechanism without the need for government subsidies. Marchenko (2008) and Wędzik et al. (2017)
3 indicate that the TGCs provide a source of income for investors. Choi et al. (2018a) analysed the
4 economic efficiency of FiT and RPS in the South Korean, where FiT was implemented from 2002 to
5 2011 followed by an RPS since 2012 (Park and Kim 2018; Choi et al. 2018b). Choi concluded that RPS
6 was more efficient for PV from the government's perspective while from an energy producers'
7 perspective the FiT was more efficient. Some scholars proposed a policy combining FiT and RPS (Cory
8 et al. 2009). Kwon (2015) and del Río et al. (2017) concluded that both FiT and RPS are effective, but
9 policy costs are higher in RPSs than FiTs. RPS, REC trading and FiT subsidy could also be implemented
10 as complementary policies (Zhang et al. 2018).

11 Tenders are a fast spreading and effective instrument to attract and procure new generation capacity
12 from renewable energy sources (Bayer et al. 2018; Bento et al. 2020; Ghazali et al. 2020; Haelg 2020;
13 Batz T. and Musgens 2019). A support scheme based on tenders allows a more precise steering of
14 expansion and lower risk of excessive support (Gephart et al. 2017). Bento et al. (2020) indicated that
15 tendering is more effective in promoting additional renewable capacity comparing to other mechanisms
16 such as FiTs. It is also important to take into account the rebound effect in energy consumption by on-
17 site PV users, which might reduce up to one fifth of the carbon benefit of renewable energy (Deng and
18 Newton 2017).

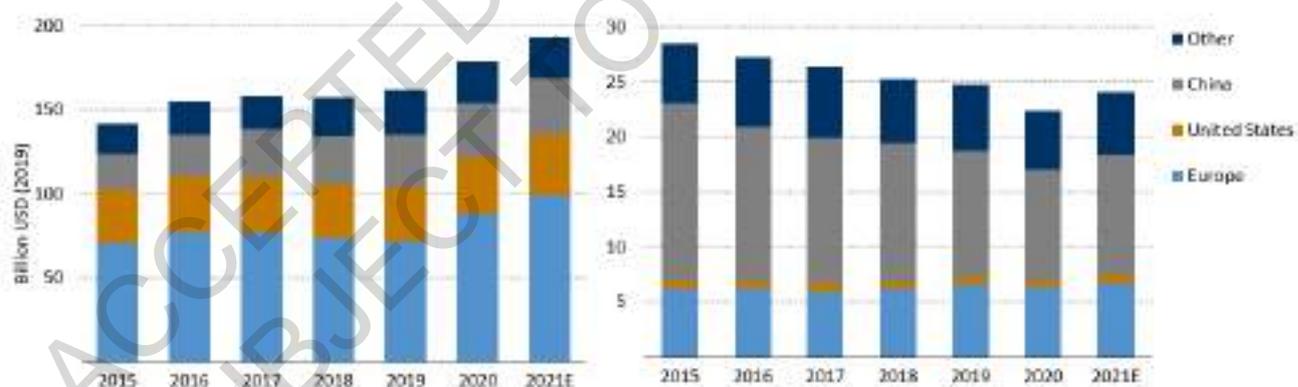

19 Financing mechanisms for RES are particularly needed in developing countries. Most of the common
20 supporting mechanisms (FiT, RPSs, PPA, auctions, net metering, etc.) have been implemented in some
21 developing countries (Donastorg et al. 2017). Stable policies and an investment-friendly environment
22 are essential to overcome financing barriers and attract investors (Donastorg et al. 2017). Kimura et al.
23 (2016) identified the following elements as essential for fostering RES in developing countries:
24 innovative business models and financial mechanisms/structures; market creation through the
25 implementation of market-based mechanisms; stability of policies and renewable energy legislation;
26 technical assistance to reduce the uncertainty of renewable energy production; electricity market design,
27 which reflects the impact on the grid capacity and grid balancing; improved availability of financial
28 resources, in particular public, and innovative financial instruments, such as carbon financing (Park et
29 al. 2018; Kim and Park 2018; Lim et al. 2013); green bonds; public foreign exchange hedging facility
30 for renewable energy financing, credit lines; grants and guarantees..

31• The end-user will be at the centre as a key participant in the future electricity system (Zepter et al. 2019;
32 Lavrijssen and Carrillo Parra, 2017) providing flexibility, storage, energy productions, peer to peer
33 trading, electric vehicle charging. Zepter indicates that “the current market designs and business models
34 lack incentives and opportunities for electricity consumers to become prosumers and actively participate
35 in the market”. Klein et al. (2019) explore the policy options for aligning prosumers with the electricity
36 wholesale market, through price and scarcity signals. Policies should allow for active markets
37 participation of small prosumers (Brown et al. 2019; Zepter et al. 2019), local energy communities and
38 new energy market actors such as aggregators (Iria and Soares 2019; Brown et al. 2019). Energy
39 Communities are new important players in the energy transition (Sokołowski, 2020; Gjorgievski, et al.,
40 2021). Citizens and local communities can establish local energy communities, providing local RES
41 production to serve the community, alleviate energy poverty and export energy into the grid (DellaValle
42 and Sareen, 2020; Hahnel et al. 2020). Energy Communities have as primary purpose to provide
43 environmental, economic, or social community benefits by engaging in generation, aggregation, energy
44 storage, energy efficiency services and charging services for electric vehicles. Energy communities help
45 in increasing public acceptance and mobilise private funding. Demand response aggregators
46 (Mahmoudi et al., 2017; Henriquez et al., 2018) can aggregate load reductions by a group of consumers,
47 and sell the resulting flexibility to the electricity market (Zancanella P. et al. 2017). Regulatory
48 frameworks for electricity markets should allow demand response to compete on equal footing in energy

1 markets and encourage new business models for the provision of flexibility to the electricity grid (Shen
2 et al., 2014). Renewable energy and sufficiency requirements could be included in building energy
3 codes and implemented in coordination with each other and with climate policies, e.g. carbon pricing
4 (Oikonomou et al. 2014).

5 **9.9.6 Investment in building decarbonisation**

6 As Section 9.6.3 points out, the incremental investment cost to decarbonise buildings at national level
7 is up to 3.5% GDP per annum during the next thirty years (the global GDP in 2019 was USD 88 trillion).
8 As the following figures illustrate, only a very small share of it is currently being invested, leaving a
9 very large investment gap still to address. The incremental capital expenditure on energy efficiency in
10 buildings has grown since AR5 to reach the estimated USD 193 billion in 2021; Europe was the largest
11 investing region, followed by the USA and China (Figure 9.21). The incremental capital expenditure
12 on renewable energy heat vice versa declined to reach USD 24 billion in this year; the leading investor
13 was China, followed by Europe (ibid). The total capital expenditure on distributed small-scale (less than
14 1MW) solar systems in 2019 was USD 52.1 billion, down from the peak of USD 71 billion in 2011;
15 most of this capacity is installed in buildings (Frankfurt School - UNEP Centre/BNEF 2020). The US
16 was the largest country market with USD 9.6 billion investment; notably USD 5 billion was deployed
17 in the Middle East and Africa (ibid). (IEA 2021b) provided an estimate of annual average incremental
18 investment needs in building sector decarbonation between 2026 and 2030 of USD 711 billion,
19 including USD 509 billion in building energy efficiency and USD 202 billion in renewable heat for
20 end-use and electrification in buildings. Such investment would allow being on track towards meeting
21 the goals of the WEO Net Zero Emissions Scenario, as presented in Box 9.2. To reach these levels, the
22 respective investment must grow from their average volumes in 2016-2020 factor 3.6 and 4.5
23 respectively. As the investment needs estimated by (IEA 2021b) are significantly lower the investment
24 intervals reported by bottom-up literature (Section 9.6.3), the actual investment gap is likely to be
25 higher.

26
27 **Notes:** (i) An energy efficiency investment is defined as the incremental spending on new energy-efficient equipment or the full cost of
28 refurbishments that reduce energy use. (ii) Renewable heat for end-use include solar thermal applications (for district, space, and water
29 heating), bioenergy and geothermal energy, as well as heat pumps. (iii) The investment in 2021 is an estimate.

30 **Figure 9.21 Incremental capital expenditure on energy efficiency investment (left) and renewable heat in**
31 **buildings, 2015-2021**

32 Source: IEA 2021b

33 **9.9.7 Governance and Institutional Capacity**

34 **9.9.7.1 Governance**

35 Multilevel and polycentric governance is essential for implementing sufficiency, energy efficiency and
36 renewable energies policies (IPCC, 2018). Policies can be implemented at different levels of

1 government and decision making, international, national, regional, and local. Policies for building have
2 be adopted at national level (Enker and Morrison 2017), at state or regional level (Fournier et al. 2019),
3 or at city level (Trencher and van der Heijden 2019). Zhao et al. (2019) find that national policies are
4 instrumental in driving low carbon developments in buildings.

5 International agreements (Kyoto, Montreal/Kigali, Paris, etc.) play an important role in establishing
6 national energy-efficiency and renewable energy policies in several countries (Dhar et al. 2018; Bertoldi
7 2018). Under the Paris Agreement, some NDCs contain emission reduction targets for subsectors, e.g.,
8 buildings, policies for subsectors and energy efficiency and/or renewable targets (see also Cross-
9 Chapter Box 5 in Chapter 4). In the EU since 2007 climate and energy policies are part of a co-ordinated
10 policy package. EU Member States have prepared energy efficiency plans every three years and long
11 term renovation strategies for buildings (Economidou et al. 2020). Under the new Energy and Climate
12 Governance Regulation EU Member States have submitted at the end of 2020 integrated National
13 Energy and Climate Plans, including energy efficiency and renewable plans. (Oberthur, 2019; Schlacke
14 and Knodt, 2019). The integration of energy and climate change policies and their governance has been
15 analysed (von Lüpke and Well, 2020), highlighting the need of reinforcing the institutions,
16 anticipatory governance, the inconsistency of energy policies and the emerging multi-
17 level governance.

18 Some policies are best implemented at international level. Efficiency requirements for traded goods and
19 the associated test methods could be set at global level in order to enlarge the market, avoid technical
20 barriers to trade; reduce the manufacturers design and compliance costs. International standards could
21 be applied to developing countries when specific enabling conditions exist, particularly in regard to
22 technology transfer, assistance for capacity buildings and financial support. This would also reduce the
23 dumping of inefficient equipment in countries with no or lower efficiency requirements. An example is
24 the dumping of new or used inefficient cooling equipment in developing countries, undermining
25 national and local efforts to manage energy, environment, health, and climate goals. Specific regulations
26 can be put in place to avoid such environmental dumping, beginning with the “prior informed consent”
27 as in the Rotterdam Convention and a later stage with the adoption of minimum efficiency requirements
28 for appliances (Andersen et al. 2018; United Nations Environment Programme (UNEP) 2017). Dreyfus
29 et al. (2020a) indicates that global policies to promote best technologies currently available have the
30 potential to reduce climate emissions from air conditionings and refrigeration equipment by 210–460
31 GtCO₂-eq by 2060, resulting from the phasing down of HFC and from improved energy efficiency.
32 Another example is the commitment by governments in promoting improvements in energy efficiency
33 of cooling equipment in parallel with the phasedown of HFC refrigerants enshrined in the Biarritz
34 Pledge for Fast Action on Efficient Cooling signed in 2019. The policy development and
35 implementation costs will be reduced as the technical analysis leading to the standard could be shared
36 among governments. However, it is important that local small manufacturing companies in developing
37 countries have the capacity to invest in updating production lines for meeting new stringent international
38 efficiency requirements.

39 Building energy consumption is dependent on local climate and building construction traditions,
40 regional and local government share an important role in promoting energy efficiency in buildings and
41 on-site RES, through local building energy codes, constructions permits and urban planning. In South
42 Korea, there is a green building certification system operated by the government, based on this, Seoul
43 has enacted Seoul's building standard, which includes more stringent requirements. Where it is difficult
44 to retrofit existing buildings, e.g., historical buildings, cities may impose target at district level, where
45 RES could be shared among buildings with energy positive buildings compensating for energy
46 consuming buildings. Local climate and urban plans could also contribute to the integration of the
47 building sector with the local transport, water, and energy sectors, requiring, for example, new
48 constructions in areas served by public transport, close to offices or buildings to be ready for e-mobility.

1 Buildings GHG emission reduction shall also be considered in greenfield and brownfield developments
2 and urban expansion (Loo et al, 2017; Salviati and Ricciardo Lamonica., 2020), including co-benefits
3 (Zapata-Diomedes et al., 2019).

4 Energy efficiency, sufficiency, and renewable policies and measures will have a large impact on
5 different stakeholders (citizens, construction companies; equipment manufacturers; utilities, etc.),
6 several studies highlighted the importance of stakeholder consultation and active participation in policy
7 making and policy implementation (Vasileiadou and Tuinstra 2013; Ingold et al. 2020), including
8 voluntary commitments and citizen assemblies. In particular, energy users role will be transformed from
9 passive role to an active role, as outlined in the concept of energy citizenship (Campos and Marín-
10 González, 2020). The energy citizens needs and voice should therefore be included in policy processes
11 among traditional business players, such as incumbent centralised power generation companies and
12 utilities (Van Veelen, 2018). Architects and engineers play an important role in the decarbonisation of
13 buildings. The professional bodies can mandate their members support energy efficiency and
14 sufficiency. For example, the US AIA states in their code of ethics that architects must inform clients
15 of climate risks and opportunities for sustainability. The capacity and quality of workforce and building
16 construction, retrofit, and service firms are essential to execute the fast transition in building systems
17 (see also Cross-Chapter Box 12 in Chapter 16).

18 **9.9.7.2 Institutional capacity**

19 The concept of institutional capacity is increasingly connected with the issue of public governance,
20 emphasising the broad institutional context within which individual policies are adopted. Institutions
21 are durable and are sources of authority (formal or informal) structuring repeated interactions of
22 individuals, companies, civil society groups, governments, and other entities. Thus, institutional
23 capacity also represents a broader “enabling environment” which forms the basis upon which
24 individuals and organisations interact. In general terms, capacity is “the ability to perform functions,
25 solve problems and set and achieve objectives” (Fukuda-Parr et al. 2002). Institutional capacity is an
26 important element for regional sustainable development (Farajirad et al. 2015). The role and importance
27 of institutional capacity is fundamental in implementing the building decarbonisation. Central and local
28 governments, regulatory organisations, financial institutions, standardisation bodies, test laboratories,
29 building construction and design companies, qualified workforce and stakeholders are key players in
30 supporting the implementation of building decarbonisation.

31 Governments (from national to local) planning to introduce efficiency, RES, and sufficiency policies
32 needs technical capacity to set sectoral targets and design policies and introduce effective and
33 enforcement with adequate structure and resources for their implementation. Policies discussed and
34 agreed with stakeholders and based on impartial data and impact assessments, have a higher possibility
35 of success. Public authorities need technical and economics competences to understand complex
36 technical issues and eliminate the knowledge gap in comparison to private sector experts, human and
37 financial resources to design, implement, revise, and evaluate policies. The role of energy efficiency
38 policy evaluation needs to be expanded, including the assessment of the rebound effect (Vine et al.
39 2013). For developing countries international support for institutional capacity for policy development,
40 implementation and evaluation is of key importance for testing laboratory, standards institute,
41 enforcement and compliances technicians and evaluation experts. Thus, in development support,
42 addition to technology transfer, also capacity buildings for national and local authorities should be
43 provided. The Paris Agreement Article 11 aims at enhancing the capacity of decision-making
44 institutions in developing countries to support effective implementation.

45 Enforcement of policies is of key importance. Policies on appliance energy standards needs to establish
46 criteria for random checks and tests of compliance, establish penalties and sanctions for non-
47 compliance. For building code compliance there is the need to verify compliance after construction to
48 verify the consistence with building design (Vine et al. 2017). Often local authorities lack resources and

1 technical capacity to carry out inspections to check code compliance. This issue is even more pressing
2 in countries and cities with large informal settlements, where buildings may not be respecting building
3 energy codes for safety and health.

4

5 **9.10 Knowledge Gaps**

6 Insights from regions, sectors, and communities

- 7 • Due to the dominating amount of literature from developed countries and rapidly developing
8 Asia (China), the evidence and therefore conclusions are limited for the developing world. In
9 particular, there is limited evidence on the potential and costs the countries of South-East Asia
10 and Developing Pacific, Africa, and Latin America and Caribbean.
- 11 • The contribution of indigenous knowledge in the evolvement of buildings is not well
12 appreciated. There is a need to understand this contribution and provide methodological
13 approaches for incorporation of indigenous knowledge.
- 14 • Analysis of emissions and energy demand trends in non-residential buildings is limited due to
15 the number of building types included in this category and the scarcity of data for each building
16 type. The use of new data gathering techniques such as machine learning, GIS combined with
17 digital technologies to fill in this data gap was not identified in the literature. Consideration of
18 embodied emissions from building stock growth has only recently entered the global scenario
19 literature, and more development is expected in this area.

20 Measures, potentials, and costs

- 21 • There is a lack of scientific reporting of case studies of exemplary buildings, specially from
22 developing countries. Also, there is a lack of identification of researchers on technologies with
23 the mitigation potential of such technologies, bringing a lack in quantification of that potential.
- 24 • There is limited evidence on sufficiency measures including those from behavioural energy
25 saving practices: updated categorisations, current adoption rates and willingness to adopt.
- 26 • There is limited evidence on circular and shared economy in buildings, including taxonomies,
27 potentials, current adoption rates and willingness to adopt
- 28 • Most of the literature on climate change impacts on buildings is focused on thermal comfort.
29 There is need for further research on climate change impacts on buildings structure, materials
30 and construction and the energy and emissions associated with those impacts. Also, more
31 studies that assess the role of passive energy efficiency measures as adaptation options are
32 needed. Finally, regional studies leave out in depth analyses of specific regions.

33 Feasibility and policies

- 34 • Applications of human centred profiles for targeted policy making and considering stages of
35 diffusion of innovation, that is: what works (motivation) for whom (different stakeholders, not
36 only households) and when (stages of market maturity)
- 37 • The multiple co-benefits of mitigation actions are rarely integrated into decision-making
38 processes. So, there is a need to further develop methodologies to quantify and monetise these
39 externalities as well as indicators to facilitate their incorporation in energy planning.

- 1 • Policies for sufficiency have to be further analysed and tested in real situation, including ex
2 ante simulation and ex-post evaluation. The same is also valid for Personable (tradable) Carbon
3 Allowances.

4 Methods and models

- 5 • There is limited literature on the integration of behavioural measures and lifestyle changes in
6 modelling exercises
- 7 • Mitigation potential resulting from the implementation of sufficiency measures is not identified
8 in global energy/climate and building scenarios despite the growing literature on sufficiency.
9 At the best, mitigation potential from behaviour change is quantified in energy scenarios;
10 savings from structural changes and resource efficiency are not identified in the literature on
11 global and building energy models.
- 12 • The actual costs of the potential could be higher to rather optimistic assumptions of the
13 modelling literature, e.g., assuming a 2-3% retrofit rate, and even higher, versus the current 1%.
14 The uncertainty ranges of potential costs are not well understood.
- 15 • Despite a large number of exemplary buildings achieving very high performance in all parts of
16 the world and a growing amount of modelling literature on the potential, if these will penetrate
17 at scale, there is a lack of modelling literature assessing the costs of respective actions at
18 national, regional, and global level based on comprehensive cost assessments.
- 19 • There is a lack of peer-reviewed literature on investment gaps, which compares the investment
20 need in the building sector decarbonisation and recent investment flows into it estimated with
21 the same costing methodologies.

22

23 Frequently Asked Questions

24 FAQ 9.1 To which GHG emissions do buildings contribute?

25 There are three categories of GHG emissions from buildings:

- 26 i. direct emissions which are defined as all on-site fossil fuel or biomass-based combustion
27 activities (i.e., use of biomass for cooking, or gas for heating and hot water) and F-gas emissions
28 (i.e., use of heating and cooling systems, aerosols, fire extinguishers, soundproof)
- 29 ii. indirect emissions which occur off-site and are related to heat and electricity production
- 30 iii. embodied emissions which are related to extracting, producing, transforming, transporting, and
31 installing the construction material and goods used in buildings

32 In 2019, global GHG emissions from buildings were at 12 GtCO₂-eq out of which 24% were direct
33 emissions, 57% were indirect emissions, and 18% were embodied emissions. More than 95% of
34 emissions from buildings were CO₂ emissions, CH₄ and N₂O represented 0.08% each and emissions
35 from halocarbon contributed by 3% to global GHG emissions from buildings.

36

37 FAQ 9.2 What are the co-benefits and trade-offs of mitigation actions in buildings?

38 Mitigation actions in buildings generate multiple co-benefits (e.g., health benefits due to the improved
39 indoor and outdoor conditions, productivity gains in non-residential buildings, creation of new jobs
40 particularly at local level, improvements in social wellbeing etc.) beyond their direct impact on reducing
41 energy consumption and GHG emissions. Most studies agree that the value of these multiple benefits
42 is greater than the value of energy savings and their inclusion in economic evaluation of mitigation

1 actions may improve substantially their cost-effectiveness. It is also worth mentioning that in several
2 cases the buildings sector is characterized by strong rebound effects, which could be considered as a
3 co-benefit in cases where the mechanisms involved provide faster access to affordable energy but also
4 a trade-off in cases where the external costs of increased energy consumption exceed the welfare
5 benefits of the increased energy service consumption, thus lowering the economic performance of
6 mitigation actions. The magnitude of these co-benefits and trade-offs are characterized by several
7 uncertainties, which may be even higher in the future as mitigation actions will be implemented in a
8 changing climate, with changing building operation style and occupant behaviour. Mitigation measures
9 influence the degree of vulnerability of buildings to future climate change. For instance, temperature
10 rise can increase energy consumption, which may lead to higher GHG emissions. Also, sea level rise,
11 increased storms and rainfall under future climate may impact building structure, materials and
12 components, resulting in increased energy consumption and household expenditure from producing and
13 installing new components and making renovations. Well-planned energy efficiency, sufficiency and
14 on-site renewable energy production can help to increase building resilience to climate change impacts
15 and reduce adaptation needs.

16

17 **FAQ 9.3 Which are the most effective policies and measures to decarbonize the building sector?**

18 Several barriers (information, financing, markets, behavioural, etc.) still prevents the decarbonisation
19 of buildings stock, despite the several co-benefits, including large energy savings. Solutions include
20 investments in technological solutions (e.g., insulation, efficient equipment, and low-carbon energies
21 and renewable energies) and lifestyle changes. In addition, the concept of sufficiency is suggested to be
22 promoted and implemented through policies and information, as technological solutions will be not
23 enough to decarbonise the building sector. Due to the different types of buildings, occupants, and
24 development stage there is not a single policy, which alone will reach the building decarbonisation
25 target. A range of policy instruments ranging from regulatory measures such as building energy code
26 for NZEBs and appliance standards, to market-based instruments (carbon tax, personal carbon
27 allowance, renewable portfolio standards, etc.), and information. Financing (grants, loans, performance
28 base incentives, pays as you save, etc.) is another key enabler for energy efficiency technologies and
29 on-site renewables. Finally, effective governance and strong institutional capacity are key to have an
30 effective and successful implementation of policies and financing.

22			

1 **Executive summary**

2 **Meeting climate mitigation goals would require transformative changes in the transport sector**
3 **(high confidence)**. In 2019, direct greenhouse gas (GHG) emissions from the transport sector were 8.7
4 Gt CO₂-eq (up from 5.0 Gt CO₂-eq in 1990) and accounted for 23% of global energy-related CO₂
5 emissions. 70% of direct transport emissions came from road vehicles, while 1%, 11%, and 12% came
6 from rail, shipping, and aviation, respectively. Emissions from shipping and aviation continue to grow
7 rapidly. Transport-related emissions in developing regions of the world have increased more rapidly
8 than in Europe or North America, a trend that is likely to continue in coming decades (*high confidence*).
9 {10.1, 10.5, 10.6}.

10 **Since AR5 there has been a growing awareness of the need for demand management solutions**
11 **combined with new technologies, such as the rapidly growing use of electromobility for land**
12 **transport and the emerging options in advanced biofuels and hydrogen-based fuels for shipping**
13 **and aviation**. There is a growing need for systemic infrastructure changes that enable behavioural
14 modifications and reductions in demand for transport services that can in turn reduce energy demand.
15 The response to the COVID-19 pandemic has also shown that behavioural interventions can reduce
16 transport-related GHG emissions. For example, COVID-19-based lockdowns have confirmed the
17 transformative value of telecommuting replacing significant numbers of work and personal journeys as
18 well as promoting local active transport. There are growing opportunities to implement strategies that
19 drive behavioural change and support the adoption of new transport technology options. {Chapter 5,
20 10.2, 10.3, 10.4, 10.8}

21 **Changes in urban form, behaviour programs, the circular economy, the shared economy, and**
22 **digitalisation trends can support systemic changes that lead to reductions in demand for transport**
23 **services or expands the use of more efficient transport modes (high confidence)**. Cities can reduce
24 their transport-related fuel consumption by around 25% through combinations of more compact land
25 use and the provision of less car-dependent transport infrastructure. Appropriate infrastructure,
26 including protected pedestrian and bike pathways, can also support much greater localised active travel¹.
27 Transport demand management incentives are expected to be necessary to support these systemic
28 changes (*high confidence*). There is mixed evidence of the effect of circular economy initiatives, shared
29 economy initiatives, and digitalisation on demand for transport services. For example, while
30 dematerialisation can reduce the amount of material that need to be transported to manufacturing
31 facilities, an increase in online shopping with priority delivery can increase demand for freight transport.
32 Similarly, while teleworking could reduce travel demand, increased ridesharing could increase vehicle-
33 km travelled. {Chapter 1, Chapter 5, 10.2, 10.8}

34 **Battery-electric vehicles (BEVs) have lower life cycle greenhouse gas emissions than internal**
35 **combustion engine vehicles (ICEVs) when BEVs are charged with low carbon electricity (high**
36 **confidence)**. Electromobility is being rapidly implemented in micro-mobility (e-autorickshaws, e-
37 scooters, e-bikes), in transit systems, especially buses, and, to a lesser degree, in the electrification of
38 personal vehicles. BEVs could also have the added benefit of supporting grid operations. The
39 commercial availability of mature Lithium-Ion Batteries (LIBs) has underpinned this growth in
40 electromobility.

41 As global battery production increases, unit costs are declining. Further efforts to reduce the GHG
42 footprint of battery production, however, are essential for maximising the mitigation potential of BEVs.
43 The continued growth of electromobility for land transport would require investments in electric
44 charging and related grid infrastructure (*high confidence*). Electromobility powered by low-carbon

FOOTNOTE ¹ Active travel is travel that requires physical effort, for example journeys made by walking or cycling.

1 electricity has the potential to rapidly reduce transport GHG and can be applied with multiple co-
2 benefits in the developing world's growing cities (*high confidence*). {10.3, 10.4, 10.8}

3 **Land-based, long-range, heavy-duty trucks can be decarbonised through battery-electric haulage**
4 **(including the use of Electric Road Systems), complemented by hydrogen- and biofuel-based fuels**
5 **in some contexts (*medium confidence*). These same technologies and expanded use of available**
6 **electric rail systems can support rail decarbonisation (*medium confidence*).** Initial deployments of
7 battery-electric, hydrogen- and bio-based haulage are underway, and commercial operations of some of
8 these technologies are considered feasible by 2030 (*medium confidence*). These technologies
9 nevertheless face challenges regarding driving range, capital and operating costs, and infrastructure
10 availability. In particular, fuel cell durability, high energy consumption, and costs continue to challenge
11 the commercialisation of hydrogen-based fuel cell vehicles. Increased capacity for low-carbon
12 hydrogen production would also be essential for hydrogen-based fuels to serve as an emissions
13 reduction strategy (*high confidence*). {10.3, 10.4, 10.8}

14 **Decarbonisation options for shipping and aviation still require R&D, though advanced biofuels,**
15 **ammonia, and synthetic fuels are emerging as viable options (*medium confidence*).** Increased
16 efficiency has been insufficient to limit the emissions from shipping and aviation, and natural gas-based
17 fuels are likely inadequate to meet stringent decarbonisation goals for these segments (*high confidence*).
18 High energy density, low carbon fuels are required, but they have not yet reached commercial scale.
19 Advanced biofuels could provide low carbon jet fuel (*medium confidence*). The production of synthetic
20 fuels using low-carbon hydrogen with CO₂ captured through DAC/BECCS could provide jet and marine
21 fuels but these options still require demonstration at scale (*low confidence*). Ammonia produced with
22 low-carbon hydrogen could also serve as a marine fuel (*medium confidence*). Deployment of these fuels
23 requires reductions in production costs. {10.2, 10.3, 10.4, 10.5, 10.6, 10.8}.

24 **Scenarios from bottom-up and top-down models indicate that without intervention, CO₂**
25 **emissions from transport could grow in the range of 16% and 50% by 2050 (*medium confidence*).**
26 The scenarios literature projects continued growth in demand for freight and passenger services,
27 particularly in developing countries in Africa and Asia (*high confidence*). This growth is projected to
28 take place across all transport modes. Increases in demand notwithstanding, scenarios that limit
29 warming to 1.5°C degree with no or limited overshoot suggest that a 59% reduction (42-68%
30 interquartile range) in transport-related CO₂ emissions by 2050, compared to modelled 2020 levels is
31 required. While many global scenarios place greater reliance on emissions reduction in sectors other
32 than transport, a quarter of the 1.5°C degree scenarios describe transport-related CO₂ emissions
33 reductions in excess of 68% (relative to modelled 2020 levels) (*medium confidence*). Illustrative
34 mitigation pathways 1.5 REN and 1.5 LD describe emission reductions of 80% and 90% in the transport
35 sector, respectively, by 2050. Transport-related emission reductions, however, may not happen
36 uniformly across regions. For example, transport emissions from the Developed Countries, and Eastern
37 Europe and West-Central Asia (EEA) countries decrease from 2020 levels by 2050 across all scenarios
38 compatible with a 1.5°C degree goal (C1 - C2 group), but could increase in Africa, Asia and developing
39 Pacific (APC), Latin America and Caribbean, and the Middle East in some of these scenarios. {10.7}

40 The scenarios literature indicates that fuel and technology shifts are crucial to reducing carbon
41 emissions to meet temperature goals. In general terms, electrification tends to play the key role in land-
42 based transport, but biofuels and hydrogen (and derivatives) could play a role in decarbonisation of
43 freight in some contexts (*high confidence*). Biofuels and hydrogen (and derivatives) are likely more
44 prominent in shipping and aviation (*high confidence*). The shifts towards these alternative fuels must
45 occur alongside shifts towards clean technologies in other sectors (*high confidence*). {10.7}.

46 **There is a growing awareness of the need to plan for the significant expansion of low-carbon**
47 **energy infrastructure, including low-carbon power generation and hydrogen production, to**
48 **support emissions reductions in the transport sector (*high confidence*).** Integrated energy planning

1 and operations that take into account energy demand and system constraints across all sectors (transport,
2 buildings, and industry) offer the opportunity to leverage sectoral synergies and avoid inefficient
3 allocation of energy resources. Integrated planning of transport and power infrastructure would be
4 particularly useful in developing countries where ‘greenfield’ development doesn’t suffer from
5 constraints imposed by legacy systems. {10.3, 10.4, 10.8}

6 **The deployment of low-carbon aviation and shipping fuels that support decarbonisation of the**
7 **transport sector could require changes to national and international governance structures**
8 **(medium confidence).** Currently, the Paris Agreement does not specifically cover emissions from
9 international shipping and aviation. Instead, accounting for emissions from international transport in
10 the Nationally Determined Contributions is at the discretion of each country. While the ICAO and IMO
11 have established emissions reductions targets, only strategies to improve fuel efficiency and demand
12 reductions have been pursued, and there has been minimal commitment to new technologies. Some
13 literature suggests that explicitly including international shipping and aviation under the governance of
14 the Paris Agreement could spur stronger decarbonisation efforts in these segments. {10.5, 10.6, 10.7}

15 **There are growing concerns about resource availability, labour rights, non-climate**
16 **environmental impacts, and costs of critical minerals needed for LIBs (medium confidence).**
17 Emerging national strategies on critical minerals and the requirements from major vehicle
18 manufacturers are leading to new, more geographically diverse mines. The standardisation of battery
19 modules and packaging within and across vehicle platforms, as well as increased focus on design for
20 recyclability are important. Given the high degree of potential recyclability of LIBs, a nearly closed-
21 loop system in the future could mitigate concerns about critical mineral issues (*medium confidence*).
22 {10.3, 10.8}

23 **Legislated climate strategies are emerging at all levels of government, and, together with pledges**
24 **for personal choices, could spur the deployment of demand and supply-side transport mitigation**
25 **strategies (medium confidence).** At the local level, legislation can support local transport plans that
26 include commitments or pledges from local institutions to encourage behaviour change by adopting an
27 organisational culture that motivates sustainable behaviour with inputs from the creative arts. Such
28 institution-led mechanisms could include bike-to-work campaigns, free transport passes, parking
29 charges, or eliminating car benefits. Community-based solutions like *solar sharing*, *community*
30 *charging*, and *mobility as a service* can generate new opportunities to facilitate low-carbon transport
31 futures. At the regional and national levels, legislation can include vehicle and fuel efficiency standards,
32 R&D support, and large-scale investments in low-carbon transport infrastructure. {10.8, Chapter 15}

33
34

1 10.1 Introduction and overview

2 This chapter examines the transport sector's role in climate change mitigation. It appraises the transport
3 system's interactions beyond the technology of vehicles and fuels to include the full life cycle analysis
4 of mitigation options, a review of enabling conditions, and metrics that can facilitate advancing
5 transport decarbonisation goals. The chapter assesses developments in the systems of land-based
6 transport and introduces, as a new feature since AR5, two separate sections focusing on the trends and
7 challenges in aviation and shipping. The chapter assesses the future trajectories emerging from global,
8 energy, and national scenarios and concludes with a discussion on enabling conditions for
9 transformative change in the sector.

10 This section (10.1) discusses how transport relates to virtually all the Sustainable Development Goals
11 (SDGs), the trends and drivers making transport a big contributor in greenhouse gas (GHG) emissions,
12 the impacts climate change is having on transport that can be addressed as part of mitigation, and the
13 overview of emerging transport disruptions with potential to shape a low carbon transport pathway.

14

15 10.1.1 Transport and the sustainable development goals

16 The adoption of the 2030 Agenda for Sustainable Development by the United Nations (UN) has
17 renewed international efforts to pursue and accurately measure global actions towards sustainable
18 development (United Nations 2015). The 17 SDGs set out the overall goals that are further specified by
19 169 targets and 232 SDG indicators, many of which relate to transport (United Nations 2017; Lisowski
20 et al. 2020). A sustainable transport system provides safe, inclusive, affordable, and clean passenger
21 and freight mobility for current and future generations (Williams 2017; Litman 2021) so transport is
22 particularly linked to SDGs 3, 7, 8, 9, 11, 12, and 13 (Move Humanity 2018; WBA 2019; SLoCaT
23 2019; Yin 2019; IRP 2019). Table 10.1 summarises transport-related topics for these SDGs and
24 corresponding research. Section 17.3.3.7 (in Chapter 17) also provides a cross sectoral overview of
25 synergies and trade-offs between climate change mitigation and the SDGs.

26

27

Table 10.1 Main transport-related SDGs

Transport-related topics (Low carbon Transport; Active transport; Electric vehicles.	Sustainable Development Goals: Synergies and trade-offs				
	Basic human needs	Earth preconditions	Sustainable resource use	Social and economic development	Universal values
					
<ul style="list-style-type: none"> - Lower air pollution contributes to positive health outcomes. - Energy access can contribute to poverty alleviation. 	<ul style="list-style-type: none"> - Reduction of GHG emissions along the entire value chain, e.g. Well-to-Wheel (WTW). - Further development addressing minor GHG emissions and pollutants. 	<ul style="list-style-type: none"> - Share of renewable energy use. - Energy efficiency of vehicles. - Clean and affordable energy off-grid. 	<ul style="list-style-type: none"> - Role of transport for economic and human development. - Decarbonised public transport rather than private vehicle use. 	<ul style="list-style-type: none"> - Gender equality in transport. - Reduced Inequalities. - Enables access to quality education. 	

	<ul style="list-style-type: none"> - Transport planning a major player in reducing poverty in cities. - Access to healthcare - Diseases from air pollution. - Injuries and deaths from traffic accidents. - Reduced stress level from driving. - Links between active transport and good health with positive effects of walking and cycling. - Improving road accessibility to disabled users. - Reduce time spent on transport/mobility. 	<ul style="list-style-type: none"> - Transport Oriented to Sustainable Development (TOD). - Circular economy principle applied to transport. 	<ul style="list-style-type: none"> - Reduce material consumption during production, life cycle analysis of vehicles and their operations including entire value chains. - Close loop carbon and nutrient cycle linked to circular economy. 	<ul style="list-style-type: none"> - Transport Oriented to Sustainable Development (TOD). - Sustainable transport infrastructure and systems for cities and rural areas. - Affordability of mobility services, this can also be covered under "universal access" to public transport. - Accessibility vs. mobility: Mobility to opportunities; Transport equity; Development as freedom. - Positive economic growth (employment) outcomes due to resource efficiency and lower productive energy cost. - Role of transport provision in accessing work, reconfiguration of social norms, as working from home. - Transport manufacturers as key employers changing role of transport-related labour due to platform economy, and innovations in autonomous vehicles. 	<ul style="list-style-type: none"> - Partnership for the goals.

-------------------	---	--	---	--	---

1 **10.1.2 Trends, drivers and the critical role of transport in GHG growth**

2 The transport sector directly emitted around 8.9 Gt Carbon dioxide equivalent (CO₂eq) in 2019, up from
3 5.1 Gt CO₂eq in 1990 (Figure 10.1). Global transport was the fourth largest source of GHG emissions
4 in 2019 following the power, industry, and the Agriculture, Forestry and Land Use (AFOLU) sectors.
5 In absolute terms, the transport sector accounts for roughly 15% of total greenhouse gas (GHG)
6 emissions and about 23% of global energy-related CO₂ emissions (IEA 2020a). Transport GHG
7 emissions have increased fast over the last two decades, and since 2010, the sector's emissions have
8 increased faster than for any other end-use sector, averaging +1.8% annual growth (see Section 10.7).
9 Addressing emissions from transport is crucial for GHG mitigation strategies across many countries, as
10 the sector represents the largest energy consuming sector in 40% of countries worldwide. In most
11 remaining countries, transport is the second largest energy-consuming sector, reflecting different levels
12 of urbanisation and land use patterns, speed of demographic changes and socio-economic development
13 (IEA 2012; Hasan et al. 2019; Xie et al. 2019; Gota et al. 2019).

14

15

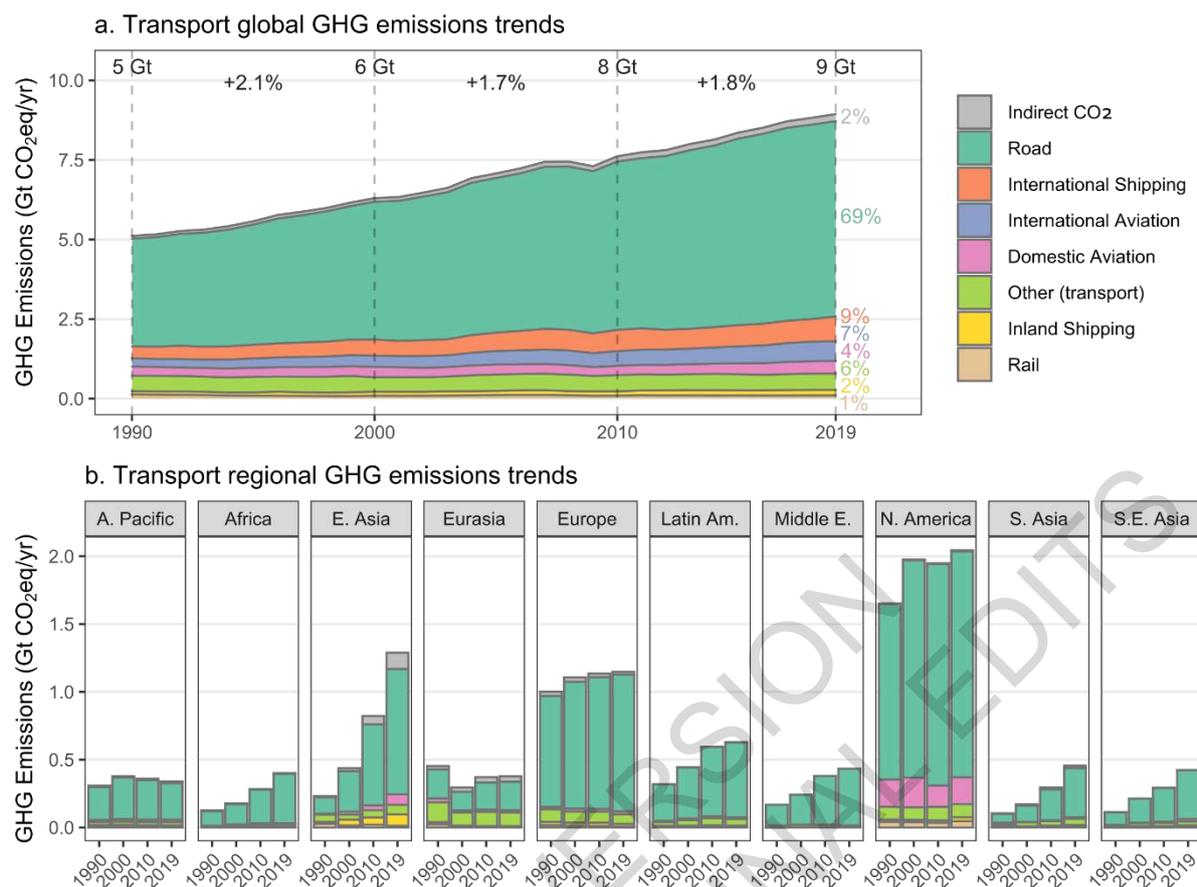

Figure 10.1 Global and regional transport GHG emissions trends. Indirect emissions from electricity and heat consumed in transport are shown in panel (a) and are primarily linked to the electrification of rail systems. These indirect emissions do not include the full life cycle emissions of transportation systems (e.g., vehicle manufacturing and infrastructure), which are assessed in section 10.4. International aviation and shipping are included in panel (a), but excluded from panel (b). Indirect emissions from fuel production, vehicle manufacturing and infrastructure construction are not included in the sector total.

Source: Adapted from (Lamb et al. 2021) using data from (Minx et al. 2021).

As of 2019, the largest source of transport emissions is the movement of passengers and freight in road transport (6.1 Gt CO₂eq, 69% of the sector's total). International shipping is the second largest emission source, contributing 0.8 Gt CO₂eq (9% of the sector's total), and international aviation is third with 0.6 Gt CO₂eq (7% of the sector's total). All other transport emissions sources, including rail, have been relatively trivial in comparison, totalling 1.4 Gt CO₂eq in 2019. Between 2010-2019, international aviation had one of the fastest growing GHG emissions among all segments (+3.4% per year), while road transport remained one of the fastest growing (+1.7% per year) among all global energy using sectors. Note that the COVID-19-induced economic lockdowns implemented since 2020 have had a very substantial impact on transport emissions – higher than any other sector (see chapter 2). Preliminary estimates from Crippa et al. (2021) suggest that global transport CO₂ emissions declined to 7.6 GtCO₂ in 2020, a reduction of 11.6% compared to 2019 (Crippa et al. 2021; Minx et al. 2021). These lockdowns affected all transport segments, and particularly international aviation (estimated -45% reduction in 2020 global CO₂ emissions), road transport (-10%), and domestic aviation (-9.3%). By comparison, aggregate CO₂ emissions across all sectors are estimated to have declined by 5.1% as a result of the COVID-19 pandemic (Chapter 2, section 2.2.2).

1 Growth in transport-related GHG emissions has taken place across most world regions (see Figure
2 10.1, panel b). Between 1990 and 2019, growth in emissions was relatively slow in Europe, Asia
3 Pacific, Eurasia, and North America while it was unprecedentedly fast in other regions. Driven by
4 economic and population growth, the annual growth rates in East Asia, South Asia, South East Asia,
5 and Africa were 6.1%, 5.2%, 4.7%, and 4.1%, respectively. Latin America and the Middle East have
6 seen somewhat slower growth in transport-related GHG emission (annual growth rates of 2.4% and
7 3.3%, respectively) (ITF 2019; Minx et al. 2021). Section 10.7 provides a more detailed
8 comparison of global transport emissions trends with those from regional and sub-sectoral
9 studies.

10 The rapid growth in global transport emissions is primarily a result of the fast growth in global transport
11 activity levels, which grew by 73% between 2000 and 2018. Passenger and freight activity growth have
12 outpaced energy efficiency and fuel economy improvements in this period (ITF 2019). The global
13 increase in passenger travel activities has taken place almost entirely in non-OECD countries, often
14 starting from low motorization rates (SLoCaT 2018a). Passenger cars, two-and-three wheelers, and mini
15 buses contribute about 75% of passenger transport-related CO₂ emissions, while collective transport
16 services (bus and railways) generates about 7% of the passenger transport-related CO₂ emissions despite
17 covering a fifth of passenger transport globally (Rodrigue 2017; Halim et al. 2018; Sheng et al. 2018;
18 SLoCaT 2018a; Gota et al. 2019). While alternative lighter powertrains have great potential for
19 mitigating GHG emissions from cars, the trend has been towards increasing vehicle size and engine
20 power within all vehicle size classes, driven by consumer preferences towards larger sport utility
21 vehicles (SUVs) (IEA 2020a). On a global scale, SUV sales have been constantly growing in the last
22 decade, with 40% of the vehicles sold in 2019 being SUVs (IEA 2020a) – see Section 10.4, Box 10.3.

23 Indirect emissions from electricity and heat shown in Figure 10.1 account for only a small fraction of
24 current emissions from the transport sector (2%) and are associated with electrification of certain modes
25 like rail or bus transport (Lamb et al. 2021). Increasing transport electrification will affect indirect
26 emissions, especially where carbon-intense electricity grids operate.

27 Global freight transport, measured in tonne-kilometres (tkm), grew by 68% between 2000 and 2015 and
28 is projected to grow 3.3 times by 2050 (ITF 2019). If unchecked, this growth will make decarbonisation
29 of freight transport very difficult (McKinnon 2018; ITF 2019). International trade and global supply
30 chains from industries frequently involving large geographical distances are responsible for the fast
31 increase of CO₂ emissions from freight transport (Yeh et al. 2017; McKinnon 2018), which are growing
32 faster than emissions from passenger transport (Lamb et al. 2021). Heavy-duty vehicles (HDVs) make
33 a disproportionate contribution to air pollution, relative to their global numbers, because of their
34 substantial emissions of particulate matter and of black carbon with high short-term warming potentials
35 (Anenberg et al. 2019).

36 On-road passenger and freight vehicles dominate global transport-related CO₂ emissions and offer the
37 largest mitigation potential (Taptich et al. 2016; Halim et al. 2018). This chapter examines a wide range
38 of possible transport emission reduction strategies. These strategies can be categorised under the
39 ‘Avoid- Shift-Improve’ (ASI) framework described in Chapter 5 (Taptich et al. 2016). Avoid strategies
40 reduce total vehicle-travel. They include compact communities and other policies that minimise travel
41 distances and promote efficient transport through pricing and demand management programs. Shift
42 strategies shift travel from higher-emitting to lower-emitting modes. These strategies include more
43 multimodal planning that improves active and collective transport modes, complete streets roadway
44 design, High Occupant Vehicle (HOV) priority strategies that favour shared mode, Mobility as a Service
45 (MaaS), and multimodal navigation and payment apps. Improve strategies reduce per-kilometre
46 emission rates. These strategies include hybrid and electric vehicle incentives, lower carbon and cleaner
47 fuels, high emitting vehicle scrappage programs, and efficient driving and anti-idling campaigns
48 (Lutsey and Sperling 2012; Gota et al. 2015). These topics are assessed within the rest of this chapter

1 including how combinations of ASI with new technologies can potentially lead from incremental
2 interventions into low carbon transformative transport improvements that include social and equity
3 benefits (see section 10.8).

5 **10.1.3 Climate adaptation on the transport sector**

6 Climate change impacts such as extremely high temperatures, intense rainfall leading to flooding, more
7 intense winds and/or storms, and sea level rise can seriously impact transport infrastructure, operations,
8 and mobility for road, rail, shipping, and aviation. Studies since AR5 confirm that serious challenges to
9 all transport infrastructures are increasing, with consequent delays or derailing (Miao et al. 2018;
10 Moretti and Loprencipe 2018; Pérez-Morales et al. 2019; Palin et al. 2021). These impacts have been
11 increasingly documented but, according to (Forzieri et al. 2018), little is known about the risks of
12 multiple climate extremes on critical infrastructures at local to continental scales. All roads, bridges,
13 rail systems, and ports are likely to be affected to some extent. Flexible pavements are particularly
14 vulnerable to extreme high temperatures that can cause permanent deformation and crumbling of
15 asphalt (Underwood et al. 2017; Qiao et al. 2019). Rail systems are also vulnerable, with a variety of
16 hazards, both meteorological and non-meteorological, affecting railway asset lifetimes. Severe impacts
17 on railway infrastructure and operations can arise from the occurrence of temperatures below freezing,
18 excess precipitation, storms and wildfires (Thaduri et al. 2020; Palin et al. 2021) as are underground
19 transport systems (Forero-Ortiz et al. 2020).

20 Most countries are examining opportunities for combined mitigation-adaptation efforts, using the need
21 to mitigate climate change through transport-related GHG emissions reductions and pollutants as the
22 basis for adaptation action (Thornbush et al. 2013; Wang et al. 2020). For example, urban sprawl
23 indirectly affects climate processes, increasing emissions and vulnerability, which worsens the potential
24 to adapt (Congedo and Munafò 2014; Macchi and Tiepolo 2014). Hence, using a range of forms of
25 rapid transit as structuring elements for urban growth can mitigate climate change-related risks as well
26 as emissions, reducing impacts on new infrastructure, often in more vulnerable areas (Newman et al.
27 2017). Such changes are increasingly seen as having economic benefit (Ha et al. 2017), especially in
28 developing nations (Chang 2016; Monioudi et al. 2018).

29 Since AR5 there has been a growing awareness of the potential and actual impacts from global sea level
30 rise due to climate change on transport systems (Dawson et al. 2016; Rasmussen et al. 2018; IPCC
31 2019; Noland et al. 2019), particularly on port facilities (Stephenson et al. 2018; Yang et al. 2018b;
32 Pérez-Morales et al. 2019). Similarly, recent studies suggest changes in global jet streams could affect
33 the aviation sector (Staples et al. 2018; Becken and Shuker 2019), and extreme weather conditions can
34 affect runways (heat buckling) and aircraft lift. Combined, climate impacts on aviation could result in
35 payload restrictions and disruptions (Coffel et al. 2017; Monioudi et al. 2018). According to (Williams
36 2017), studies have indicated that the amount of moderate-or-greater clear-air turbulence on
37 transatlantic flight routes in winter will increase significantly in the future as the climate changes. More
38 research is needed to fully understand climate induced risks to transportation systems.

40 **10.1.4 Transport disruption and transformation**

41 Available evidence suggests that transport-related CO₂ emissions would need to be restricted to about
42 2 to 3 Gt in 2050 (1.5°C scenario-1.5DS, B2DS), or about 70 to 80% below 2015 levels, to meet the
43 goals set in the Paris Agreement. It also indicates that a balanced and inter-modal application of Avoid,
44 Shift, and Improve measures is capable of yielding an estimated reduction in transport emissions of
45 2.39 Gt of CO₂-equivalent by 2030 and 5.74 Gt of CO₂-equivalent by 2050 (IPCC 2018; Gota et al.
46 2019). Such a transformative decarbonisation of the global transport system requires, in addition to

1 technological changes, a paradigm shift that ensures prioritisation of high-accessibility transport
2 solutions that minimise the amount of mobility required to meet people's needs, and favours transit and
3 active transport modes (Lee and Handy 2018; SLoCaT 2021). These changes are sometimes called
4 disruptive as they are frequently surprising in how they accelerate through a technological system.

5 The assessment of transport innovations and their mitigation potentials is at the core of how this chapter
6 examines the possibilities for changing transport-related GHG trajectories. The transport technology
7 innovation literature analysed in this chapter emphasises how a mixture of mitigation technology
8 options and social changes are now converging and how, in combination, they may have potential to
9 accelerate trends toward a low carbon transport transition. Such changes are considered disruptive or
10 transformative (Sprei 2018). Of the current transport trends covered in the literature, this chapter focuses
11 on three key technology and policy areas: electro-mobility in land-based transport vehicles, new fuels
12 for ships and planes, and overall demand reductions and efficiency. These strategies are seen as being
13 necessary to integrate at all levels of governance and, in combination with the creation of fast, extensive,
14 and affordable multi-modal public transport networks, can help achieve multiple advantages in
15 accordance with SDGs

16 Electrification of passenger transport in light-duty vehicles (LDVs) is well underway as a commercial
17 process with socio-technical transformative potential and will be examined in detail in Sections 10.3
18 and 10.4. But the rapid mainstreaming of EV's will still need enabling conditions for land transport to
19 achieve the shift away from petroleum fuels, as outlined in Chapter 3 and detailed in Section 10.8. The
20 other mitigation options reviewed in this chapter are so far only incremental and are less commercial,
21 especially shipping and aviation fuels, so stronger enabling conditions are likely, as detailed further in
22 Sections 10.5 to 10.8. The enabling conditions that would be needed for the development of an emerging
23 technological solution for such fuels are likely to be very different to electromobility, but nevertheless
24 they both will need demand and efficiency changes to ensure they are equitable and inclusive.

25 Section 10.2 sets out the transformation of transport through examining systemic changes that affect
26 demand for transport services and the efficiency of the system. Section 10.3 looks at the most promising
27 technological innovations in vehicles and fuels. The next three sections (10.4, 10.5, and 10.6) examine
28 mitigation options for land transport, aviation, and shipping. Section 10.7 describes the space of
29 solutions assessed in a range of integrated modelling and sectoral transport scenarios; Finally, Section
30 10.8 sets out what would be needed for the most transformative scenario that can manage to achieve
31 the broad goals set out in Chapter 3 and the transport goals set out in Section 10.7.

33 **10.2 Systemic changes in the transport sector**

34 Systemic change is the emergence of new organisational patterns that affect the structure of a system.
35 While much attention has been given to engine and fuel technologies to mitigate GHG emissions from
36 the transport sector, population dynamics, finance and economic systems, urban form, culture, and
37 policy also drive emissions from the sector. Thus, systemic change requires innovations in these
38 components. These systemic changes offer the opportunity to decouple transport emissions from
39 economic growth. In turn, such decoupling allows environmental improvements like reduced GHG
40 emissions without loss of economic activity (UNEP 2011, 2013; Newman et al. 2017; IPCC 2018).

41 There is evidence that suggests decoupling of transport emissions and economic growth is already
42 happening in developed and developing countries. Europe and China have shown the most dramatic
43 changes (Huizenga et al. 2015; Gao and Newman 2018; SLoCaT 2018b) and many cities are
44 demonstrating decoupling of transport-related emissions through new net zero urban economic activity
45 (Loo and Banister 2016; SLoCaT 2018a). A continued and accelerated decoupling of the growth of
46 transport-related GHG emissions from economic growth is crucial for meeting the SDGs outlined in

1 Section 1. This section focuses on several overlapping components of systemic change in the transport
 2 sector that affect the drivers of GHG emissions: Urban form, physical geography, and infrastructure;
 3 behaviour and mode choice; and new demand concepts. Table 10.3, at the end of the section provides a
 4 high-level summary of the effect of these systemic changes on emissions from the transport sector.
 5

6 **10.2.1 Urban form, physical geography, and transport infrastructure**

7 The physical characteristics that make up built areas define the urban form. These physical
 8 characteristics include the shape, size, density, and configuration of the human settlements. Urban form
 9 is intrinsically coupled with the infrastructure that allows human settlements to operate. In the context
 10 of the transport sector, urban form and urban infrastructure influence the time and cost of travel, which,
 11 in turn, drive travel demand and modal choice (Marchetti and Ausubel 2004; Newman and Kenworthy
 12 2015).

13 Throughout history, three main urban fabrics have developed, each with different effects on transport
 14 patterns based on a fixed travel time budget of around one hour (Newman et al. 2016). The high-density
 15 urban fabric developed over the past several millennia favoured walking and active transport for only a
 16 few kilometres (kms). In the mid-19th century, urban settlements developed a medium density fabric
 17 that favoured trains and trams traveling over 10 to 30-km corridors. Finally, since the mid-20th century,
 18 urban form has favoured automobile travel, enabling mass movement between 50-60 kms. Table 10.2
 19 describes the effect of these urban fabrics on GHG emissions and other well-being indicators.
 20
 21

Table 10.2 The systemic effect of city form and transport emissions

Annual Transport Emissions and Co-Benefits	Walking Urban Fabric	Transit Urban Fabric	Automobile Urban Fabric
Transport GHG	4 t/person	6 t/person	8 t/person
Health benefits from walkability	High	Medium	Low
Equity of locational accessibility	High	Medium	Low
Construction and household waste	0.87 t/person	1.13 t/person	1.59 t/person
Water consumption	35 kl/person	42 kl/person	70 kl/person
Land	133 m ² /person	214 m ² /person	547 m ² /person
Economics of infrastructure and transport operations	High	Medium	Low

22 Source: (Newman et al. 2016; Thomson and Newman 2018; Seto et al. 2021)

23 Since AR5, urban design has increasingly been seen as a major way to influence the GHG emissions
 24 from urban transport systems. Indeed, research suggests that implementing urban form changes could
 25 reduce GHG emissions from urban transport by 25% in 2050, compared with a business-as-usual
 26 scenario (Creutzig et al. 2015b; Creutzig 2016). Researchers have identified a variety of variables to
 27 study the relationship between urban form and transport-related GHG emissions. Three notable aspects
 28 summarise these relationships: urban space utilisation, urban spatial form, and urban transportation
 29 infrastructure (Tian et al. 2020). Urban density (population or employment density) and land use mix
 30 define the urban space utilisation. Increases in urban density and mixed function can effectively reduce
 31 per capita car use by reducing the number of trips and shortening travel distances. Similarly, the
 32 continuity of urban space and the dispersion of centres reduces travel distances (Tian et al. 2020),
 33 though such changes are rarely achieved without shifting transport infrastructure investments away
 34 from road capacity increases (Newman and Kenworthy 2015; McIntosh et al. 2017) For example,

1 increased investment in public transport coverage, optimal transfer plans, shorter transit travel time, and
2 improved transit travel efficiency make public transit more attractive (Heinen et al. 2017; Nugroho et
3 al. 2018a,b) and hence increase density and land values (Sharma and Newman 2020). Similarly,
4 forgoing the development of major roads for the development of pedestrian and bike pathways enhances
5 the attractiveness of active transport modes (Zahabi et al. 2016; Keall et al. 2018; Tian et al. 2020).

6 Ultimately, infrastructure investments influence the structural dependence on cars, which in turn
7 influence the lock-in or path dependency of transport options with their greenhouse emissions (Newman
8 et al. 2015b; Grieco and Urry 2016). The 21st century saw a new trend to reach peak car use in some
9 countries as a result of a revival in walking and transit use (Grieco and Urry 2016; Newman et al. 2017;
10 Gota et al. 2019). While some cities continue on a trend towards reaching peak car use on a per-capita
11 basis, for example Shanghai and Beijing (Gao and Newman 2020), there is a need for increased
12 investments in urban form strategies that can continue to reduce car-dependency around the world.

13 14 **START CROSS-CHAPTER BOX HERE**

15 16 **Cross-Chapter Box 7 Urban Form: Simultaneously reducing urban transport emissions, avoiding** 17 **infrastructure lock-in, and providing accessible services**

18 **Authors:** Felix Creutzig (Germany), Karen Seto (the United States of America), Peter Newman
19 (Australia)

20 Urban transport is responsible for about 8% of global CO₂ emissions or 3 Gt CO₂ per year (see Chapters
21 5 and 8). In contrast to energy supply technologies, urban transport directly interacts with mobility
22 lifestyles (see Section 5.4). Similarly, non-GHG emission externalities, such as congestion, air
23 pollution, noise, and safety, directly affect urban quality of life, and result in considerable welfare
24 losses. Low-carbon, highly accessible urban design is not only a major mitigation option, it also
25 provides for more inclusive city services related to wellbeing (Chapter 5, Sections 5.1 and 5.2). Urban
26 planning and design of cities for people are central to realise emission reductions without relying simply
27 on technologies, though the modes of transport favoured will influence the ability to overcome the lock-
28 in around automobile use (Gehl 2010; Creutzig et al. 2015b).

29 Where lock-in has occurred, other strategies may alleviate the GHG emissions burden. Urban planning
30 still plays a key role in recreating local hubs. Available land can be used to build rail-based transit,
31 made financially viable by profiting from land value captured around stations (Ratner and Goetz 2013).
32 Shared or pooled mobility can offer flexible on-demand mobility solutions that are efficient also in
33 suburbs and for integrating with longer commuting trips (ITF 2017).

34 Global emission trajectories of urban transport will be decided in rapidly urbanising Asia and Africa.
35 Urban transport-related GHG emissions are driven by incomes and car ownership but there is
36 considerable variation amongst cities with similar income and car ownership levels (Newman and
37 Kenworthy 2015). While electrification is a key strategy to decarbonise urban transport, urban
38 infrastructures can make a difference of up to a factor of 10 in energy use and induced GHG emissions
39 (Erdogan 2020). Ongoing urbanisation patterns risk future lock-in of induced demand on GHG
40 emissions, constraining lifestyles to energy intensive and high CO₂-related technologies (See Section
41 5.4; 8.2.3; 10.2.1; (Erickson and Tempest 2015; Seto et al. 2016). Instead, climate solutions can be
42 locked into urban policies and infrastructures (Ürge-Vorsatz et al. 2018) especially through the
43 enhancement of the walking and transit urban fabric. Avoiding urban sprawl, associated with several
44 externalities (Dieleman and Wegener 2004), is a necessary decarbonisation condition, and can be
45 guided macro-economically by increasing fuel prices and marginal costs of motorised transport
46 (Creutzig 2014). Resulting urban forms not only reduce GHG emission from transport but also from
47 buildings, as greater compactness results in reduced thermal loss (Borck and Brueckner 2018). Health

1 benefits from reduced car dependence are an increasing element driving this policy agenda (Section
2 10.8; (Speck 2018)).

3 Low-carbon highly accessible urban design is not only a major mitigation option, it also provides for
4 more inclusive city services related to wellbeing (Chapter 5, Sections 5.1 and 5.2). Solutions involve
5 planning cities around walkable sub-centres, where multiple destinations, such as shopping, jobs, leisure
6 activities, and others, can be accessed within a 10 minute walk or bicycle ride (Newman and Kenworthy
7 2006). Overall, the mitigation potential of urban planning is about 25% in 2050 compared with a
8 business as usual scenario (Creutzig et al. 2015a,b). Much higher levels of decarbonisation can be
9 achieved if cities take on a regenerative development approach and act as geo-engineering systems on
10 the atmosphere (Thomson and Newman 2016).

11 **END CROSS-CHAPTER BOX HERE**

12

13 **10.2.2 Behaviour and mode choice**

14 Behaviour continues to be a major source of interest in the decarbonisation of transport as it directly
15 addresses demand. Behaviour is about people's actions based on their preferences. Chapter 5 described
16 an 'Avoid, Shift, Improve' process for demand-side changes that affect sectoral emissions. This section
17 discusses some of the drivers of behaviour related to the transport sector and how they link to this
18 'Avoid, Shift, Improve' process.

19 ***Avoid - the effect of prices and income on demand:*** Research has shown that household income and
20 price have a strong influence on people's preferences for transport services (Bakhat et al. 2017; Palmer
21 et al. 2018). The relationship between income and demand is defined by the income elasticity of
22 demand. For example, research suggests that in China, older and wealthier populations continued to
23 show a preference for car travel (Yang et al. 2019) while younger and low-income travellers sought
24 variety in transport modes (Song et al. 2018). Similarly, (Bergantino et al. 2018b) evaluated the income
25 elasticity of transport by mode in the UK. They found that the income elasticity for private cars is 0.714,
26 while the income elasticities of rail and bus use are 3.253 (The greater elasticity the greater the demand
27 will grow or decline, depending on income). Research has also shown a positive relationship between
28 income and demand for air travel, with income elasticities of air travel demand being positive and as
29 large as 2 (Gallet and Doucouliagos 2014; Valdes 2015; Hakim and Merkert 2016, 2019; Hanson et al.
30 2022). A survey in 98 Indian cities also showed income as the main factor influencing travel demand
31 (Ahmad and de Oliveira 2016). Thus, as incomes and wealth across the globe rise, demand for travel is
32 likely to increase as well.

33 The price elasticity of demand measures changes in demand as a result of changes in the prices of the
34 services. In a meta-analysis of the price elasticity of energy demand, (Labandeira et al. 2017) report the
35 average long-term price elasticity of demand for gasoline and diesel to be -0.773 and -0.443,
36 respectively. That is, demand will decline with increasing prices. A similar analysis of long-term data
37 in the United States (US), the United Kingdom (UK), Sweden, Australia, and Germany reports the
38 gasoline price elasticity of demand for car travel (as measured through vehicle-kilometre -vkm- per
39 capita) ranges between -0.1 and -0.4 (Bastian et al. 2016). For rail travel, the price elasticity of demand
40 has been found to range between -1.05 and -1.1 (Zeng et al. 2021). Similarly, price elasticities for air
41 travel range from -0.53 to -1.91 depending on various factors such as purpose of travel (business or
42 leisure), season, and month and day of departure (Morlotti et al. 2017). The price elasticities of demand
43 suggest that car use is inelastic to prices, while train use is relatively inelastic to the cost of using rail.
44 Conversely, consumers seem to be more responsive to the cost of flying, so that strategies that increase
45 the cost of flying are likely to contribute to some avoidance of aviation-related GHG emissions.

1 While the literature continues to show that time, cost, and income dominate people's travel choices
2 (Ahmad and de Oliveira 2016; Capurso et al. 2019; He et al. 2020), there is also evidence of a role for
3 personal values, and environmental values in particular, shaping choices within these structural
4 limitations (Bouman and Steg 2019). For example, individuals are more likely to drive less when they
5 care about the environment (De Groot et al. 2008; Abrahamse et al. 2009; Jakovcevic and Steg 2013;
6 Hiratsuka et al. 2018; Ünal et al. 2019). Moreover, emotional and symbolic factors affect the level of
7 car use (Steg 2005). Differences in behaviour may also result due to differences in gender, age, norms,
8 values, and social status. For example, women have been shown to be more sensitive to parking pricing
9 than men (Simićević et al. 2020).

10 Finally, structural shocks, such as a financial crisis, a pandemic, or the impacts of climate change could
11 affect the price and income elasticities of demand for transport services (van Ruijven et al. 2019).
12 COVID-19 lock-downs reduced travel demand by 19% (aviation by 32%) and some of the patterns that
13 have emerged from the lockdowns could permanently change the elasticity of demand for transport
14 (Tirachini and Cats 2020; Hendrickson and Rilett 2020; Newman 2020a; SLoCaT 2021; Hanson et al.
15 2022). In particular, the COVID-19 lock-downs have spurred two major trends: electronic
16 communications replacing many work and personal travel requirements; and, revitalised local active
17 transport and e-micro-mobility (Newman 2020a; SLoCaT 2021). The permanence of these changes
18 post- COVID-19 is uncertain but possible ((Early and Newman 2021); see Box on COVID-19, chapter
19 1). However, these changes will require growth of infrastructure for better ICT bandwidths in
20 developing countries, and better provision for micro-mobility in all cities.

21 **Shift - Mode choice for urban and intercity transport:** Shifting demand patterns (as opposed to
22 avoiding demand) can be particularly important in decarbonising the transport sector. As a result, the
23 cross-elasticity of demand across transport modes is of particular interest for understanding the
24 opportunities for modal shift. The cross-elasticity represents the demand effect on mode i (e.g. bus)
25 when an attribute of mode j (e.g. rail) changes marginally. Studies on the cross-elasticities of mode
26 choice for urban travel suggest that the cross-elasticity for car demand is low, but the cross-elasticities
27 of walking, bus, and rail with respect to cars are relatively large (Fearnley et al. 2017; Wardman et al.
28 2018). In practice, these cross-elasticities suggest that car drivers are not very responsive to increased
29 prices for public transit, but transit users are responsive to reductions in the cost of driving. When
30 looking at the cross-elasticities of public transit options (bus vs. metro vs. rail), research suggests that
31 consumers are particularly sensitive to in-vehicle and waiting time when choosing public transit modes
32 (Fearnley et al. 2018). These general results provide additional evidence that increasing the use of active
33 and public transport requires interventions that make car use more expensive while making public
34 transit more convenient (e.g. with smart apps that explain the exact time for transit arrival, see Box
35 10.1).

36 The literature on mode competition for intercity travel reveals that while cost of travel is a significant
37 factor (Zhang et al. 2017), sensitivity decreases with increasing income as well as when the cost of the
38 trip was paid by someone else (Capurso et al. 2019). Some research suggests little competition between
39 bus and air travel but the cross-elasticity between air and rail suggest strong interactions (Wardman et
40 al. 2018). Price reduction strategies such as discounted rail fares could enhance the switch from air
41 travel to high-speed rail. Both air fares and flight frequency impact high speed rail (HSR) usage (Zhang
42 et al. 2019b). Airline companies reduce fares on routes that are directly competing with HSR
43 (Bergantino et al. 2018a) and charge high fares on non-HSR routes (Xia and Zhang 2016). On the
44 Rome-Milan route, better frequency and connections, and low costs of HSR resulting from competition
45 between HSR companies has significantly reduced air travel and shares of buses and cars (Desmaris
46 and Croccolo 2018).

47 Finally, and as noted in Chapter 5, recent research shows that individual, social, and infrastructure
48 factors also affect people's mode choices. For example, perceptions about common travel behaviour

1 (what people perceive to be “normal” behaviour) influences their travel mode choice. The research
2 suggests that well-informed individuals whose personal norms match low-carbon objectives, and who
3 believe they have control over their decisions are most motivated to shift mode. Nonetheless, such
4 individual and social norms can only marginally influence mode choice unless infrastructure factors
5 can enable reasonable time and cost savings (Convery and Williams 2019; Javaid et al. 2020; Feng et
6 al. 2020; Wang et al. 2021).

7 **Improve – consumer preferences for improved and alternative vehicles:** While reductions in demand
8 for travel and changes in the mode choice can contribute to reducing GHG emissions from the transport
9 sector, cars are likely to continue to play a prominent role. As a result, improving the performance of
10 cars will be crucial for the decarbonisation of the transport sector. Sections 10.3 and 10.4 describe the
11 technological options available for reduced CO₂ emissions from vehicles. The effectiveness in
12 deploying such technologies will partly depend on consumer preferences and their effect on adoption
13 rates. Given the expanded availability of electric vehicles, there is also a growing body of work on the
14 drivers of vehicle choice. A survey in Nanjing found women had more diverse travel purposes than
15 men, resulting in a greater acceptance of electric bikes (Lin et al. 2017). Individuals are more likely to
16 adopt an electric vehicle (EV) when they think this adoption benefits the environment or implies a
17 positive personal attribute (Noppers et al. 2014, 2015; Hausteine and Jensen 2018). Other work suggests
18 that people’s preference for EVs depends upon vehicle attributes, infrastructure availability, and
19 policies that promote EV adoption, specifically, purchasing and operating costs, driving range, charging
20 duration, vehicle performance, and brand diversity (Liao et al. 2016). Behaviour change to enable
21 transport transformations will need to make the most of these factors whilst also working on the more
22 structural issues of time, space, and cost.

24 10.2.3 New demand concepts

25 Structural and behavioural choices that drive transport-related GHG emissions, such as time and cost
26 based on geography of freight and urban fabric, are likely to continue to be major factors. But there is
27 also a variation within each structural choice that is based around personal demand factors related to
28 values that indirectly change choices in transport. Chapter 5 identified three megatrends that affect
29 demand for services, including circular economy, the shared economy, and digitalisation. These three
30 megatrends can have specific effect on transport emissions, as described below.

31 **Circular Economy:** The problem of resources and their environmental impacts is driving the move to
32 a circular economy (Bleischwitz et al. 2017). Circular economy principles include increased material
33 efficiency, re-using or extending product lifetimes, recycling, and green logistics. Dematerialisation,
34 the reduction in the quantity of the materials used in the production of one unit of output, is a circular
35 economy principle that can affect the operations and emissions of the transport sector, as reductions in
36 the quantities of materials used reduces transport needs, while reductions in the weight of products
37 improves the efficiency of transporting them. Dematerialisation can occur through more efficient
38 production processes but also when a new product is developed to provide the same functionality as
39 multiple products. The best example of this trend is a smart phone, which provides the service of at
40 least 22 other former devices (Rivkin 2019). A move to declutter lifestyles can also drive
41 dematerialisation (Whitmarsh et al. 2017). Some potential for dematerialisation has been suggested due
42 to 3-D printing, which would also reduce transport emissions through localised production of product
43 components (d’Aveni 2015; UNCTAD 2018). There is evidence to suggest, however, that reductions
44 in material use resulting from more efficient product design or manufacturing are offset by increased
45 consumer demand (Kasulaitis et al. 2019). Whether or not dematerialisation can lead to reduction of
46 emissions from the transport sector is still an open questions that requires evaluating the entire product
47 ecosystem (Van Loon et al. 2014; Coroama et al. 2015; Kasulaitis et al. 2019).

1 **Shared Economy.** Shared mobility is arguably the most rapidly growing and evolving sector of the
2 sharing economy and includes bike sharing, e-scooter sharing, car-sharing, and on-demand mobility
3 (Greenblatt and Shaheen 2015). The values of creating a more shared economy are related to both
4 reduced demand and greater efficiency, as well as the notion of community well-being associated with
5 the act of sharing instead of simply owning for oneself (Maginn et al. 2018; Sharp 2018). The literature
6 on shared mobility is expanding, but there is much uncertainty about the effect shared mobility will
7 have on transport demand and associated emissions (Nijland and Jordy 2017; ITF 2018a; Tikoudis et
8 al. 2021).

9 Asia represents the largest car-sharing region with 58% of worldwide membership and 43% of global
10 fleets deployed (Dhar et al. 2020). Europe accounts for 29% of worldwide members and 37% of shared
11 vehicle fleets (Shaheen et al. 2018). Ride-sourcing and carpooling systems are amongst the many new
12 entrants in the short-term shared mobility options. On-demand transport options complemented with
13 technology have enhanced the possibility of upscaling (Alonso-González et al. 2018). Car-sharing could
14 provide the same level of service as taxis, but taxis could be three times more expensive (Cuevas et al.
15 2016). The sharing economy, as an emerging economic-technological phenomenon (Kaplan and
16 Haenlein 2010), is likely to be a key driver of demand for transport of goods although data shows
17 increasing container movement due to online shopping (Suel and Polak 2018).

18 There is growing evidence that this more structured form of behavioural change through shared
19 economy practices, supported by a larger group than a single family, has a much greater potential to
20 save transport emissions, especially when complemented with decarbonised grid electricity (Greenblatt
21 and Shaheen 2015; Sharp 2018). Carpooling, for example, could result in an 11% reduction in vkm and
22 a 12% reduction in emissions, as carpooling requires less empty or non-productive passenger-
23 kilometres (pkm) (ITF 2020a,b). However, the use of local shared mobility systems such as on-demand
24 transport may create more transport emissions if there is an overall modal shift out of transit (ITF 2018a;
25 Schaller 2018). Similarly, some work suggests that commercial shared vehicle services such as Uber
26 and Lyft are leading to increased vehicle kms travelled (and associated GHG emissions) in part due to
27 deadheading (Schaller 2018; Tirachini and Gomez-Lobo 2020; Ward et al. 2021). Successful providers
28 compete by optimising personal comfort and convenience rather than enabling a sharing culture
29 (Eckhardt and Bardhi 2015), and concerns have been raised regarding the wider societal impacts of
30 these systems and for specific user groups such as older people (Fitt 2018; Marsden 2018). Concerns
31 have also been expressed over the financial viability of demand-responsive transport systems (Ryley et
32 al. 2014; Marsden 2018), how the mainstreaming of shared mobility systems can be institutionalised
33 equitably, and the operation and governance of existing systems that are only mode and operator-
34 focused (Akyelken et al. 2018; Jittrapirom et al. 2018; Pangbourne et al. 2020; Marsden 2018).

35 **Digitalisation:** In the context of the transport sector, digitalisation has enabled teleworking, which in
36 turn reduces travel demand. On the other hand, the prevalence of online shopping, enabled by the digital
37 economy, could have mixed effects on transport emissions (Le et al. 2021). For example, online
38 shopping could reduce vkm travelled but the move to expedited or rush delivery could mitigate some
39 benefits as they prevent consolidation of freight (Jaller and Pahwa 2020).

40 Digitalisation could also lead to systemic changes by enabling smart mobility. The smart mobility
41 paradigm refers to the process and practices of assimilation of ICTs and other sophisticated hi-
42 technology innovations into transport (Noy and Givoni 2018). Smart mobility can be used to influence
43 transport demand and efficiency (Benevolo et al. 2016). The synergies of emerging technologies (ICT,
44 IOT, Big Data) and shared economy could overcome some of the challenges facing the adoption of
45 emerging technologies (Marletto 2014; Chen et al. 2016; Weiss et al. 2018; Taiebat and Xu 2019) and
46 enable the expected large growth in emerging cities to be more sustainable (Docherty et al. 2018).
47 However, ICT, in particular IoT, could also cause more global energy demand (Hittinger and Jaramillo
48 2019). Box 10.1 summarises the main smart technologies being adopted rapidly by cities across the

1 world and their use in transport. There is a growing body of literature about the effect of smart
2 technology (including sensors guiding vehicles) on the demand for transport services. Smart
3 technologies can improve competitiveness of transit and active transport over personal vehicle use by
4 combining the introduction of new electro-mobility that improves time and cost along with behaviour
5 change factors (Henrik et al. 2017; SLoCaT 2018a,b, 2021). However, it is unclear what will be the net
6 effect of smart technology on the GHG emissions from the transport sector (Debnath et al. 2014; Lenz
7 and Heinrichs 2017).

9 **START BOX HERE**

10 **Box 10.1 Smart city technologies and transport**

11 *Information and Communication Technology (ICT):* ICT is at the core of Smart Mobility and will
12 provide the avenue for data to be collected and shared across the mobility system. The use of ICT can
13 help cities by providing real-time information on mobility options that can inform private vehicles along
14 with transit users or those using bikes, or who are walking. ICT can help with ticketing and payment
15 for transit or for road user charges (Tafidis et al. 2017; Gössling 2018) when combined with other
16 technologies such as Blockchain (Hargroves et al. 2020).

17 *Internet of Things (IoT) Sensors:* Sensors can be used to collect data to improve road safety, improve
18 fuel efficiency of vehicles, and reduce CO₂ emissions (Kubba and Jiang 2014; Kavitha et al. 2018).
19 Sensors can also provide data to digitally simulate transport planning options, inform the greater
20 utilisation of existing infrastructure and modal interconnections, and significantly improve disaster and
21 emergency responses (Hargroves et al. 2017). In particular, IoT sensors can be used to inform the
22 operation of fast-moving Trackless Tram and its associated last mile connectivity shuttles as part of a
23 transit activated corridor (Newman et al. 2019, 2021).

24 *Mobility as a Service (MaaS):* New, app-based mobility platforms will allow for the integration of
25 different transport modes (such as last mile travel, shared transit, and even micro-transit such as scooters
26 or bikes) into easy-to-use platforms. By integrating these modes, users will be able to navigate from A
27 to B to C based on which modes are most efficient with the necessary bookings and payments being
28 made through the one service. With smart city planning, these platforms can steer users towards shared
29 and rapid-transit (which should be the centre-piece of these systems), rather than encourage more people
30 to opt for the perceived convenience of booking a single-passenger ride (Becker et al. 2020). In low
31 density car-dependent cities, however, MaaS services such as the use of electric scooters/bikes are less
32 effective as the distances are too long and they do not enable the easy sharing that can happen in dense
33 station precincts (Jittrapirom et al. 2017).

34 *Artificial Intelligence (AI) and Big Data Analytics:* The rapidly growing level of technology enablement
35 of vehicles and urban infrastructure, combined with the growing ability to analyse larger and larger data
36 sets, presents a significant opportunity for transport planning, design, and operation in the future. These
37 technologies are used together to enable decisions about what kind of transport planning is used down
38 particular corridors. Options such as predictive congestion management of roads and freeways,
39 simulating planning options, and advanced shared transit scheduling can provide value to new and
40 existing transit systems (Toole et al. 2015; Anda et al. 2017; Hargroves et al. 2017).

41 *Blockchain or Distributed Ledger Technology:* Blockchain Technology provides a non-hackable
42 database that can be programmed to enable shared services like a local, solar microgrid where both solar
43 and shared electric vehicles can be managed (Green and Newman 2017). Blockchain can be used for
44 many transport-related applications including being the basis of MaaS or any local shared mobility
45 service as it facilitates shared activity without intermediary controls. Other applications include verified
46 vehicle ownership documentation, establishing identification, real-time road user pricing, congestion

1 zone charging, vehicle generated collision information, collection of tolls and charges, enhanced freight
2 tracking and authenticity, and automated car parking and payments (Hargroves et al. 2020). This type
3 of functionality will be particularly valuable for urban regeneration along a transit-activated corridor
4 where it can be used for managing shared solar in and around station precincts as well as managing
5 shared vehicles linked to the whole transport system (Newman et al. 2021). This technology can also
6 be used for road user charging along any corridor and by businesses accessing any services and in
7 managing freight (Carter and Koh 2018; Nguyen et al. 2019; Sedlmeir et al. 2020; Hargroves et al.
8 2020).

9 **END BOX HERE**

10
11 Autonomous vehicles are the other emerging transport technology that have the potential to
12 significantly improve ride quality and safety. Planes and high-speed trains are already largely
13 autonomous as they are guided in all their movements, especially coming into stations and airports,
14 although that does not necessarily mean they are driverless. Automation is also being used in new on-
15 road transit systems like Trackless Trams (Ndlovu and Newman 2020)). Private vehicles are being fitted
16 with more and more levels of autonomy and many are being trialled as ‘driverless’ in cities (Aria et al.
17 2016; Skeete 2018). If autonomous systems can be used to help on-road transit become more time and
18 cost competitive with cars, then the kind of transformative and disruptive changes needed to assist
19 decarbonisation of transport become more feasible (Bösch et al. 2018; Kassens-Noor et al. 2020; Abe
20 2021). Similarly, vehicle automation could improve vehicle efficiency and reduce congestion, which
21 would in turn reduce emissions (Vahidi and Sciarretta 2018; Massar et al. 2021). On the other hand, if
22 autonomous cars make driving more convenient, they could reduce demand for transit (Auld et al. 2017;
23 Sonnleitner et al. 2021). Paradoxically, autonomous cars could provide access to marginal groups such
24 as the elderly, people with disabilities, and those who cannot drive, which could in turn increase travel
25 demand (as measured by pkm) (Harper et al. 2016).

26 Heavy haulage trucks in the mining industry are already autonomous (Gaber et al. 2021) and automation
27 of long-haul trucks may happen sooner than automation of LDVs (Hancock et al. 2019). Autonomous
28 trucks may facilitate route, speed optimisation, and reduced fuel use, which can in turn reduce emissions
29 (Nasri et al. 2018; Paddeu and Denby 2021). There is growing interest in using drones for package
30 delivery. Drones could have lower impacts than ground-based delivery and, if deployed carefully,
31 drones could reduce energy use and GHG emissions from freight transport (Stolaroff et al. 2018).
32 Overall, some commentators are optimistic that smart and autonomous technologies can transform the
33 GHG from the transport sector (Seba 2014; Rivkin 2019; Sedlmeir et al. 2020). Others are more
34 sanguine unless policy interventions can enable the technologies to be used for purposes that include
35 zero carbon and the SDGs (Faisal et al. 2019; Hancock et al. 2019).

36 37 **10.2.4 Overall perspectives on systemic change**

38 The interactions between systemic factors set out here and technology factors discussed in much more
39 detail in the next sections, show that there is always going to be a need to integrate both approaches.
40 Good technology that has the potential to transform transport will not be used unless it fulfils broad
41 mobility and accessibility objectives related to time, cost, and well-being. Chapter 5 has set out three
42 transport transformations based on demand-side factors with highly transformative potential. Table 10.3
43 provides a summary of these systemic changes and their likely impact on GHG emissions. Note that the
44 quantitative estimates provided in the table may not be additive and the combined effect of
45 these strategies on GHG emissions from the transport sector require additional analysis.

46 **Table 10.3 Components of systemic change and their impacts on the transport sector**

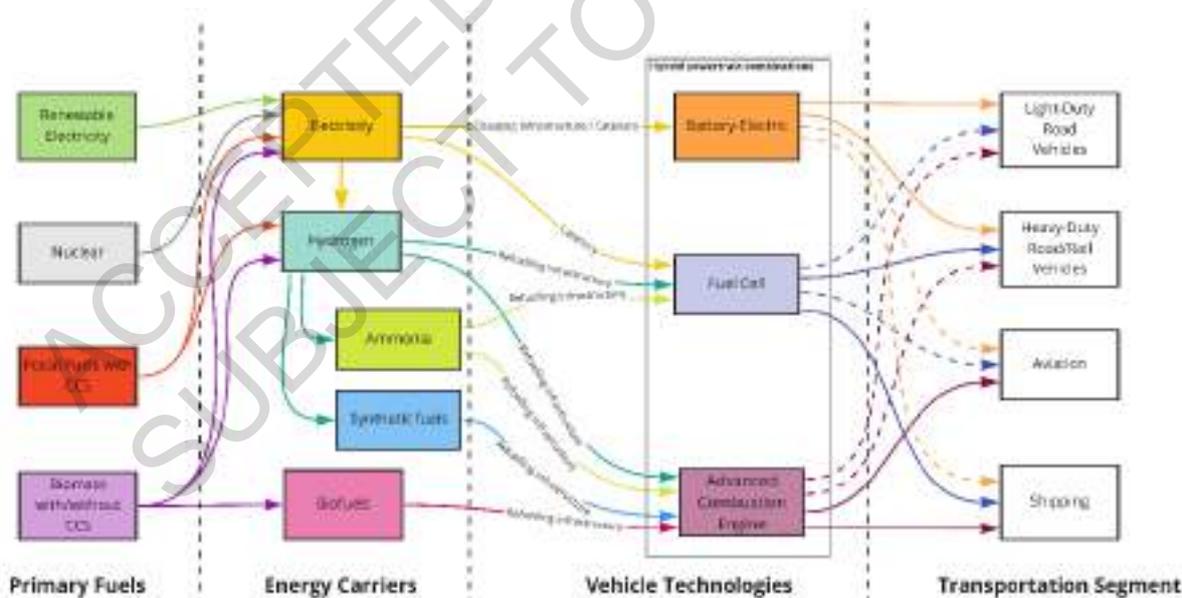

Systemic Change	Mechanisms through which it affects emissions in transport sector and likely impact on emissions
Changes in urban form	Denser, more compact polycentric cities with mixed land use patterns can reduce the distance between where people live, work, and pursue leisure activities, which can reduce travel demand. Case studies suggest that these changes in urban form could reduce transport-related GHG emissions between 4-25%, depending on the setting (Creutzig et al. 2015a,b; Pan et al. 2020).
Investments in transit and active transport infrastructure	Improving public transit systems and building infrastructure to support active transport modes (walking and biking) could reduce car travel. Case studies suggest that active mobility could reduce emissions from urban transport by 2%-10% depending on the setting (Creutzig et al. 2016; Zahabi et al. 2016; Keall et al. 2018; Gilby et al. 2019; Neves and Brand 2019; Bagheri et al. 2020; Ivanova et al. 2020; Brand et al. 2021). A shift to public transit modes can likely offer significant emissions reductions, but estimates are uncertain.
Changes in economic structures	Higher demand as a result of higher incomes could increase emissions, particularly in aviation and shipping. Higher prices could have the opposite effect and reduce emission. Structural changes associated with financial crises, pandemics, or the impacts of climate change could affect the elasticity of demand in uncertain ways. Thus, the effect of changes in economic structures on the GHG emissions from the transport sectors is uncertain.
Teleworking	A move towards a digital economy that allows workers to work remotely and access information remotely could reduce travel demand. Case studies suggest that teleworking could reduce transport emissions by 20% in some instances, but are likely 1%, at most, across the entire transport system (Roth et al. 2008; O'Keefe et al. 2016; Shabanpour et al. 2018; O'Brien and Aliabadi 2020).
Dematerialisation of the economy	A reduction in goods needed due to combining multiple functions into one device would reduce the need for transport. Reduced weights associated with dematerialisation would improve the efficiency of freight transport. However, emissions reductions from these efforts are likely dwarfed by increased consumption of goods.
Supply chain management	Supply chains could be optimised to reduce the movement or travel distance of product components. Logistics planning could optimise the use of transport infrastructure to increase utilization rates and decrease travel. The effect of these strategies on the GHG emissions from the transport sector is uncertain.
e-commerce	The effect of e-commerce on transport emissions is uncertain. Increased e-commerce would reduce demand for trips to stores but could increase demand for freight transport (particularly last-mile delivery) (Jaller and Pahwa 2020; Le et al. 2021).
Smart mobility	ICT and smart city technologies can be used to improve the efficiency of operating the transport system. Furthermore, smart technologies can improve competitiveness of transit and active transport over personal vehicle use by streamlining mobility options to compete with private cars. The effect of smart mobility on the GHG emissions from the transport sector is uncertain (Creutzig 2021).

<p>Shared mobility</p>	<p>Shared mobility could increase utilisation rates of LDVs, thus improving the efficiency of the system. However, shared mobility could also divert users from transit systems or active transport modes. Studies on ride-sourcing have reported both potential for reductions and increases in transport-related emissions (Schaller 2018; Ward et al. 2021). Other case studies suggests that carpooling to replace 20% of private car trips could result in a 12% reduction in GHG (ITF 2020a,b). Thus, the effect of shared mobility on transport-related GHG emissions is highly uncertain.</p>
<p>Vehicle automation</p>	<p>Vehicle automation could have positive or negative effects on emissions. Improved transit operations, more efficient traffic management, and better routing for light- and heavy-duty transport could reduce emissions (Vahidi and Sciarretta 2018; Nasri et al. 2018; Massar et al. 2021; Paddeu and Denby 2021). However, autonomous cars could make car travel more convenient, removing users from transit systems and increasing access to marginalised groups, which would in turn increase vkms travelled (Harper et al. 2016; Auld et al. 2017; Sonnleitner et al. 2021). Drones could reduce energy use and GHG emissions from freight transport (Stolaroff et al. 2018)</p>

1 **10.3 Transport technology innovations for decarbonisation**

2 This section focuses on vehicle technology and low-carbon fuel innovations to support decarbonisation
 3 of the transport sector. Figure 10.2 summarises the major pathways reviewed in this section. The
 4 advancements in energy carriers described in Figure 10.2 are discussed in greater detail in Chapter 6
 5 (Energy) and Chapter 11 (Industry) but the review presented in this chapter highlights their application
 6 in the transport sector. This section pays attention to the advancements in alternative fuels, electric, and
 7 fuel cell technologies since AR5.

Figure 10.2 Energy pathways for low-carbon transport technologies. Primary energy sources are shown in the far left, while the segments of the transport system are in the far right. Energy carriers and vehicle technologies are represented in the middle. Primary pathways are shown with solid lines, while dashed lined represent secondary pathways.

10.3.1 Alternative fuels – an option for decarbonising internal combustion engines

The average fuel consumption of new Internal Combustion Engine (ICE) vehicles has improved significantly in recent years due to more stringent emission regulations. However, improvements are now slowing down. The average fuel consumption of LDVs decreased by only 0.7 % between 2016 and 2017, reaching 7.2 litres of gasoline-equivalent (Lge) per 100 km in 2017, much slower than the 1.8 % improvement per year between 2005 and 2016 (GFEI 2020). Table 10.4 summarises recent and forthcoming improvements to ICE technologies and their effect on emissions from these vehicles. However, these improvements are not sufficient to meet deep decarbonisation levels in the transport sector. While there is significant and growing interest in electric and fuel-cell vehicles, future scenarios indicate that a large number of LDV may continue to be operated by ICE in conventional, hybrid, and plug-in hybrid configurations over the next 30 years (IEA 2019a) unless they are regulated away through ICE vehicle sales bans (as some nations have announced) (IEA 2021a). Moreover, ICE technologies are likely to remain the prevalent options for shipping and aviation. Thus, reducing CO₂ and other emissions from ICEs through the use of low-carbon or zero-carbon fuels is essential to a balanced strategy for limiting atmospheric pollutant levels. Such alternative fuels for ICE vehicles include natural gas-based fuels, biofuels, Ammonia, and other synthetic fuels.

Table 10.4 Engine technologies to reduce emissions from light-duty ICE vehicles and their implementation stage. Table nomenclature: GDI = Gasoline direct injection, VVT = Variable valve technology, CDA = Cylinder deactivation, CR = compression ratio, GDCI = Gasoline direct injection compression ignition, EGR = exhaust gas recirculation, RCCI = Reactivity controlled compression ignition, GCI = Gasoline compression ignition. Source: (Joshi 2020)

Implementation Stage	Engine Technology	CO ₂ Reduction (%)
Implemented	Baseline: GDI, turbo, stoichiometry.	0
Development	Atkinson cycle (+ VVT)	3 - 5
	Dynamic CDA + Mild Hybrid or Miller	10 -15
	Lean-burn GDI	10 - 20
	Variable CR	10
	Spark assisted GCI	10
	GDCI	15 - 25
	Water Injection	5 - 10
	Pre-chamber concepts	15 - 20
	Homogeneous Lean	15 - 20
	Dedicated EGR	15 - 20
	2-stroke opp. piston Diesel	25 - 35
RCCI	20 - 30	

1

2 *Natural Gas:* Natural gas could be used as an alternative fuel to replace gasoline and diesel. Natural gas
3 in vehicles can be used as compressed natural gas (CNG) and liquefied natural gas (LNG). CNG is
4 gaseous at relatively high pressure (10 to 25 MPa) and temperature (-40 to 30°C). In contrast, LNG is
5 used in liquid form at relatively low pressure (0.1 MPa) and temperature (-160°C). Therefore, CNG is
6 particularly suitable for commercial vehicles and light- to medium-duty vehicles, whereas LNG is better
7 suited to replace diesel in HDVs (Dubov et al. 2020; Dziejatkowski et al. 2020; Yaïci and Ribberink
8 2021). CNG vehicles have been widely deployed in some regions, particularly in Asian-Pacific
9 countries. For example, there are about 6 million CNG vehicles domiciled in China, the most of any
10 country (Qin et al. 2020). However, only 20% of vehicles that operate using CNG were originally
11 designed as CNG vehicles, with the rest being gasoline-fuelled vehicles that have been converted to
12 operate with CNG (Chala et al. 2018).

13 Natural gas-based vehicles have certain advantages over conventional fuel-powered ICE vehicles,
14 including lower emissions of criteria air pollutants, no soot or particulate, low carbon to Hydrogen ratio,
15 moderate noise, a wide range of flammability limits, and high-octane numbers (Kim 2019; Bayat and
16 Ghazikhani 2020). Furthermore, the technology readiness of natural gas vehicles is very high (TRL 8-
17 9), with direct modification of existing gasoline and diesel vehicles possible (Transport and
18 Environment 2018; Peters et al. 2021; Sahoo and Srivastava 2021). On the other hand, methane
19 emissions from the natural gas supply chain and tailpipe CO₂ emissions remain a significant concern
20 (Trivedi et al. 2020). As a result, natural gas as a transition transportation fuel may be limited due to
21 better alternative options being available and due to regulatory pressure to decarbonise the transport
22 sector rapidly. For example, the International Maritime Office (IMO) has set a target of 40% less carbon
23 intensity in shipping by 2030, which cannot be obtained by simply switching to natural gas.

24 *Biofuels:* Since AR5, the faster than anticipated adoption of electromobility, primarily for LDVs, has
25 partially shifted the debate around the primary use of biofuels from land transport to the shipping and
26 aviation sectors (Davis et al. 2018; IEA 2017a). At the same time, other studies highlight that biofuels
27 may have to complement electromobility in road transport, particularly in developing countries, offering
28 relevant mitigation opportunities in the short- and mid-term (up to 2050) (IEA 2021b). An important
29 advantage of biofuels is that they can be converted into energy carriers compatible with existing
30 technologies, including current powertrains and fuel infrastructure. Also, biofuels can diversify the
31 supply of transport fuel, raise energy self-sufficiency in many countries, and be used as a strategy to
32 diversify and strengthen the agro-industrial sector (Puricelli et al. 2021). The use of biofuels as a
33 mitigation strategy is driven by a combination of factors, including not only the costs and technology
34 readiness levels of the different biofuel conversion technologies, but also the availability and costs of
35 both biomass feedstocks and alternative mitigation options, and the relative speed and scale of the
36 energy transition in energy and transport sectors (Box 10.2).

37

38 **START BOX HERE**

39

40

41 **Box 10.2 – Bridging land use and feedstock conversion footprints for biofuels**

42

43 Under specific conditions, biofuels may represent an important climate mitigation strategy for the
44 transport sector (Muratori et al. 2020; Daioglou et al. 2020). Both SR1.5 and SRCL highlighted that
45 biofuels could be associated with climate mitigation co-benefits and adverse side effects to many SDGs.
46 These side-effects depend on context-specific conditions, including deployment scale, associated land-
47 use changes and agricultural management practices (see Section 7.4.4 and Box 7.10 in Chapter 7). There
48 is broad agreement in the literature that the most important factors in determining the climate footprint
of biofuels are the land use and land use change characteristics associated with biofuel deployment

1 scenarios e.g. (Elshout et al. 2015; Daioglou et al. 2020). This issue is covered in more detail in Chapter
2 7, Box 7.1. While the mitigation literature primarily focuses on the GHG-related climate forcings, note
3 that land is an integral part of the climate system through multiple geophysical and geochemical
4 mechanisms (albedo, evaporation, etc.). For example, Sections 2.2.7, 7.3.4 in the WGI report indicate
5 that geophysical aspects of historical land use change outweigh the geochemical effects, leading to a
6 net cooling effect. The land-related carbon footprints of biofuels presented in sections 10.4-10.6 are
7 adopted from Chapter 7 (See section 7.4.4 and Box 7, Figure 7.1). The results show how the land-related
8 footprint increases due to an increased outtake of biomass, as estimated with different models that rely
9 on global supply scenarios of biomass for energy and fuel of 100 EJ. The integrated assessment models
10 and scenarios used include the EMF 33 scenarios (IAM-EMF33), from partial models with constant
11 land cover (PM-CLC), and from partial models with natural regrowth (PM-NGR). These results are
12 combined with both biomass cultivation emission ranges for advanced biofuels aligned with (Edwards
13 et al. 2017; El Akkari et al. 2018; Jeswani et al. 2020; Puricelli et al. 2021) and conversion efficiencies
14 and conversion phase emissions as described in Table 10.5. The modelled footprints resulting from land
15 use changes related to delivering 100 EJ of biomass at global level are in the range of 3 – 77 gCO₂eq./MJ
16 of advanced biofuel (median 38 gCO₂eq./MJ) at an aggregate level for IAMs and partial models, with
17 constant land cover (Rose et al. 2020; Daioglou et al. 2020). The results for partial models with natural
18 regrowth are much higher (91-246 CO₂eq./MJ advanced biofuel. The latter ranges may appear in
19 contrast with the results from the scenario literature in 10.7, where biofuels play a role in many scenarios
20 compatible low warming levels. This contrast is a result of different underlying modelling practices.
21 The general modelling approach used for the scenarios in the AR6 database accounts for the land-use
22 change and all other GHG emissions along a given transformation trajectory, enabling assessments of
23 the warming level incurred. The results labelled "EMF33" and "partial models with constant land cover"
24 are obtained with this modelling approach. The results in the category "partial models with natural
25 regrowth" attribute additional CO₂ emissions to the bioenergy system, corresponding to estimated
26 uptake of CO₂ in a counterfactual scenario where land is not used for bioenergy, but instead subject to
27 natural vegetation regrowth. While the partial analysis provides insights into the implications of
28 alternative land-use strategies, such analysis does not identify the actual emissions of bioenergy
29 production. As a result, the partial analysis is not compatible with the identification of warming levels
30 incurred by an individual transformation trajectory, and therefore not aligned with the general approach
31 applied for the scenarios in the AR6 database.

32 More details on land-use change impacts and the potential to deliver the projected demands of biofuels
33 at the global level are further addressed in Chapter 7. While, in general, the above results cover most of
34 the variety of GHG range intensities of biofuel options presented in the literature, the more specific
35 LCA literature should be consulted when considering specific combinations of biomass feedstock and
36 conversion technologies in specific regions.

37
38 **END BOX HERE**

39
40 Many studies have addressed the life cycle emissions of biofuel conversion pathways for land transport,
41 aviation, and marine applications, e.g. (Edwards et al. 2017; Staples et al. 2018; Tanzer et al. 2019).
42 Bioenergy technologies generally struggle to compete with existing fossil fuel-based ones because of
43 the higher costs involved. However, the extent of the cost gap depends critically on the availability and
44 costs of biomass feedstock (IEA 2021b). Ethanol from corn and sugarcane is commercially available in
45 countries such as Brazil and the US. Biodiesel from oil crops and hydro-processed esters and fatty acids
46 are available in various countries, notably in Europe and parts of Southeast Asia. On the infrastructure
47 side, biomethane blending is being implemented in some regions of the US and Europe, particularly in
48 Germany, with the help of policy measures (IEA 2021b). While many of these biofuel conversion

1 technologies could also be implemented using seaweed feedstock options, these value chains are not
2 yet mature (Jiang et al. 2016).

3 Technologies to produce advanced biofuels from lignocellulosic feedstocks have suffered from slow
4 technology development and are still struggling to achieve full commercial scale. Their uptake is likely
5 to require carbon pricing and/or other regulatory measures, such as clean fuel standards in the transport
6 sector or blending mandates. Several commercial-scale advanced biofuels projects are in the pipeline
7 in many parts of the world, encompassing a wide selection of technologies and feedstock choices,
8 including carbon capture and sequestration (CCS) that supports carbon dioxide removal (CDR). The
9 success of these projects is vital to moving forward the development of advanced biofuels and bringing
10 many of the advanced biofuels' value chains closer to the market (IEA 2021b). Finally, biofuel
11 production and distribution supply chains involve notable transport and logistical challenges that need
12 to be overcome. (Mawhood et al. 2016; Skeer et al. 2016; IEA 2017a; Puricelli et al. 2021).

13

14 Table 10.5 summarises performance data for different biofuel technologies, while Figure 10.3 shows
15 the technology readiness levels, which are based on (Mawhood et al. 2016; Skeer et al. 2016; IEA
16 2017a; Puricelli et al. 2021).

17

18 **Table 10.5 Ranges of efficiency, GHG emissions, and relative costs of selected biofuel conversion**
19 **technologies for road, marine, and aviation biofuels.**

Main application	Conversion technology	Energy efficiency of conversion ^a	GHG emissions of conversion process (gCO _{2eq} /MJ _{fuel}) ^b	Relative cost of conversion process
Road	Lignocellulosic ethanol	35% ^c	5 ^d	Medium
Road/Aviation	Gasification and Fischer-Tropsch synthesis	57% ^e	<1 ^d	High
Road	Ethanol from sugar and starch	60-70% ^f	1 – 31 ^d	Low
Road	Biodiesel from oil crops	95% ^g	12 - 30 ^d	Low
Marine	Upgraded pyrolysis oil	30 - 61% ^h	1-4 ^h	Medium
Aviation/Marine	Hydro-processed esters and fatty acids	80% ⁱ	3 ⁱ	Medium
Aviation	Alcohol to jet	90% ^j	<1 ^k	High
Road/Marine	Biomethane from residues	60% ^l	n.a.	Low
Marine/Aviation	Hydrothermal liquefaction	35-69% ^h	<1 ^h	High
Aviation	Sugars to hydrocarbons	65% ^m	15 ^m	High

Road	Gasification and syngas fermentation	40% ⁿ	30-40 ⁿ	High
------	--------------------------------------	------------------	--------------------	------

Notes: ^aCalculated as liquid fuels output divided by energy in feedstock entering the conversion plant; ^bGHG emission here refers only the conversion process. Impacts from the different biomass options are not included here as they are addressed in Chapter 7; ^c(Olofsson et al. 2017); ^d(Edwards et al. 2017); ^e(Simell et al. 2014); ^f(de Souza Dias et al. 2015); ^g(Castanheira et al. 2015); ^h(Tanzer et al. 2019); ⁱ(Klein et al. 2018); ^j(Narula et al. 2017); ^k(de Jong et al. 2017); ^l(Salman et al. 2017); ^m(Moreira et al. 2014; Roy et al. 2015; Handler et al. 2016)

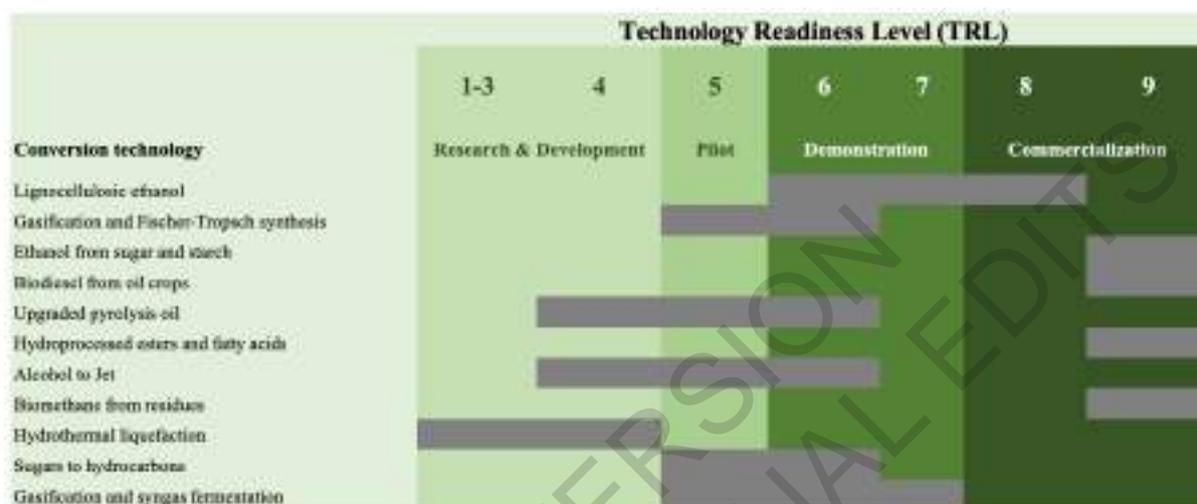

Figure 10.3 Commercialisation status of selected biofuels conversion technologies. The grey boxes represent the current TRL of each conversion technology.

Within the aviation sector, jet fuels produced from biomass resources (so-called sustainable aviation fuels, SAF) could offer significant climate mitigation opportunities under the right policy circumstances. Despite the growing interest in aviation biofuels, demand and production volumes remain negligible compared to conventional fossil aviation fuels. Nearly all flights powered by biofuels have used fuels derived from vegetable oils and fats, and the blending level of biofuels into conventional aviation fuels for testing is up to 50% today (Mawhood et al. 2016). To date, only one facility in the US is regularly producing sustainable aviation fuels based on waste oil feedstocks. The potential to scale up bio-based SAF volumes is severely restricted by the lack of low cost and sustainable feedstock options (see Chapter 7). Lignocellulosic feedstocks are considered to have a great potential for the production of financially competitive bio-based SAF in many regions. However, production facilities involve significant capital investment and estimated levelised costs are typically more than twice the selling price of conventional jet fuel. In some cases (notably for vegetable oils), the feedstock price is already higher than that of the fossil jet fuel (Mawhood et al. 2016). Some promising technological routes for producing SAF from lignocellulosic feedstocks are below technology readiness level (TRL) 6 (pilot scale) with just a few players involved in the development of these technologies. Although it would be physically possible to address the mid-century projections for substantial use of biofuels in the aviation sector (from IEA and other sectoral organisations (ICAO 2017)), this fuel deployment scale could only be achieved with very large capital investments in bio-based SAF production infrastructure, and substantial policy support.

In comparison to the aviation sector, the prospects for technology deployment are better in the shipping sector. The advantage of shipping fuels is that marine engines have a much higher operational flexibility on a mix of fuels, and shipping fuels do not need to undergo as extensive refining processes as road and aviation fuels to be considered drop-in. However, biofuels in marine engines have only been tested at

1 an experimental or demonstration stage, leaving open the question about the scalability of the
2 operations, including logistics issues. Similar to the aviation sector, securing a reliable, sustainable
3 biomass feedstock supply and mature processing technologies to produce price-competitive biofuels at
4 a large scale remains a challenge for the shipping sector (Hsieh and Felby 2017). Other drawbacks
5 include industry concerns about oxidation, storage, and microbial stability for less purified or more
6 crude biofuels. Assuming that biofuels are technically developed and available for the shipping sector
7 in large quantities, a wider initial introduction of biofuels in the sector is likely to depend upon increased
8 environmental regulation of particulate and GHG emissions. Biofuels may also offer a significant
9 advantage in meeting ambitious sulphur emission reduction targets set by the sectoral organisations.
10 More extensive use of marine biofuels will most likely be first implemented in inner-city waterways,
11 inland river freight routes, and coastal green zones. Given the high efficiency of the diesel engine, a
12 large-scale switch to a different standard marine propulsion method in the near to medium-term future
13 seems unlikely. Thus, much of the effort has been placed on developing biofuels compatible with diesel
14 engines. So far, biodiesel blends look promising, as used in land transport. Hydrotreated vegetable oil
15 (HVO) is also a technically good alternative and is compatible with current engines and supply chains,
16 while the introduction of multifuel engines may open the market for ethanol fuels (Hsieh and Felby
17 2017).

18 *Ammonia:* At room temperature and atmospheric pressure, Ammonia is a colourless gas with a distinct
19 odour. Due to relatively mild conditions for liquefaction, Ammonia is transferred and stored as a
20 liquefied or compressed gas and has been used as an essential industrial chemical resource for many
21 products. In addition, since the chemical structure of Ammonia is without carbon molecules, Ammonia
22 has attracted attention as a carbon-neutral fuel that can also improve combustion efficiency (Gill et al.
23 2012). Furthermore, Ammonia could also serve as a Hydrogen carrier and used in fuel cells. These
24 characteristics have driven increased interest in the low-carbon production of Ammonia, which would
25 have to be coupled to low-carbon Hydrogen production (with low-carbon electricity providing the
26 needed energy or with CCS).

27 For conventional internal combustion engines, the use of Ammonia remains challenging due to the
28 relatively low burning velocity and high ignition temperature. Therefore, Frigo and Gentili (2014) have
29 suggested a dual-fuelled spark-ignition engine operated by liquid Ammonia and Hydrogen, where
30 Hydrogen is generated from Ammonia using the thermal energy of exhaust gas. On the other hand, the
31 high-octane number of Ammonia means good knocking resistance of spark ignition engines and is
32 promising for improving thermal efficiency. For compression ignition engines, the high-ignition
33 temperature of Ammonia requires a high compression ratio causing an increase in mechanical friction.
34 Since Gray et al. (1966), many studies have shown that the compression ratio can be reduced by mixing
35 combustion with secondary fuels such as diesel and Hydrogen with low self-ignition temperatures, as
36 summarised by Dimitriou and Javaid (2020). Using a secondary fuel with a high cetane number and the
37 adoption of a suitable fuel injection timing has enabled highly efficient combustion of compression
38 ignition engines in the dual fuel mode with Ammonia ratios up to 95% (Dimitriou and Javaid 2020).
39 One major challenge for realising an Ammonia-fuelled engine is the reduction of unburned Ammonia,
40 as described in Section 6.4.5. (Reiter and Kong 2011). Processes being examined include the use of
41 exhaust gas recirculation (EGR) (Pochet et al. 2017) and after treatment systems. However, these
42 processes require space, which is a constraint for LDVs and air transport but more practical for ships.
43 Shipbuilders are developing an Ammonia engine based on the existing diesel dual-fuel engine to launch
44 a service in 2025 (Brown 2019; MAN-ES 2019). Ammonia could therefore contribute significantly to
45 decarbonisation in the shipping sector (as expanded in section 10.6) with potential niche applications
46 elsewhere.

47 *Synthetic fuels:* Synthetic fuels can contribute to transport decarbonisation through synthesis from
48 electrolytic Hydrogen produced with low carbon electricity or Hydrogen produced with CCS, and

1 captured CO₂ using the Fischer-Tropsch process (Liu et al. 2020a). Due to similar properties of synthetic
2 fuels to those of fossil fuels, synthetic fuels can reduce GHG emissions in both existing and new
3 vehicles without significant changes to the engine design. While the Fischer-Tropsch process is a well-
4 established technology (Liu et al. 2020a), low-carbon synthetic fuel production is still in the
5 demonstration stage. Even though their production costs are expected to decline in the future due to
6 lower renewable electricity prices, increased scale of production, and learning effects, synthetic fuels
7 are still up to 3 times more expensive than conventional fossil fuels (Section 6.6.2.4). Furthermore,
8 since the production of synthetic fuels involves thermodynamic conversion loss, there is a concern that
9 the total energy efficiency is lower than that of electric vehicles (Soler 2019). Given these high costs
10 and limited scales, the adoption of synthetic fuels will likely focus on the aviation, shipping, and long-
11 distance road transport segments, where decarbonisation by electrification is more challenging. In
12 particular, synthetic fuels are considered promising as an aviation fuel (as expanded in section 10.5).

14 10.3.2 Electric technologies

15 Widespread electrification of the transport sector is likely crucial for reducing transport emissions and
16 depends on appropriate energy storage systems (EES). However, large-scale diffusion of EES depends
17 on improvements in energy density (energy stored per unit volume), specific energy (energy stored per
18 unit weight), and costs (Cano et al. 2018). Recent trends suggest EES-enabled vehicles are on a path of
19 becoming the leading technology for LDVs, but their contribution to heavy-duty freight is more
20 uncertain.

21 *Electrochemical storage of light and medium-duty vehicles:* Electrochemical storage, i.e., batteries, are
22 one of the most promising forms of energy storage for the transport sector and have dramatically
23 improved in their commerciality since AR5. Rechargeable batteries are of primary interest for
24 applications within the transport sector, with a range of mature and emerging chemistries able to support
25 the electrification of vehicles. The most significant change since AR5 and SPR1.5 is the dramatic rise
26 in lithium-ion batteries (LIB), which has enabled electromobility to become a major feature of
27 decarbonisation.

28 Before the recent growth in market share of LIBs, lead-acid batteries, nickel batteries, high-temperature
29 sodium batteries, and redox flow batteries were of particular interest for the transport sector (Placke et
30 al. 2017). Due to their low costs, lead-acid batteries have been used in smaller automotive vehicles, e.g.
31 e-scooters and e-rickshaws (Dhar et al. 2017). However, their application in electric vehicles will be
32 limited due to their low specific energy (Andwari et al. 2017). Nickel-metal hydride (NiMH) batteries
33 have a better energy density than lead-acid batteries and have been well-optimised for regenerative
34 braking (Cano et al. 2018). As a result, NiMH batteries were the battery of choice for hybrid electric
35 vehicles (HEVs). Ni-Cadmium (NiCd) batteries have energy densities lower than NiMH batteries and
36 cost around ten times more than lead-acid batteries (Table 6.5, Chapter 6). For this reason, NiCd
37 batteries do not have major prospects within automotive applications. There are also no examples of
38 high-temperature sodium or redox flow batteries being used within automotive applications.

39 Commercial application of LIBs in automotive applications started around 2000 when the price of LIBs
40 was more than 1,000 USD per kWh (Schmidt et al. 2017). By 2020, the battery manufacturing capacity
41 for automotive applications was around 300 GWh per year (IEA 2021a). Furthermore, by 2020, the
42 average battery pack cost had come down to 137 USD per kWh, a reduction of 89% in real terms since
43 2010 (Henze 2020). Further improvements in specific energy, energy density (Nykqvist et al. 2015;
44 Placke et al. 2017) and battery service life (Liu et al. 2017) of LIBs are expected through additional
45 design optimisation (Table 6.5, Chapter 6). These advancements are expected to lead to EVs with even
46 longer driving ranges, further supporting the uptake of LIBs for transport applications (Cano et al.
47 2018). However, the performance of LIBs under freezing and high temperatures is a concern (Liu et al.

1 2017) for reliability. Auto manufacturers have some pre-heating systems for batteries to see that they
2 perform well in very cold conditions (Wu et al. 2020).

3 For EVs sold in 2018, the material demand was about 11 kilotonnes (kt) of optimised lithium, 15 kt of
4 cobalt, 11 kt of manganese, and 34 kt of nickel (IEA 2019a, 2021a). IEA projections for 2030 in the EV
