INTERGOVERNMENTAL PANEL ON climate change

Climate Change 2022

Mitigation of Climate Change

WGIII

Working Group III contribution to the
Sixth Assessment Report of the
Intergovernmental Panel on Climate Change

**WORKING GROUP III CONTRIBUTION
TO THE IPCC SIXTH ASSESSMENT REPORT (AR6)**

Summary for Policymakers

Drafting Authors:

Jim Skea (United Kingdom), Priyadarshi R Shukla (India), Andy Reisinger (New Zealand), Raphael Slade (United Kingdom), Minal Pathak (India), Alaa Al Khourdajie (United Kingdom/Syria), Renée van Diemen (the Netherlands/United Kingdom), Amjad Abdulla (Maldives), Keigo Akimoto (Japan), Mustafa Babiker (Sudan/Saudi Arabia), Quan Bai (China), Igor Bashmakov (Russian Federation), Christopher Bataille (Canada), Göran Berndes (Sweden), Gabriel Blanco (Argentina), Kornelis Blok (the Netherlands), Mercedes Bustamante (Brazil), Edward Byers (Austria), Luisa F. Cabeza (Spain), Katherine Calvin (the United States of America), Carlo Carraro (Italy), Leon Clarke (the United States of America), Annette Cowie (Australia), Felix Creutzig (Germany), Diriba Korecha Dadi (Ethiopia), Dipak Dasgupta (India), Heleen de Coninck (the Netherlands), Fatima Denton (the Gambia), Shobhakar Dhakal (Nepal/Thailand), Navroz K. Dubash (India), Oliver Geden (Germany), Michael Grubb (United Kingdom), Céline Guivarch (France), Shreekanth Gupta (India), Andrea Hahmann (Chile), Kirsten Halsnaes (Denmark), Paulina Jaramillo (the United States of America), Kejun Jiang (China), Frank Jotzo (Australia), Tae Yong Jung (Republic of Korea), Suzana Kahn Ribeiro (Brazil), Smail Khennas (Algeria), Şiir Kılış (Turkey), Silvia Kreibiehl (Germany), Volker Krey (Austria), Elmar Kriegler (Germany), William Lamb (Germany), Franck Lecocq (France), Shuaib Lwasa (Uganda), Nagmeldin Mahmoud (Sudan), Cheikh Mbow (Senegal), David McCollum (the United States of America), Jan Christoph Minx (Germany), Catherine Mitchell (United Kingdom), Rachid Mrabet (Morocco), Yacob Mulugetta (Ethiopia), Gert-Jan Nabuurs (the Netherlands), Gregory Nemet (the United States of America/Canada), Peter Newman (Australia), Leila Niamir (Germany/Iran), Lars J. Nilsson (Sweden), Sudarmanto Budi Nugroho (Indonesia), Chukwumerije Okereke (Nigeria/United Kingdom), Shonali Pachauri (India), Anthony Patt (Switzerland), Ramón Pichs-Madruga (Cuba), Joana Portugal Pereira (Brazil), Lavanya Rajamani (India), Keywan Riahi (Austria), Joyashree Roy (India/Thailand), Yamina Saheb (France/Algeria), Roberto Schaeffer (Brazil), Karen Seto (the United States of America), Shreya Some (India), Linda Steg (the Netherlands), Ferenc L. Toth (Hungary), Diana Ürge-Vorsatz (Hungary), Detlef van Vuuren (the Netherlands), Elena Verdolini (Italy), Purvi Vyas (India), Yi-Ming Wei (China), Mariama Williams (Jamaica/the United States of America), Harald Winkler (Republic of South Africa).

A. Introduction and framing

The Working Group III (WG III) contribution to the IPCC's Sixth Assessment Report (AR6) assesses literature on the scientific, technological, environmental, economic and social aspects of mitigation of climate change. [FOOTNOTE 1] Levels of confidence [FOOTNOTE 2] are given in () brackets. Numerical ranges are presented in square [] brackets. References to Chapters, Sections, Figures and Boxes in the underlying report and Technical Summary (TS) are given in {} brackets.

FOOTNOTE 1: The Report covers literature accepted for publication by 11 October 2021.

FOOTNOTE 2: Each finding is grounded in an evaluation of underlying evidence and agreement. A level of confidence is expressed using five qualifiers, typeset in italics: *very low*, *low*, *medium*, *high* and *very high*. The assessed likelihood of an outcome or a result is described as: virtually certain 99–100% probability, very likely 90–100%, likely 66–100%, more likely than not 50–100%, about as likely as not 33–66%, unlikely 0–33%, very unlikely 0–10%, exceptionally unlikely 0–1%. Additional terms may also be used when appropriate, consistent with the IPCC uncertainty guidance: <https://www.ipcc.ch/site/assets/uploads/2018/05/uncertainty-guidance-note.pdf>.

The report reflects new findings in the relevant literature and builds on previous IPCC reports, including the WG III contribution to the IPCC's Fifth Assessment Report (AR5), the WG I and WG II contributions to AR6 and the three Special Reports in the Sixth Assessment cycle, [FOOTNOTE 3] as well as other UN assessments. Some of the main developments relevant for this report include {TS.1, TS.2}:

FOOTNOTE 3: The three Special Reports are: Global Warming of 1.5°C: an IPCC Special Report on the impacts of global warming of 1.5°C above pre-industrial levels and related global greenhouse gas emission pathways, in the context of strengthening the global response to the threat of climate change, sustainable development, and efforts to eradicate poverty (2018); Climate Change and Land: an IPCC Special Report on climate change, desertification, land degradation, sustainable land management, food security, and greenhouse gas fluxes in terrestrial ecosystems (2019); IPCC Special Report on the Ocean and Cryosphere in a Changing Climate (2019).

- **An evolving international landscape.** The literature reflects, among other factors: developments in the UN Framework Convention on Climate Change (UNFCCC) process, including the outcomes of the Kyoto Protocol and the adoption of the Paris Agreement {13, 14, 15, 16}; the UN 2030 Agenda for Sustainable Development including the Sustainable Development Goals (SDGs) {1, 3, 4, 17}; and the evolving roles of international cooperation {14}, finance {15} and innovation {16}.
- **Increasing diversity of actors and approaches to mitigation.** Recent literature highlights the growing role of non-state and sub-national actors including cities, businesses, Indigenous Peoples, citizens including local communities and youth, transnational initiatives, and public-private entities in the global effort to address climate change {5, 13, 14, 15, 16, 17}. Literature documents the global spread of climate policies and cost declines of existing and emerging low emission technologies, along with varied types and levels of mitigation efforts, and sustained reductions in greenhouse gas (GHG) emissions in some countries {2, 5, 6, 8, 12, 13, 16}, and the impacts of, and some lessons from, the COVID-19 pandemic. {1, 2, 3, 5, 13, 15, Box TS.1, Cross-Chapter Box 1 in Chapter 1}

- **Close linkages between climate change mitigation, adaptation and development pathways.** The development pathways taken by countries at all stages of economic development impact GHG emissions and hence shape mitigation challenges and opportunities, which vary across countries and regions. Literature explores how development choices and the establishment of enabling conditions for action and support influence the feasibility and the cost of limiting emissions {1, 3, 4, 5, 13, 15, 16}. Literature highlights that climate change mitigation action designed and conducted in the context of sustainable development, equity, and poverty eradication, and rooted in the development aspirations of the societies within which they take place, will be more acceptable, durable and effective {1, 3, 4, 5}. This report covers mitigation from both targeted measures, and from policies and governance with other primary objectives.
- **New approaches in the assessment.** In addition to the sectoral and systems chapters {3, 6, 7, 8, 9, 10, 11, 12}, the report includes, for the first time in a WG III report, chapters dedicated to demand for services, and social aspects of mitigation {5, Box TS.11}, and to innovation, technology development and transfer {16}. The assessment of future pathways in this report covers near term (to 2030), medium term (up to 2050), and long term (to 2100) timescales, combining assessment of existing pledges and actions {4, 5}, with an assessment of emissions reductions, and their implications, associated with long-term temperature outcomes up to the year 2100 {3}. [FOOTNOTE 4] The assessment of modelled global pathways addresses ways of shifting development pathways towards sustainability. Strengthened collaboration between IPCC Working Groups is reflected in Cross-Working Group boxes that integrate physical science, climate risks and adaptation, and the mitigation of climate change. [FOOTNOTE 5]

FOOTNOTE 4: The term ‘temperature’ is used in reference to “global surface temperatures” throughout this SPM as defined in footnote 8 of WG I SPM. See FOOTNOTE 14 of Table SPM.1. Emission pathways and associated temperature changes are calculated using various forms of models, as summarised in Box SPM.1 and Chapter 3 and discussed in Annex III.

FOOTNOTE 5: Namely: Economic Benefits from Avoided Climate Impacts along Long-Term Mitigation Pathways {Cross-Working Group Box 1 in Chapter 3}; Urban: Cities and Climate Change {Cross-Working Group Box 2 in Chapter 8}; and Mitigation and Adaptation via the Bioeconomy {Cross-Working Group Box 3 in Chapter 12}.

- **Increasing diversity of analytic frameworks from multiple disciplines including social sciences.** This report identifies multiple analytic frameworks to assess the drivers of, barriers to and options for, mitigation action. These include: economic efficiency including the benefits of avoided impacts; ethics and equity; interlinked technological and social transition processes; and socio-political frameworks, including institutions and governance {1, 3, 13, Cross-Chapter Box 12 in Chapter 16}. These help to identify risks and opportunities for action including co-benefits and just and equitable transitions at local, national and global scales. {1, 3, 4, 5, 13, 14, 16, 17}

Section B of this Summary for Policymakers (SPM) assesses *Recent developments and current trends*, including data uncertainties and gaps. Section C, *System transformations to limit global warming*, identifies emission pathways and alternative mitigation portfolios consistent with limiting global warming to different levels, and assesses specific mitigation options at the sectoral and system level. Section D addresses *Linkages between mitigation, adaptation, and sustainable development*. Section E, *Strengthening the response*, assesses knowledge of how enabling conditions of institutional design, policy, finance, innovation and governance arrangements can contribute to climate change mitigation in the context of sustainable development.

B. Recent developments and current trends

B.1 Total net anthropogenic GHG emissions [FOOTNOTE 6] have continued to rise during the period 2010–2019, as have cumulative net CO₂ emissions since 1850. Average annual GHG emissions during 2010–2019 were higher than in any previous decade, but the rate of growth between 2010 and 2019 was lower than that between 2000 and 2009. (*high confidence*) (Figure SPM.1) {Figure 2.2, Figure 2.5, Table 2.1, 2.2, Figure TS.2}

FOOTNOTE 6: Net GHG emissions in this report refer to releases of greenhouse gases from anthropogenic sources minus removals by anthropogenic sinks, for those species of gases that are reported under the common reporting format of the United Nations Framework Convention on Climate Change (UNFCCC): CO₂ from fossil fuel combustion and industrial processes (CO₂-FFI); net CO₂ emissions from land use, land use change and forestry (CO₂-LULUCF); methane (CH₄); nitrous oxide (N₂O); and fluorinated gases (F-gases) comprising hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulphur hexafluoride (SF₆) as well as nitrogen trifluoride (NF₃). Different datasets for GHG emissions exist, with varying time horizons and coverage of sectors and gases, including some that go back to 1850. In this report, GHG emissions are assessed from 1990, and CO₂ sometimes also from 1850. Reasons for this include data availability and robustness, scope of the assessed literature, and the differing warming impacts of non-CO₂ gases over time.

B.1.1 Global net anthropogenic GHG emissions were 59±6.6 GtCO₂-eq [FOOTNOTE 7, 8] in 2019, about 12% (6.5 GtCO₂-eq) higher than in 2010 and 54% (21 GtCO₂-eq) higher than in 1990. The annual average during the decade 2010–2019 was 56±6.0 GtCO₂-eq, 9.1 GtCO₂-eq yr⁻¹ higher than in 2000–2009. This is the highest increase in average decadal emissions on record. The average annual rate of growth slowed from 2.1% yr⁻¹ between 2000 and 2009 to 1.3% yr⁻¹ between 2010 and 2019. (*high confidence*) (Figure SPM.1) {Figure 2.2, Figure 2.5, Table 2.1, 2.2, Figure TS.2}

FOOTNOTE 7: GHG emission metrics are used to express emissions of different greenhouse gases in a common unit. Aggregated GHG emissions in this report are stated in CO₂-equivalent (CO₂-eq) using the Global Warming Potential with a time horizon of 100 years (GWP100) with values based on the contribution of Working Group I to the AR6. The choice of metric depends on the purpose of the analysis and all GHG emission metrics have limitations and uncertainties, given that they simplify the complexity of the physical climate system and its response to past and future GHG emissions. {Chapter 2 SM 2.3, Cross-Chapter Box 2 in Chapter 2, Box TS.2, WG I Chapter 7 Supplementary Material}

FOOTNOTE 8: In this SPM, uncertainty in historic GHG emissions is reported using 90 % uncertainty intervals unless stated otherwise. GHG emission levels are rounded to two significant digits; as a consequence, small differences in sums due to rounding may occur.

B.1.2 Growth in anthropogenic emissions has persisted across all major groups of GHGs since 1990, albeit at different rates. By 2019, the largest growth in absolute emissions occurred in CO₂ from fossil fuels and industry followed by CH₄, whereas the highest relative growth occurred in fluorinated gases, starting from low levels in 1990 (*high confidence*). Net anthropogenic CO₂ emissions from land use, land-use change and forestry (CO₂-LULUCF) are subject to large uncertainties and high annual variability, with *low confidence* even in the direction of the long-term trend [FOOTNOTE 9]. (Figure SPM.1) {Figure 2.2, Figure 2.5, 2.2, Figure TS.2}

FOOTNOTE 9: Global databases make different choices about which emissions and removals occurring on land are considered anthropogenic. Currently, net CO₂ fluxes from land reported by global book-keeping models used here are estimated to be about ~5.5 GtCO₂ yr⁻¹ higher than the aggregate

global net emissions based on national GHG inventories. This difference, which has been considered in the literature, mainly reflects differences in how anthropogenic forest sinks and areas of managed land are defined. Other reasons for this difference, which are more difficult to quantify, can arise from the limited representation of land management in global models and varying levels of accuracy and completeness of estimated LULUCF fluxes in national GHG inventories. Neither method is inherently preferable. Even when the same methodological approach is applied, the large uncertainty of CO₂-LULUCF emissions can lead to substantial revisions to estimated emissions. {Cross-Chapter Box 3 in Chapter 3, 7.2, SRCCL SPM A.3.3}

B.1.3 Historical cumulative net CO₂ emissions from 1850 to 2019 were 2400±240 GtCO₂ (*high confidence*). Of these, more than half (58%) occurred between 1850 and 1989 [1400±195 GtCO₂], and about 42% between 1990 and 2019 [1000±90 GtCO₂]. About 17% of historical cumulative net CO₂ emissions since 1850 occurred between 2010 and 2019 [410±30 GtCO₂]. [FOOTNOTE 10] By comparison, the current central estimate of the remaining carbon budget from 2020 onwards for limiting warming to 1.5°C with a probability of 50% has been assessed as 500 Gt CO₂, and as 1150 Gt CO₂ for a probability of 67% for limiting warming to 2°C. Remaining carbon budgets depend on the amount of non-CO₂ mitigation (±220 Gt CO₂) and are further subject to geophysical uncertainties. Based on central estimates only, cumulative net CO₂ emissions between 2010-2019 compare to about four fifths of the size of the remaining carbon budget from 2020 onwards for a 50% probability of limiting global warming to 1.5°C, and about one third of the remaining carbon budget for a 67% probability to limit global warming to 2°C. Even when taking uncertainties into account, historical emissions between 1850 and 2019 constitute a large share of total carbon budgets for these global warming levels [FOOTNOTE 11, 12]. Based on central estimates only, historical cumulative net CO₂ emissions between 1850-2019 amount to about four fifths [FOOTNOTE 12] of the total carbon budget for a 50% probability of limiting global warming to 1.5°C (central estimate about 2900 GtCO₂), and to about two thirds [FOOTNOTE 12] of the total carbon budget for a 67% probability to limit global warming to 2°C (central estimate about 3550 GtCO₂). {Figure 2.7, 2.2, Figure TS.3, WG I Table SPM.2}

FOOTNOTE 10: For consistency with WGI, historical cumulative CO₂ emissions from 1850-2019 are reported using 68% confidence intervals.

FOOTNOTE 11: The carbon budget is the maximum amount of cumulative net global anthropogenic CO₂ emissions that would result in limiting global warming to a given level with a given likelihood, taking into account the effect of other anthropogenic climate forcers. This is referred to as the total carbon budget when expressed starting from the pre-industrial period, and as the remaining carbon budget when expressed from a recent specified date. The total carbon budgets reported here are the sum of historical emissions from 1850 to 2019 and the remaining carbon budgets from 2020 onwards, which extend until global net zero CO₂ emissions are reached. {Annex I: Glossary; WG I SPM}

FOOTNOTE 12: Uncertainties for total carbon budgets have not been assessed and could affect the specific calculated fractions.

B.1.4 Emissions of CO₂-FFI dropped temporarily in the first half of 2020 due to responses to the COVID-19 pandemic (*high confidence*), but rebounded by the end of the year (*medium confidence*). The annual average CO₂-FFI emissions reduction in 2020 relative to 2019 was about 5.8% [5.1-6.3%], or 2.2 [1.9-2.4] GtCO₂ (*high confidence*). The full GHG emissions impact of the COVID-19 pandemic could not be assessed due to a lack of data regarding non-CO₂ GHG emissions in 2020. {Cross-Chapter Box 1 in Chapter 1, Figure 2.6, 2.2, Box TS.1, Box TS.1 Figure 1}

Global net anthropogenic emissions have continued to rise across all major groups of greenhouse gases.

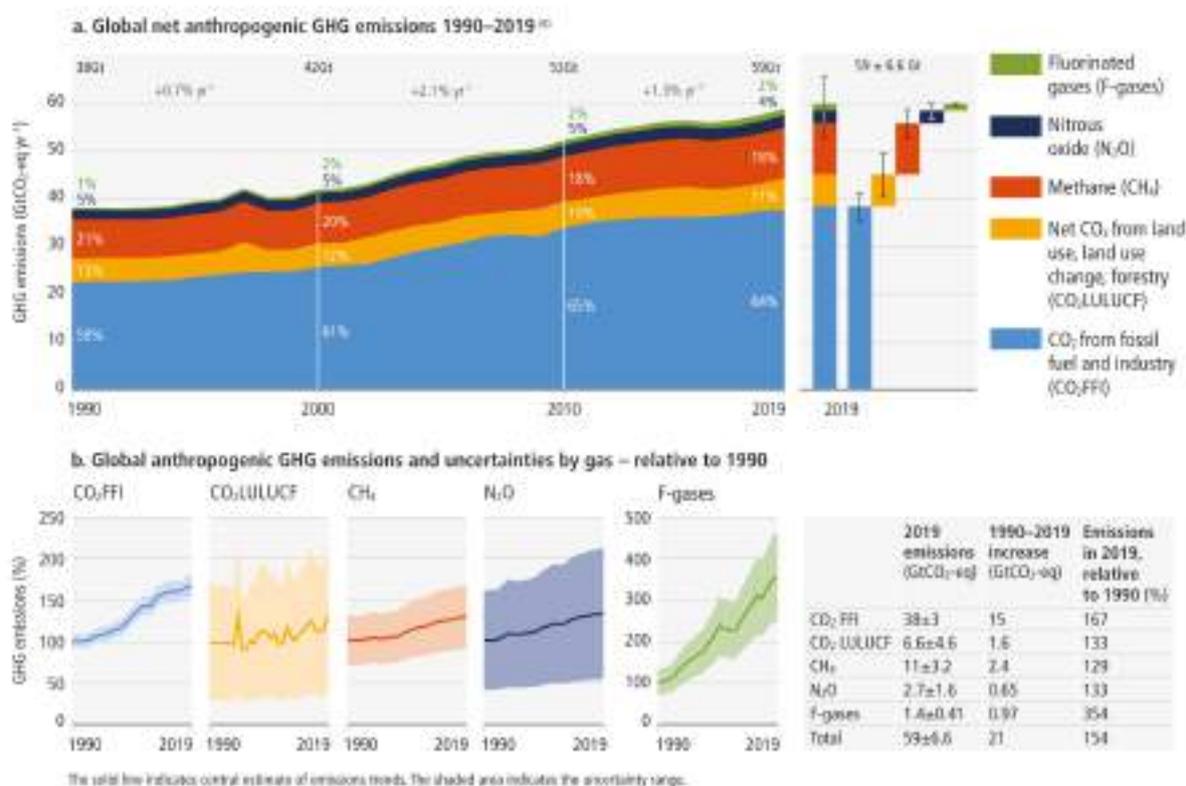

Figure SPM.1: Global net anthropogenic GHG emissions (GtCO₂-eq yr⁻¹) 1990–2019

Global net anthropogenic GHG emissions include CO₂ from fossil fuel combustion and industrial processes (CO₂-FFI); net CO₂ from land use, land use change and forestry (CO₂-LULUCF) [FOOTNOTE 9]; methane (CH₄); nitrous oxide (N₂O); fluorinated gases (HFCs; PFCs, SF₆, NF₃). [FOOTNOTE 6]

Panel a shows aggregate annual global net anthropogenic GHG emissions by groups of gases from 1990 to 2019 reported in GtCO₂-eq converted based on global warming potentials with a 100-year time horizon (GWP100-AR6) from the IPCC Sixth Assessment Report Working Group I (Chapter 7). The fraction of global emissions for each gas is shown 1990, 2000, 2010, 2019; as well as the aggregate average annual growth rate between these decades. At the right side of Panel a, GHG emissions in 2019 are broken down into individual components with the associated uncertainties [90% confidence interval] indicated by the error bars: CO₂ FFI ±8%, CO₂-LULUCF ±70%, CH₄ ±30%, N₂O ±60%, F-gases ±30%, GHG ±11%. Uncertainties in GHG emissions are assessed in the Supplementary Material to Chapter 2. The single year peak of emissions in 1997 was due to higher CO₂-LULUCF emissions from a forest and peat fire event in South East Asia.

Panel b shows global anthropogenic CO₂-FFI, net CO₂-LULUCF, CH₄, N₂O and fluorinated gas emissions individually for the period 1990–2019, normalised relative to 100 in 1990. Note the different scale for the included fluorinated gas emissions compared to other gases, highlighting its rapid growth from a low base. Shaded areas indicate the uncertainty range. Uncertainty ranges as shown here are specific for individual groups of greenhouse gases and cannot be compared. The table shows the central estimate for: absolute emissions in 2019, the absolute change in emissions between 1990 and 2019, and emissions in 2019 expressed as a percentage of 1990 emissions. {2.2, Figure 2.5, Figure TS.2, Chapter 2 SM}

FOOTNOTE 9: Global databases make different choices about which emissions and removals occurring on land are considered anthropogenic. Currently, net CO₂ fluxes from land reported by global book-keeping models used here are estimated to be about ~5.5 GtCO₂ yr⁻¹ higher than the aggregate global net emissions based on national GHG inventories. This difference, which has been considered in the literature, mainly reflects differences in how anthropogenic forest sinks and areas of managed land are defined. Other reasons for this difference, which are more difficult to quantify, can arise from the limited representation of land management in global models and varying levels of accuracy and completeness of estimated LULUCF fluxes in national GHG inventories. Neither method is inherently preferable. Even when the same methodological approach is applied, the large uncertainty of CO₂-LULUCF emissions can lead to substantial revisions to estimated emissions. {Cross-Chapter Box 3 in Chapter 3, 7.2, SRCCL SPM A.3.3}

FOOTNOTE 6: Net GHG emissions in this report refer to releases of greenhouse gases from anthropogenic sources minus removals by anthropogenic sinks, for those species of gases that are reported under the common reporting format of the United Nations Framework Convention on Climate Change (UNFCCC): CO₂ from fossil fuel combustion and industrial processes (CO₂-FFI); net CO₂ emissions from land use, land use change and forestry (CO₂-LULUCF); methane (CH₄); nitrous oxide (N₂O); and fluorinated gases (F-gases) comprising hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulphur hexafluoride (SF₆) as well as nitrogen trifluoride (NF₃). Different datasets for GHG emissions exist, with varying time horizons and coverage of sectors and gases, including some that go back to 1850. In this report, GHG emissions are assessed from 1990, and CO₂ sometimes also from 1850. Reasons for this include data availability and robustness, scope of the assessed literature, and the differing warming impacts of non-CO₂ gases over time.

B.2 Net anthropogenic GHG emissions have increased since 2010 across all major sectors globally. An increasing share of emissions can be attributed to urban areas. Emissions reductions in CO₂ from fossil fuels and industrial processes, due to improvements in energy intensity of GDP and carbon intensity of energy, have been less than emissions increases from rising global activity levels in industry, energy supply, transport, agriculture and buildings. (*high confidence*) {2.2, 2.4, 6.3, 7.2, 8.3, 9.3, 10.1, 11.2}

B.2.1 In 2019, approximately 34% [20 GtCO₂-eq] of total net anthropogenic GHG emissions came from the energy supply sector, 24% [14 GtCO₂-eq] from industry, 22% [13 GtCO₂-eq] from agriculture, forestry and other land use (AFOLU), 15% [8.7 GtCO₂-eq] from transport and 6% [3.3 GtCO₂-eq] from buildings.¹³ If emissions from electricity and heat production are attributed to the sectors that use the final energy, 90% of these indirect emissions are allocated to the industry and buildings sectors, increasing their relative GHG emissions shares from 24% to 34%, and from 6% to 16%, respectively. After reallocating emissions from electricity and heat production, the energy supply sector accounts for 12% of global net anthropogenic GHG emissions. (*high confidence*) {Figure 2.12, 2.2, 6.3, 7.2, 9.3, 10.1, 11.2, Figure TS.6}

FOOTNOTE 13: Sector definitions can be found in Annex II 9.1.

B.2.2 Average annual GHG emissions growth between 2010 and 2019 slowed compared to the previous decade in energy supply [from 2.3% to 1.0%] and industry [from 3.4% to 1.4%], but remained roughly constant at about 2% per year in the transport sector (*high confidence*). Emissions growth in AFOLU, comprising emissions from agriculture (mainly CH₄ and N₂O) and forestry and other land use (mainly CO₂) is more uncertain than in other sectors due to the high share and uncertainty of CO₂-LULUCF emissions (*medium confidence*). About half of total net AFOLU emissions are from CO₂-LULUCF, predominantly from deforestation. [FOOTNOTE 14] (*medium confidence*). {Figure 2.13, 2.2, 6.3, 7.2, Figure 7.3, 9.3, 10.1, 11.2, TS.3}

FOOTNOTE 14: Land overall constituted a net sink of $-6.6 (\pm 4.6)$ GtCO₂ yr⁻¹ for the period 2010–2019, comprising a gross sink of $-12.5 (\pm 3.2)$ GtCO₂ yr⁻¹ resulting from responses of all land to both anthropogenic environmental change and natural climate variability, and net anthropogenic CO₂-LULUCF emissions $+5.9 (\pm 4.1)$ GtCO₂ yr⁻¹ based on book-keeping models. {2.2, 7.2, Table 7.1}

B.2.3 The global share of emissions that can be attributed to urban areas is increasing. In 2015, urban emissions were estimated to be 25 GtCO₂-eq (about 62% of the global share) and in 2020, 29 GtCO₂-eq (67–72% of the global share).¹⁵ The drivers of urban GHG emission are complex and include population size, income, state of urbanisation and urban form. (*high confidence*) {8.1, 8.3}

FOOTNOTE 15: This estimate is based on consumption-based accounting, including both direct emissions from within urban areas, and indirect emissions from outside urban areas related to the production of electricity, goods and services consumed in cities. These estimates include all CO₂ and CH₄ emission categories except for aviation and marine bunker fuels, land-use change, forestry and agriculture. {8.1, Annex I: Glossary}

B.2.4 Global energy intensity (total primary energy per unit GDP) decreased by 2% yr⁻¹ between 2010 and 2019. Carbon intensity (CO₂ from fossil fuel combustion and industrial processes (CO₂ FFI) per unit primary energy) decreased by 0.3% yr⁻¹, with large regional variations, over the same period mainly due to fuel switching from coal to gas, reduced expansion of coal capacity, and increased use of renewables. This reversed the trend observed for 2000–2009. For comparison, the carbon intensity of primary energy is projected to decrease globally by about 3.5% yr⁻¹ between 2020 and 2050 in modelled scenarios that limit warming to 2°C (>67%), and by about 7.7% yr⁻¹ globally in scenarios that limit warming to 1.5°C (>50%) with no or limited overshoot.¹⁶ (*high confidence*) {Figure 2.16, 2.2, 2.4, Table 3.4, 3.4, 6.3}

FOOTNOTE 16: See Box SPM.1 for the categorisation of modelled long-term emission scenarios based on projected temperature outcomes and associated probabilities adopted in this report.

B.3 Regional contributions [FOOTNOTE 17] to global GHG emissions continue to differ widely. Variations in regional, and national per capita emissions partly reflect different development stages, but they also vary widely at similar income levels. The 10% of households with the highest per capita emissions contribute a disproportionately large share of global household GHG emissions. At least 18 countries have sustained GHG emission reductions for longer than 10 years. (*high confidence*) (Figure SPM.2) {Figure 1.1, Figure 2.9, Figure 2.10, Figure 2.25, 2.2, 2.3, 2.4, 2.5, 2.6, Figure TS.4, Figure TS.5}

FOOTNOTE 17: See Working Group III Annex II, Part 1 for regional groupings adopted in this report.

B.3.1 GHG emissions trends over 1990–2019 vary widely across regions and over time, and across different stages of development as shown in Figure SPM.2. Average global per capita net anthropogenic GHG emissions increased from 7.7 to 7.8 tCO₂-eq, ranging from 2.6 tCO₂-eq to 19 tCO₂-eq across regions. Least Developed Countries (LDCs) and Small Island Developing States (SIDS) have much lower per capita emissions (1.7 tCO₂-eq, 4.6 tCO₂-eq, respectively) than the global average (6.9 tCO₂-eq), excluding CO₂-LULUCF [FOOTNOTE 18]. (*high confidence*) (Figure SPM.2) {Figure 1.2, Figure 2.9, Figure 2.10, 2.2, Figure TS.4}

FOOTNOTE 18: In 2019, LDCs are estimated to have emitted 3.3% of global GHG emissions, and SIDS are estimated to have emitted 0.60% of global GHG emissions, excluding CO₂-LULUCF. These

country groupings cut across geographic regions and are not depicted separately in Fig SPM2. {Figure 2.10}

B.3.2 Historical contributions to cumulative net anthropogenic CO₂ emissions between 1850 and 2019 vary substantially across regions in terms of total magnitude, but also in terms of contributions to CO₂-FFI (1650 +/- 73 GtCO₂-eq) and net CO₂-LULUCF (760 +/- 220 GtCO₂-eq) emissions.[FOOTNOTE 19] Globally, the major share of cumulative CO₂-FFI emissions is concentrated in a few regions, while cumulative CO₂-LULUCF [FOOTNOTE 9] emissions are concentrated in other regions. LDCs contributed less than 0.4% of historical cumulative CO₂-FFI emissions between 1850 and 2019, while SIDS contributed 0.5%. (*high confidence*) (Figure SPM.2) {Figure 2.10, 2.2, TS.3, Figure 2.7}

FOOTNOTE 9: Global databases make different choices about which emissions and removals occurring on land are considered anthropogenic. Currently, net CO₂ fluxes from land reported by global book-keeping models used here are estimated to be about ~5.5 GtCO₂ yr⁻¹ higher than the aggregate global net emissions based on national GHG inventories. This difference, which has been considered in the literature, mainly reflects differences in how anthropogenic forest sinks and areas of managed land are defined. Other reasons for this difference, which are more difficult to quantify, can arise from the limited representation of land management in global models and varying levels of accuracy and completeness of estimated LULUCF fluxes in national GHG inventories. Neither method is inherently preferable. Even when the same methodological approach is applied, the large uncertainty of CO₂-LULUCF emissions can lead to substantial revisions to estimated emissions. {Cross-Chapter Box 3 in Chapter 3, 7.2, SRCL SPM A.3.3}

FOOTNOTE 19: For consistency with WGI, historical cumulative CO₂ emissions from 1850-2019 are reported using 68% confidence intervals.

B.3.3 In 2019, around 48% of the global population lives in countries emitting on average more than 6t CO₂-eq per capita, excluding CO₂-LULUCF. 35% live in countries emitting more than 9 tCO₂-eq per capita. Another 41% live in countries emitting less than 3 tCO₂-eq per capita. A substantial share of the population in these low emitting countries lack access to modern energy services (FOOTNOTE 20). Eradicating extreme poverty, energy poverty, and providing decent living standards (FOOTNOTE 21) to all in these regions in the context of achieving sustainable development objectives, in the near-term, can be achieved without significant global emissions growth. (*high confidence*) (Figure SPM.2) {Figure 1.2, 2.2, 2.4, 2.6, 3.7, 4.2, 6.7, Figure TS.4, Figure TS.5}

FOOTNOTE 20: In this report, access to modern energy services is defined as access to clean, reliable and affordable energy services for cooking and heating, lighting, communications, and productive uses (See Annex I: Glossary)

FOOTNOTE 21: In this report, decent living standards are defined as a set of minimum material requirements essential for achieving basic human well-being, including nutrition, shelter, basic living conditions, clothing, health care, education, and mobility. (See 5.1)

B.3.4 Globally, the 10% of households with the highest per capita emissions contribute 34-45% of global consumption-based household GHG emissions [FOOTNOTE 22], while the middle 40% contribute 40-53%, and the bottom 50% contribute 13-15%. (*high confidence*) {2.6, Figure 2.25}

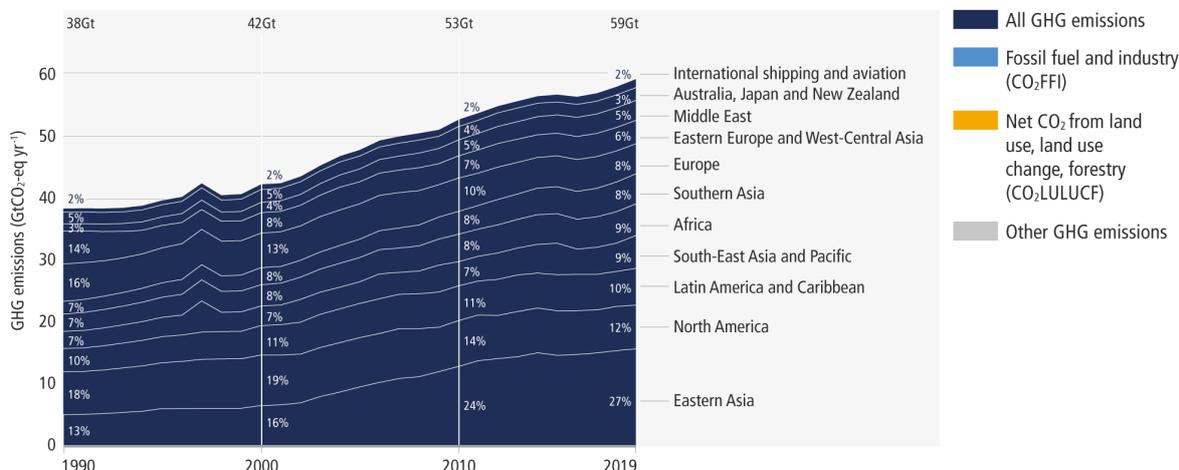

FOOTNOTE 22: Consumption-based emissions refer to emissions released to the atmosphere to generate the goods and services consumed by a certain entity (e.g., a person, firm, country, or region).

The bottom 50% of emitters spend less than USD3PPP per capita per day. The top 10% of emitters (an open-ended category) spend more than USD23PPP per capita per day. The wide range of estimates for the contribution of the top 10% result from the wide range of spending in this category and differing methods in the assessed literature. {Annex I: Glossary; 2.6}

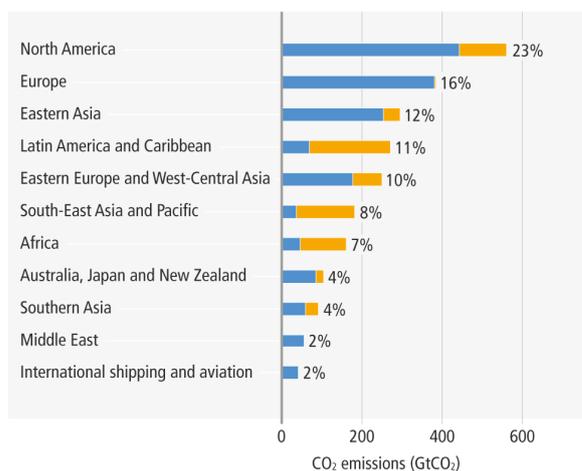

B.3.5 At least 18 countries have sustained production-based GHG and consumption-based CO₂ emission reductions for longer than 10 years. Reductions were linked to energy supply decarbonisation, energy efficiency gains, and energy demand reduction, which resulted from both policies and changes in economic structure. Some countries have reduced production-based GHG emissions by a third or more since peaking, and some have achieved several years of consecutive reduction rates of around 4 %/yr, comparable to global reductions in scenarios limiting warming to 2°C (>67%) or lower. These reductions have only partly offset global emissions growth. (*high confidence*) (Figure SPM.2) {Figure TS.4, 2.2, 1.3.2}

Emissions have grown in most regions but are distributed unevenly, both in the present day and cumulatively since 1850.

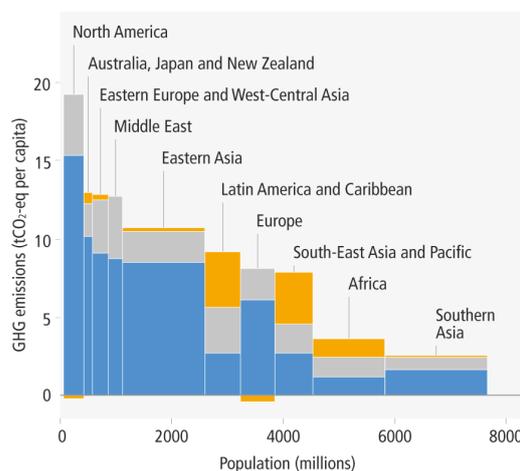

a. Global net anthropogenic GHG emissions by region (1990–2019)

b. Historical cumulative net anthropogenic CO₂ emissions per region (1850–2019)

c. Net anthropogenic GHG emissions per capita and for total population, per region (2019)

d. Regional indicators (2019) and regional production vs consumption accounting (2018)

	Africa	Australia, Japan, New Zealand	Eastern Asia	Eastern Europe, West-Central Asia	Europe	Latin America and Caribbean	Middle East	North America	South-East Asia and Pacific	Southern Asia
Population (million persons, 2019)	1292	157	1471	291	620	646	252	366	674	1836
GDP per capita (USD1000 _{ppp} 2017 per person) ¹	5.0	43	17	20	43	15	20	61	12	6.2

¹ GDP per capita in 2019 in USD2017 currency purchasing power basis.

² Includes CO₂FFI, CO₂LULUCF and Other GHGs, excluding international aviation and shipping.

The regional groupings used in this figure are for statistical purposes only and are described in Annex II, Part I.

Figure SPM.2: Regional GHG emissions, and the regional proportion of total cumulative production-based CO₂ emissions from 1850–2019

Panel a shows global net anthropogenic GHG emissions by region (in GtCO₂-eq yr⁻¹ (GWP100 AR6)) for the time period 1990–2019 [FOOTNOTE 6]. Percentage values refer to the contribution of each region to total GHG emissions in each respective time period. The single year peak of emissions in 1997 was due to higher CO₂-LULUCF emissions from a forest and peat fire event in South East Asia. Regions are as grouped in Annex II.

Panel b shows the share of historical cumulative net anthropogenic CO₂ emissions per region from 1850 to 2019 in GtCO₂. This includes CO₂ from fossil fuel combustion and industrial processes (CO₂-FFI) and net CO₂ Land use, land use change, forestry (CO₂-LULUCF). Other GHG emissions are not included [FOOTNOTE 6]. CO₂-LULUCF emissions are subject to high uncertainties, reflected by a global uncertainty estimate of $\pm 70\%$ (90% confidence interval).

Panel c shows the distribution of regional GHG emissions in tonnes CO₂-eq per capita by region in 2019. GHG emissions are categorised into: CO₂-FFI, net CO₂-LULUCF and other GHG emissions (methane, nitrous oxide, fluorinated gases, expressed in CO₂-eq using GWP100-AR6). The height of each rectangle shows per-capita emissions, the width shows the population of the region, so that the area of the rectangles refers to the total emissions for each region. Emissions from international aviation and shipping are not included. In the case of two regions, the area for CO₂-LULUCF is below the axis, indicating net CO₂ removals rather than emissions. CO₂-LULUCF emissions are subject to high uncertainties, reflected by a global uncertainty estimate of $\pm 70\%$ (90% confidence interval).

Panel d shows population, GDP per person, emission indicators by region in 2019 for percentage GHG contributions, total GHG per person, and total GHG emissions intensity, together with production-based and consumption-based CO₂-FFI data, which is assessed in this report up to 2018. Consumption-based emissions are emissions released to the atmosphere in order to generate the goods and services consumed by a certain entity (e.g., region). Emissions from international aviation and shipping are not included. {1.3, Figure 1.2, 2.2, Figure 2.9, Figure 2.10, Figure 2.11, Annex II}

B.4 The unit costs of several low-emission technologies have fallen continuously since 2010. Innovation policy packages have enabled these cost reductions and supported global adoption. Both tailored policies and comprehensive policies addressing innovation systems have helped overcome the distributional, environmental and social impacts potentially associated with global diffusion of low-emission technologies. Innovation has lagged in developing countries due to weaker enabling conditions. Digitalisation can enable emission reductions, but can have adverse side-effects unless appropriately governed. (*high confidence*) (Figure SPM.3) {2.2, 6.3, 6.4, 7.2, 12.2, 16.2, 16.4, 16.5, Cross-Chapter Box 11 in Chapter 16}

B.4.1 From 2010–2019, there have been sustained decreases in the unit costs of solar energy (85%), wind energy (55%), and lithium-ion batteries (85%), and large increases in their deployment, e.g., >10x for solar and >100x for electric vehicles (EVs), varying widely across regions (Figure SPM.3). The mix of policy instruments which reduced costs and stimulated adoption includes public R&D, funding for demonstration and pilot projects, and demand pull instruments such as deployment subsidies to attain scale. In comparison to modular small-unit size technologies, the empirical record shows that multiple large-scale mitigation technologies, with fewer opportunities for learning, have seen minimal cost reductions and their adoption has grown slowly. (*high confidence*) {1.3, 1.5, Figure 2.5, 2.5, 6.3, 6.4, 7.2, 11.3, 12.2, 12.3, 12.6, 13.6, 16.3, 16.4, 16.6}

B.4.2 Policy packages tailored to national contexts and technological characteristics have been effective in supporting low-emission innovation and technology diffusion. Appropriately designed policies and governance have helped address distributional impacts and rebound effects. Innovation has provided opportunities to lower emissions and reduce emission growth and created social and environmental co-benefits. (*high confidence*) Adoption of low-emission technologies lags in most

developing countries, particularly least developed ones, due in part to weaker enabling conditions, including limited finance, technology development and transfer, and capacity. In many countries, especially those with limited institutional capacities, several adverse side-effects have been observed as a result of diffusion of low-emission technology, e.g., low-value employment, and dependency on foreign knowledge and suppliers. Low-emission innovation along with strengthened enabling conditions can reinforce development benefits, which can, in turn, create feedbacks towards greater public support for policy. (*medium confidence*) {9.9, 13.6, 13.7, 16.3, 16.4, 16.5, 16.6, Cross-Chapter Box 12 in Chapter 16, TS.3}

B.4.3 Digital technologies can contribute to mitigation of climate change and the achievement of several SDGs (*high confidence*). For example, sensors, Internet of Things, robotics, and artificial intelligence can improve energy management in all sectors, increase energy efficiency, and promote the adoption of many low-emission technologies, including decentralised renewable energy, while creating economic opportunities (*high confidence*). However, some of these climate change mitigation gains can be reduced or counterbalanced by growth in demand for goods and services due to the use of digital devices (*high confidence*). Digitalisation can involve trade-offs across several SDGs, e.g., increasing electronic waste, negative impacts on labour markets, and exacerbating the existing digital divide. Digital technology supports decarbonisation only if appropriately governed (*high confidence*). {5.3, 10, 12.6, 16.2, Cross-Chapter Box 11 in Chapter 16, TS.5, Box TS.14}

The unit costs of some forms of renewable energy and of batteries for passenger EVs have fallen, and their use continues to rise.

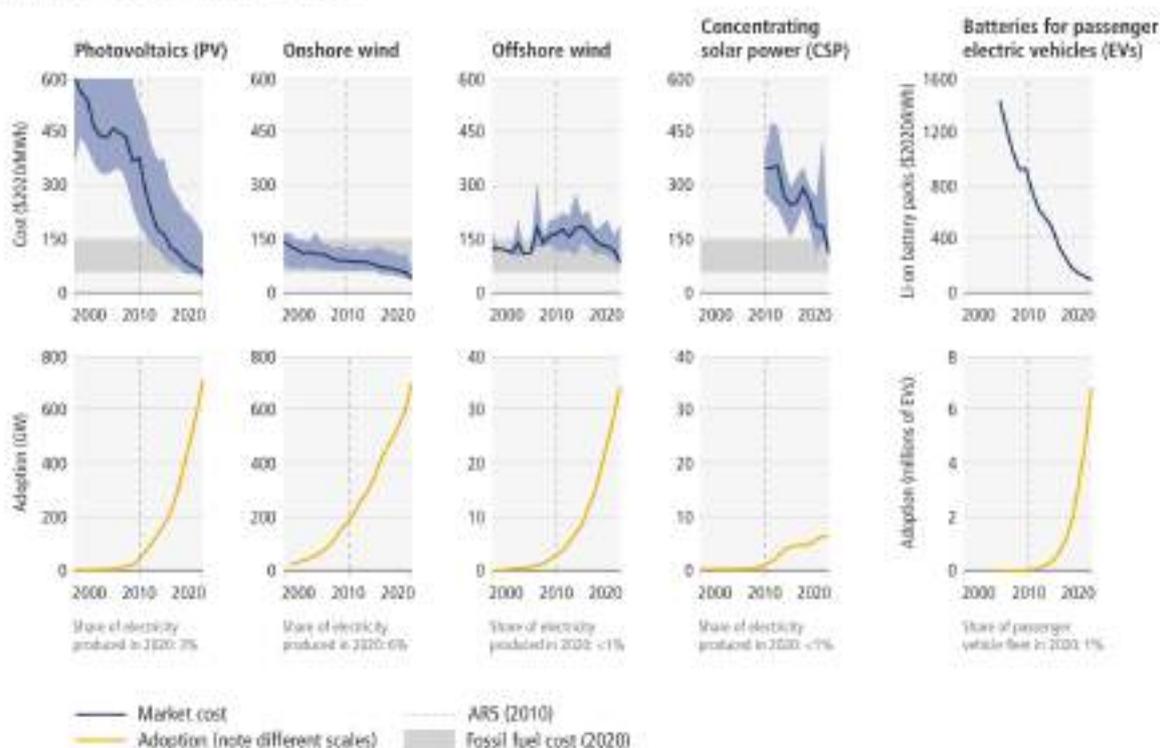

Figure SPM.3: Unit cost reductions and use in some rapidly changing mitigation technologies

The top panel shows global costs per unit of energy (USD/MWh) for some rapidly changing mitigation technologies. Solid blue lines indicate average unit cost in each year. Light blue shaded areas show the range between the 5th and 95th percentiles in each year. Grey shading indicates the range of unit costs for new fossil fuel (coal and gas) power in 2020 (corresponding to USD55–148 per MWh). In 2020, the levelised costs of energy (LCOE) of the four renewable energy technologies could compete with fossil fuels in many places. For batteries, costs shown are for 1 kWh of battery storage capacity; for the others, costs are LCOE, which includes installation, capital, operations, and maintenance costs per MWh of electricity produced. The literature uses LCOE because it allows consistent comparisons of cost trends across a diverse set of energy technologies to be made. However, it does not include the costs of grid integration or climate impacts. Further, LCOE does not take into account other environmental and social externalities that may modify the overall (monetary and non-monetary) costs of technologies and alter their deployment.

The bottom panel shows cumulative global adoption for each technology, in GW of installed capacity for renewable energy and in millions of vehicles for battery-electric vehicles. A vertical dashed line is placed in 2010 to indicate the change since AR5. Shares of electricity produced and share of passenger vehicle fleet are indicated in text for 2020 based on provisional data, i.e., percentage of total electricity production (for PV, onshore wind, offshore wind, CSP) and of total stock of passenger vehicles (for electric vehicles). The electricity production share reflects different capacity factors; e.g., for the same amount of installed capacity, wind produces about twice as much electricity as solar PV. {2.5, 6.4}

Renewable energy and battery technologies were selected as illustrative examples because they have recently shown rapid changes in costs and adoption, and because consistent data are available. Other mitigation options assessed in the report are not included as they do not meet these criteria.

B.5 There has been a consistent expansion of policies and laws addressing mitigation since AR5. This has led to the avoidance of emissions that would otherwise have occurred and increased investment in low-GHG technologies and infrastructure. Policy coverage of emissions is uneven across sectors. Progress on the alignment of financial flows towards the goals of the Paris Agreement remains slow and tracked climate finance flows are distributed unevenly across regions and sectors. (*high confidence*) {5.6, 13.2, 13.4, 13.5, 13.6, 13.9, 14.3, 14.4, 14.5, Cross-Chapter Box 10 in Chapter 14, 15.3, 15.5}

B.5.1 The Kyoto Protocol led to reduced emissions in some countries and was instrumental in building national and international capacity for GHG reporting, accounting and emissions markets (*high confidence*). At least 18 countries that had Kyoto targets for the first commitment period have had sustained absolute emission reductions for at least a decade from 2005, of which two were countries with economies in transition (*very high confidence*). The Paris Agreement, with near universal participation, has led to policy development and target-setting at national and sub-national levels, in particular in relation to mitigation, as well as enhanced transparency of climate action and support (*medium confidence*). {14.3, 14.6}

B.5.2 The application of diverse policy instruments for mitigation at the national and sub-national levels has grown consistently across a range of sectors (*high confidence*). By 2020, over 20% of global GHG emissions were covered by carbon taxes or emissions trading systems, although coverage and prices have been insufficient to achieve deep reductions (*medium confidence*). By 2020, there were ‘direct’ climate laws focused primarily on GHG reductions in 56 countries covering 53% of global emissions (*medium confidence*). Policy coverage remains limited for emissions from agriculture and

the production of industrial materials and feedstocks (*high confidence*). {5.6, 7.6, 11.5, 11.6, 13.2, 13.6}

B.5.3 In many countries, policies have enhanced energy efficiency, reduced rates of deforestation and accelerated technology deployment, leading to avoided and in some cases reduced or removed emissions (*high confidence*). Multiple lines of evidence suggest that mitigation policies have led to avoided global emissions of several Gt CO₂.eq yr⁻¹ (*medium confidence*). At least 1.8 Gt CO₂.eq yr⁻¹ can be accounted for by aggregating separate estimates for the effects of economic and regulatory instruments. Growing numbers of laws and executive orders have impacted global emissions and were estimated to result in 5.9 Gt CO₂.eq yr⁻¹ less in 2016 than they otherwise would have been. (*medium confidence*) (Figure SPM.3) {2.2, 2.8, 6.7, 7.6, 9.9, 10.8, 13.6, Cross-chapter Box 10 in Chapter 14}

B.5.4 Annual tracked total financial flows for climate mitigation and adaptation increased by up to 60% between 2013/14 and 2019/20 (in USD2015), but average growth has slowed since 2018²³ (*medium confidence*). These financial flows remained heavily focused on mitigation, are uneven, and have developed heterogeneously across regions and sectors (*high confidence*). In 2018, public and publicly mobilised private climate finance flows from developed to developing countries were below the collective goal under the UNFCCC and Paris Agreement to mobilize USD 100 billion per year by 2020 in the context of meaningful mitigation action and transparency on implementation (*medium confidence*). Public and private finance flows for fossil fuels are still greater than those for climate adaptation and mitigation (*high confidence*). Markets for green bonds, ESG (environmental, social and governance) and sustainable finance products have expanded significantly since AR5. Challenges remain, in particular around integrity and additionality, as well as the limited applicability of these markets to many developing countries. (*high confidence*) {Box 15.4, 15.3, 15.5, 15.6, Box 15.7}

FOOTNOTE 23: Estimates of financial flows (comprising both private and public, domestic and international flows) are based on a single report which assembles data from multiple sources and which has applied various changes to their methodology over the past years. Such data can suggest broad trends but is subject to uncertainties.

B.6 Global GHG emissions in 2030 associated with the implementation of nationally determined contributions (NDCs) announced prior to COP26 [FOOTNOTE 24] would make it *likely* that warming will exceed 1.5°C during the 21st century.[FOOTNOTE 25] *Likely* limiting warming to below 2°C would then rely on a rapid acceleration of mitigation efforts after 2030. Policies implemented by the end of 2020 [FOOTNOTE 26] are projected to result in higher global GHG emissions than those implied by NDCs. (*high confidence*) (Figure SPM.4) {3.3, 3.5, 4.2, Cross-Chapter Box 4 in Chapter 4}

FOOTNOTE 24: NDCs announced prior to COP26 refer to the most recent nationally determined contributions submitted to the UNFCCC up to the literature cut-off date of this report, 11 October 2021, and revised NDCs announced by China, Japan and the Republic of Korea prior to October 2021 but only submitted thereafter. 25 NDC updates were submitted between 12 October 2021 and prior to the start of COP26.

FOOTNOTE 25: This implies that mitigation after 2030 can no longer establish a pathway with less than 67% probability to exceed 1.5°C during the 21st century, a defining feature of the class of pathways that limit warming to 1.5°C (>50%) with no or limited overshoot assessed in this report (Category C1 in Table SPM.1). These pathways limit warming to 1.6°C or lower throughout the 21st century with a 50% likelihood.

FOOTNOTE 26: The policy cut-off date in studies used to project GHG emissions of “policies implemented by the end of 2020” varies between July 2019 and November 2020. {Table 4.2}

B.6.1 Policies implemented by the end of 2020 are projected to result in higher global GHG emissions than those implied by NDCs, indicating an implementation gap. A gap remains between global GHG emissions in 2030 associated with the implementation of NDCs announced prior to COP26 and those associated with modelled mitigation pathways assuming immediate action (for quantification see Table SPM.X). [FOOTNOTE 27] The magnitude of the emission gap depends on the global warming level considered and whether only unconditional or also conditional elements of NDCs [FOOTNOTE 28] are considered.[FOOTNOTE 29] (*high confidence*) {3.5, 4.2, Cross-Chapter Box 4 in Chapter 4}

Table SPM.X: Projected global emissions in 2030 associated with policies implemented by the end of 2020 and NDCs announced prior to COP26, and associated emission gaps. *Emissions projections for 2030 and absolute differences in emissions are based on emissions of 52-56 GtCO₂-eq yr⁻¹ in 2019 as assumed in underlying model studies. (*medium confidence*){4.2, Table 4.3, Cross-Chapter Box 4 in Chapter 4}

GtCO ₂ -eq yr ⁻¹	Implied by policies implemented by the end of 2020	Implied by NDCs announced prior to COP26	
		Unconditional elements	Inc. conditional elements
Median (Min–Max)*	57 (52–60)	53 (50–57)	50 (47–55)
Implementation gap between implemented policies and NDCs (Median)		4	7
Emission gap between NDCs and pathways that limit warming to 2°C (>67%) with immediate action		10–16	6–14
Emissions gap between NDCs and pathways that limit warming to 1.5°C (>50%) with no or limited overshoot with immediate action		19–26	16–23

FOOTNOTE 27: Immediate action in modelled global pathways refers to the adoption between 2020 and at latest before 2025 of climate policies intended to limit global warming to a given level. Modelled

pathways that limit warming to 2°C (>67%) based on immediate action are summarised in Category C3a in Table SPM.1. All assessed modelled global pathways that limit warming to 1.5°C (>50%) with no or limited overshoot assume immediate action as defined here (Category C1 in Table SPM.1).

FOOTNOTE 28: In this report, “unconditional” elements of NDCs refer to mitigation efforts put forward without any conditions. “Conditional” elements refer to mitigation efforts that are contingent on international cooperation, for example bilateral and multilateral agreements, financing or monetary and/or technological transfers. This terminology is used in the literature and the UNFCCC’s NDC Synthesis Reports, not by the Paris Agreement. {4.2.1, 14.3.2}

FOOTNOTE 29: Two types of gaps are assessed: The implementation gap is calculated as the difference between the median of global emissions in 2030 implied by policies implemented by the end of 2020 and those implied by NDCs announced prior to COP26. The emissions gap is calculated as the difference between GHG emissions implied by the NDCs (minimum/maximum emissions in 2030) and the median of global GHG emissions in modelled pathways limiting warming to specific levels based on immediate action and with stated likelihoods as indicated (Table SPM.1).

B.6.2 Global emissions in 2030 associated with the implementation of NDCs announced prior to COP26 are lower than the emissions implied by the original NDCs [FOOTNOTE 30] (*high confidence*). The original emission gap has fallen by about 20% to one third relative to pathways that limit warming to 2°C (>67%) with immediate action (Category C3a in Table SPM.1), and by about 15-20% relative to pathways limiting warming to 1.5°C (>50%) with no or limited overshoot (Category C1 in Table SPM.1) (*medium confidence*). (Figure SPM.4) {3.5, 4.2, Cross-Chapter Box 4 in Chapter 4}

FOOTNOTE 30: Original NDCs refer to those submitted to the UNFCCC in 2015 and 2016. Unconditional elements of NDCs announced prior to COP26 imply global GHG emissions in 2030 that are 3.8 [3.0–5.3] GtCO₂-eq yr⁻¹ lower than those from the original NDCs, and 4.5 [2.7–6.3] GtCO₂-eq yr⁻¹ lower when conditional elements of NDCs are included. NDC updates at or after COP26 could further change the implied emissions.

B.6.3 Modelled global emission pathways consistent with NDCs announced prior to COP26 that limit warming to 2°C (>67%) (Category C3b in Table SPM.1) imply annual average global GHG emissions reduction rates of 0–0.7 GtCO₂-eq per year during the decade 2020-2030, with an unprecedented acceleration to 1.4–2.0 GtCO₂-eq per year during 2030-2050 (*medium confidence*). Continued investments in unabated high emitting infrastructure and limited development and deployment of low emitting alternatives prior to 2030 would act as barriers to this acceleration and increase feasibility risks (*high confidence*). {3.3, 3.5, 3.8, Cross-Chapter Box 5 in Chapter 4}

B.6.4 Modelled global emission pathways consistent with NDCs announced prior to COP26 will *likely* exceed 1.5°C during the 21st century. Those pathways that then return warming to 1.5°C by 2100 with a likelihood of 50% or greater imply a temperature overshoot of 0.15-0.3°C (42 pathways in category C2 in Table SPM.1). In such pathways, global cumulative net-negative CO₂ emissions are -380 [-860 to -200] GtCO₂ [FOOTNOTE 31] in the second half of the century, and there is a rapid acceleration of other mitigation efforts across all sectors after 2030. Such overshoot pathways imply increased climate-related risk, and are subject to increased feasibility concerns[FOOTNOTE 32], and greater social and environmental risks, compared to pathways that limit warming to 1.5°C (>50%) with no or limited overshoot. (*high confidence*) (Figure SPM.4, Table SPM.1) {3.3, 3.5, 3.8, 12.3; WG II SPM.B.6}

FOOTNOTE 31: Median and very likely range [5th to 95th percentile].

FOOTNOTE 32: Returning to below 1.5°C in 2100 from GHG emissions levels in 2030 associated with the implementation of NDCs is infeasible for some models due to model-specific constraints on the deployment of mitigation technologies and the availability of net negative CO₂ emissions.

Projected global GHG emissions from NDCs announced prior to COP26 would make it likely that warming will exceed 1.5°C and also make it harder after 2030 to limit warming to below 2°C.

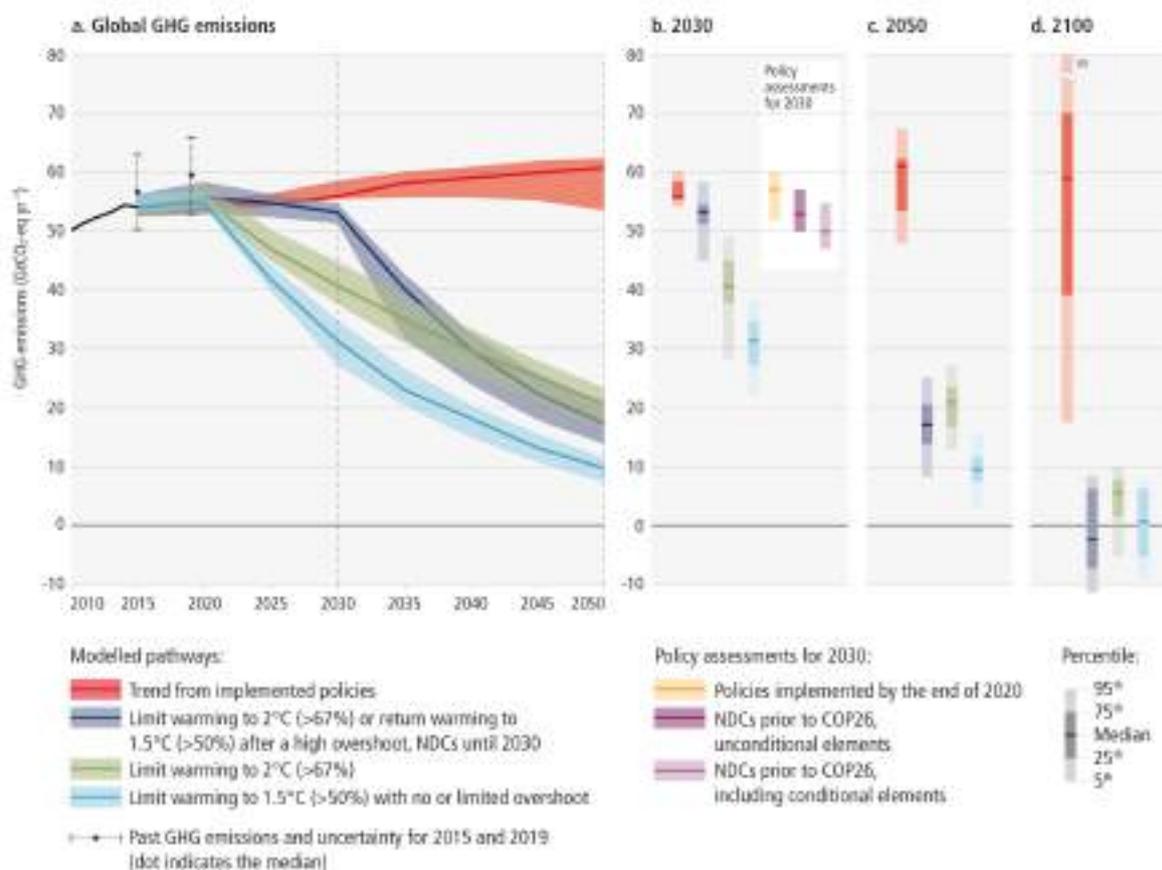

Figure SPM.4: Global GHG emissions of modelled pathways (funnels in Panel a. and associated bars in Panels b, c, d) and projected emission outcomes from near-term policy assessments for 2030 (Panel b).

Panel a shows global GHG emissions over 2015-2050 for four types of assessed modelled global pathways:

- Trend from implemented policies: Pathways with projected near-term GHG emissions in line with policies implemented until the end of 2020 and extended with comparable ambition levels beyond 2030 (29 scenarios across categories C5-C7, Table SPM.1)
- Limit to 2°C (>67%) or return warming to 1.5°C (>50%) after a high overshoot, NDCs until 2030: Pathways with GHG emissions until 2030 associated with the implementation of NDCs announced prior to COP26, followed by accelerated emissions reductions *likely* to limit warming to 2°C (C3b, Table SPM.1) or to return warming to 1.5°C with a probability of 50% or greater after high overshoot (subset of 42 scenarios from C2, Table SPM.1).

- Limit to 2°C (>67%) with immediate action: Pathways that limit warming to 2°C (>67%) with immediate action after 2020²⁷ (C3a, Table SPM.1).
- Limit to 1.5°C (>50%) with no or limited overshoot: Pathways limiting warming to 1.5°C with no or limited overshoot (C1, Table SPM.1 C1). All these pathways assume immediate action after 2020.

Past GHG emissions for 2010-2015 used to project global warming outcomes of the modelled pathways are shown by a black line [FOOTNOTE 33] and past global GHG emissions in 2015 and 2019 as assessed in Chapter 2 are shown by whiskers.

FOOTNOTE 33: See the Box SPM.1 for a description of the approach to project global warming outcomes of modelled pathways and its consistency between the climate assessment in AR6 WG I.

Panels b, c and d show snapshots of the GHG emission ranges of the modelled pathways in 2030, 2050, and 2100, respectively. Panel b also shows projected emissions outcomes from near-term policy assessments in 2030 from Chapter 4.2 (Tables 4.2 and 4.3; median and full range). GHG emissions are in CO₂-equivalent using GWP100 from AR6 WG I. {3.5, 4.2, Tables 4.2 and 4.3, Cross-Chapter Box 4 in Chapter 4}

B.7 Projected cumulative future CO₂ emissions over the lifetime of existing and currently planned fossil fuel infrastructure without additional abatement exceed the total cumulative net CO₂ emissions in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot. They are approximately equal to total cumulative net CO₂ emissions in pathways that limit warming to 2°C (>67%). (*high confidence*) {2.7, 3.3}

B.7.1 If historical operating patterns are maintained, [FOOTNOTE 34] and without additional abatement [FOOTNOTE 35], estimated cumulative future CO₂ emissions from existing fossil fuel infrastructure, the majority of which is in the power sector, would, from 2018 until the end of its lifetime, amount to 660 [460–890] GtCO₂. They would amount to 850 [600–1100] GtCO₂ when unabated emissions from currently planned infrastructure in the power sector is included. These estimates compare with cumulative global net CO₂ emissions from all sectors of 510 [330–710] GtCO₂ until the time of reaching net zero CO₂ emissions [FOOTNOTE 36] in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, and 890 [640–1160] GtCO₂ in pathways that limit warming to 2°C (>67%). (Table SPM.1) (*high confidence*) {2.7, Figure 2.26, Figure TS.8}

FOOTNOTE 34: Historical operating patterns are described by load factors and lifetimes of fossil fuel installations as observed in the past (average and range).

FOOTNOTE 35: Abatement here refers to human interventions that reduce the amount of greenhouse gases that are released from fossil fuel infrastructure to the atmosphere.

FOOTNOTE 36: Total cumulative CO₂ emissions up to the time of global net zero CO₂ emissions are similar but not identical to the remaining carbon budget for a given temperature limit assessed by Working Group I. This is because the modelled emission scenarios assessed by Working Group III cover a range of temperature levels up to a specific limit, and exhibit a variety of reductions in non-CO₂ emissions that also contribute to overall warming. {Box 3.4}

B.7.2 In modelled global pathways that limit warming to 2°C (>67%) or lower, most remaining fossil fuel CO₂ emissions until the time of global net zero CO₂ emissions are projected to occur outside the power sector, mainly in industry and transport. Decommissioning and reduced utilisation of existing

fossil fuel based power sector infrastructure, retrofitting existing installations with CCS [FOOTNOTE 37] switches to low carbon fuels, and cancellation of new coal installations without CCS are major options that can contribute to aligning future CO₂ emissions from the power sector with emissions in the assessed global modelled least-cost pathways. The most appropriate strategies will depend on national and regional circumstances, including enabling conditions and technology availability. (*high confidence*) {Table 2.7, 2.7, 3.4, 6.3, 6.5, 6.7, Box SPM.1}

FOOTNOTE 37: In this context, capture rates of new installations with CCS are assumed to be 90-95% + {11.3.5}. Capture rates for retrofit installations can be comparable, if plants are specifically designed for CCS retrofits {11.3.6}.

C. System transformations to limit global warming

C.1 Global GHG emissions are projected to peak between 2020 and at the latest before 2025 in global modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot and in those that limit warming to 2°C (>67%) and assume immediate action. [Table SPM footnote [#9], FOOTNOTE 38] **In both types of modelled pathways, rapid and deep GHG emissions reductions follow throughout 2030, 2040 and 2050 (*high confidence*). Without a strengthening of policies beyond those that are implemented by the end of 2020, GHG emissions are projected to rise beyond 2025, leading to a median global warming of 3.2 [2.2 to 3.5] °C by 2100 [FOOTNOTE 39, 40] (*medium confidence*). (Table SPM.1, Figure SPM.4, Figure SPM.5) {3.3, 3.4}**

FOOTNOTE 38: All reported warming levels are relative to the period 1850–1900. If not otherwise specified, ‘pathways’ always refer to pathways computed with a model. Immediate action in the pathways refers to the adoption of climate policies between 2020 and at latest 2025 intended to limit global warming at a given level.

FOOTNOTE 39: Long-term warming is calculated from all modelled pathways assuming mitigation efforts consistent with national policies that were implemented by the end of 2020 (scenarios that fall into policy category P1b of Chapter 3) and that pass through the 2030 GHG emissions ranges of such pathways assessed in Chapter 4 (See FOOTNOTE 25) {3.2, Table 4.2}

FOOTNOTE 40: Warming estimates refer to the 50th and [5th–95th] percentile across the modelled pathways and the median temperature change estimate of the probabilistic WG I climate model emulators[Footnote 1¹ (Table SPM1).

C.1.1 Net global GHG emissions are projected to fall from 2019 levels by 27% [13–45%] by 2030 and 63% [52-76%] [FOOTNOTE 41] by 2050 in global modelled pathways that limit warming to 2°C (>67%) and assuming immediate action (category C3a, Table SPM.1). This compares with reductions of 43% [34–60%] by 2030 and 84% [73–98%] by 2050 in pathways that limit warming to 1.5°C (>50%) with no or limited overshoot (C1, Table SPM.1) (*high confidence*). [FOOTNOTE 42] In modelled pathways that return warming to 1.5°C (>50%) after a high overshoot [FOOTNOTE 43], GHG emissions are reduced by 23 [0-44%] in 2030 and by 75 [62-91%] in 2050 (C2, Table SPM.1) (*high confidence*). Modelled pathways that are consistent with NDCs announced prior to COP26 until 2030 and assume no increase in ambition thereafter have higher emissions, leading to a median global warming of 2.8°C [2.1-3.4°C] by 2100 (*medium confidence*). [FOOTNOTE 24] (Figure SPM .4). {3.3}

FOOTNOTE 41: In this report, emissions reductions are reported relative to 2019 modelled emission levels, while in SR1.5 emissions reductions were calculated relative to 2010. Between 2010 and 2019 global GHG and global CO₂ emissions have grown by 12% (6.5 GtCO₂eq) and 13% (5.0 Gt CO₂) respectively. In global modelled pathways assessed in this report that limit warming to 1.5°C (>50%) with no or limited overshoot, GHG emissions are projected to be reduced by 37% [28-57%] in 2030 relative to 2010. In the same type of pathways assessed in SR1.5, GHG emissions are reduced by 45% (40-60% interquartile range) relative to 2010. In absolute terms, the 2030 GHG emissions levels of pathways that limit warming to 1.5°C (>50%) with no or limited overshoot are higher in AR6 (31 [21-36] GtCO₂eq) than in SR1.5 (28 (26-31 interquartile range) GtCO₂eq). (Figure SPM. 1, Table SPM.1) {3.3, SR1.5}

FOOTNOTE 42: Scenarios in this category limit peak warming to 2°C throughout the 21st century with close to, or more than, 90% likelihood.

FOOTNOTE 43: This category contains 91 scenarios with immediate action and 42 scenarios that are consistent with the NDCs until 2030.

C.1.2 In modelled pathways that limit warming to 2°C (>67%) assuming immediate action, global net CO₂ emissions are reduced compared to modelled 2019 emissions by 27% [11–46%] in 2030 and by 52% [36–70%] in 2040; and global CH₄ emissions are reduced by 24% [9–53%] in 2030 and by 37% [20–60%] in 2040. In pathways that limit warming to 1.5°C (>50%) with no or limited overshoot global net CO₂ emissions are reduced compared to modelled 2019 emissions by 48% [36–69%] in 2030 and by 80% [61–109%] in 2040; and global CH₄ emissions are reduced by 34% [21–57%] in 2030 and 44% [31–63%] in 2040. There are similar reductions of non-CO₂ emissions by 2050 in both types of pathways: CH₄ is reduced by 45% [25–70%]; N₂O is reduced by 20% [-5 – 55%]; and F-Gases are reduced by 85% [20–90%]. [FOOTNOTE 44] Across most modelled pathways, this is the maximum technical potential for anthropogenic CH₄ reductions in the underlying models (*high confidence*). Further emissions reductions, as illustrated by the IMP-SP pathway, may be achieved through changes in activity levels and/or technological innovations beyond those represented in the majority of the pathways (*medium confidence*). Higher emissions reductions of CH₄ could further reduce peak warming. (*high confidence*) (Figure SPM.5) {3.3}

FOOTNOTE 44: These numbers for CH₄, N₂O, and F-gases are rounded to the nearest 5% except numbers below 5%.

C.1.3 In modelled pathways consistent with the continuation of policies implemented by the end of 2020, GHG emissions continue to rise, leading to global warming of 3.2 [2.2–3.5]°C by 2100 (within C5-C7, Table SPM.1) (*medium confidence*). Pathways that exceed warming of >4°C (≥50%) (C8, SSP5-8.5, Table SPM.1) would imply a reversal of current technology and/or mitigation policy trends (*medium confidence*). Such warming could occur in emission pathways consistent with policies implemented by the end of 2020 if climate sensitivity is higher than central estimates (*high confidence*). (Table SPM.1, Figure SPM.4) {3.3, Box 3.3}

C.1.4 Global modelled pathways falling into the lowest temperature category of the assessed literature (C1, Table SPM.1) are on average associated with a higher median peak warming in AR6 compared to pathways in the same category in SR1.5. In the modelled pathways in AR6, the likelihood of limiting warming to 1.5°C has on average declined compared to SR1.5. This is because GHG emissions have risen since 2017, and many recent pathways have higher projected emissions by 2030, higher cumulative net CO₂ emissions and slightly later dates for reaching net zero CO₂ or net zero GHG emissions. High mitigation challenges, for example, due to assumptions of slow technological change, high levels of global population growth, and high fragmentation as in the Shared Socioeconomic Pathway SSP3, may render modelled pathways that limit warming to 2°C (> 67%) or lower infeasible. (*medium confidence*) (Table SPM.1, Box SPM.1) {3.3, 3.8, Annex III Figure II.1, Annex III Figure II.3}

Table SPM.1 | Key characteristics of the modelled global emissions pathways: Summary of projected CO₂ and GHG emissions, projected net zero timings and the resulting global warming outcomes. Pathways are categorised (rows), according to their likelihood of limiting warming to different peak warming levels (if peak temperature occurs before 2100) and 2100 warming levels.

Values shown are for the median [p50] and 5th-95th percentiles [p5-p95], noting that not all pathways achieve net zero CO₂ or GHGs.

1 Values in the table refer to the 50th and [5th–95th] percentile values across the pathways falling within a given category as defined in Box SPM.1. For emissions-related columns these values relate to the distribution of all the pathways in that category. Harmonized emissions values are given for consistency with projected global warming outcomes using climate emulators. Based on the assessment of climate emulators in AR6 WG I (Chapter 7, Box 7.1), two climate emulators are used for the probabilistic assessment of the resulting warming of the pathways. For the ‘Temperature Change’ and ‘Likelihood’ columns, the single upper row values represent the 50th percentile across the pathways in that category and the median [50th percentile] across the warming estimates of the probabilistic MAGICC climate model emulator. For the bracketed ranges, the median warming for every pathway in that category is calculated for each of the two climate model emulators (MAGICC and FaIR). Subsequently, the 5th and 95th percentile values across all pathways for each emulator are calculated. The coolest and warmest outcomes (i.e. the lowest p5 of two emulators, and the highest p95, respectively) are shown in square brackets. These ranges therefore cover both the uncertainty of the emissions pathways as well as the climate emulators’ uncertainty.

2 For a description of pathways categories see Box SPM.1.

3 All global warming levels are relative to 1850–1900. See Table SPM 1 Footnote 13 below and SPM Scenarios Box FOOTNOTE 46 for more details.

4 C3 pathways are sub-categorised according to the timing of policy action to match the emissions pathways in Figure SPM.4. Two pathways derived from a cost-benefit analysis have been added to C3a, whilst 10 pathways with specifically designed near-term action until 2030, whose emissions fall below those implied by NDCs announced prior to COP26, are not included in either of the two subsets.

5 Alignment with the categories of the illustrative SSP scenarios considered in AR6 WG I, and the Illustrative (Mitigation) Pathways (IPs/IMPs) of WG III. The IMPs have common features such as deep and rapid emissions reductions, but also different combinations of sectoral mitigation strategies. See SPM Box 1 for an introduction of the IPs and IMPs and Chapter 3 for full descriptions. {3.2, 3.3, Annex III.II.4}

6 The Illustrative Mitigation Pathway ‘Neg’ has extensive use of carbon dioxide removal (CDR) in the AFOLU, energy and the industry sectors to achieve net negative emissions. Warming peaks around 2060 and declines to below 1.5°C (50% likelihood) shortly after 2100. Whilst technically classified as C3, it strongly exhibits the characteristics of C2 high overshoot pathways, hence it has been placed in the C2 category. See SPM C3.1 for an introduction of the IPs and IMPs.

7 The 2019 range of harmonized GHG emissions across the pathways [53–58 GtCO₂eq] is within the uncertainty ranges of 2019 emissions assessed in Chapter 2 [53–66 GtCO₂-eq]. {Fig SPM 1, Fig SPM 2, Box SPM1 FOOTNOTE 50}

8 Rates of global emission reduction in mitigation pathways are reported on a pathway-by-pathway basis relative to harmonized modelled global emissions in 2019 rather than the global emissions reported in SPM Section B and Chapter 2; this ensures internal consistency in assumptions about emission sources and activities, as well as consistency with temperature projections based on the physical climate science assessment by WG I. {Annex III.II.2.5, FOOTNOTE 50} Negative values (e.g., in C7, C8) represent an increase in emissions.

9 Emissions milestones are provided for 5-year intervals in order to be consistent with the underlying 5-year time-step data of the modelled pathways. Peak emissions (CO₂ and GHGs) are assessed for 5 year reporting intervals starting in 2020. The interval 2020–2025 signifies that projected emissions peak as soon as possible between 2020 and at latest before 2025. The upper 5-year interval refers to the median interval within which the emissions peak or reach net zero. Ranges in square brackets underneath refer to the range across the pathways, comprising the lower bound of the 5th percentile 5-year interval and the upper bound of the 95th percentile 5-year interval. Numbers in round brackets signify the fraction of pathways that reach specific milestones.

10 Percentiles reported across all pathways in that category include those that do not reach net zero before 2100 (fraction of pathways reaching net zero is given in round brackets). If the fraction of pathways that reach net zero before 2100 is lower than the fraction of pathways covered by a percentile (e.g., 0.95 for the 95th percentile), the percentile is not defined and denoted with "...". The fraction of pathways reaching net zero includes all with reported non-harmonised, and / or harmonised emissions profiles that reach net zero. Pathways were counted when at least one of the two profiles fell below 100 MtCO₂ yr⁻¹ until 2100.

11 The timing of net zero is further discussed in SPM C2.4 and the Cross-Chapter Box 3 in Chapter 3 on net zero CO₂ and net zero GHG emissions.

12 For cases where models do not report all GHGs, missing GHG species are infilled and aggregated into a Kyoto basket of GHG emissions in CO₂-eq defined by the 100 year global warming potential. For each pathway, reporting of CO₂, CH₄, and N₂O emissions was the minimum required for the assessment of the climate

response and the assignment to a climate category. Emissions pathways without climate assessment are not included in the ranges presented here. See Annex III.II.5.

13 Cumulative emissions are calculated from the start of 2020 to the time of net zero and 2100, respectively. They are based on harmonized net CO₂ emissions, ensuring consistency with the WG I assessment of the remaining carbon budget. {Box 3.4, FOOTNOTE 51 in SPM C.2}.

14 Global mean temperature change for category (at peak, if peak temperature occurs before 2100, and in 2100) relative to 1850–1900, based on the median global warming for each pathway assessed using the probabilistic climate model emulators calibrated to the AR6 WG I assessment, see also SPM Scenarios Box. {SPM FOOTNOTE 12, WG I Cross Chapter Box 7.1, Annex III.II.2.5}.

15 Probability of staying below the temperature thresholds for the pathways in each category, taking into consideration the range of uncertainty from the climate model emulators consistent with the AR6 WG I assessment. The probabilities refer to the probability at peak temperature. Note that in the case of temperature overshoot (e.g., category C2 and some pathways in C1), the probabilities of staying below at the end of the century are higher than the probabilities at peak temperature.

<START BOX SPM.1 HERE>

Box SPM.1: Assessment of modelled global emission scenarios

A wide range of modelled global emission pathways and scenarios from the literature is assessed in this report, including pathways and scenarios with and without mitigation.[FOOTNOTE 45] Emissions pathways and scenarios project the evolution of GHG emissions based on a set of internally consistent assumptions about future socio-economic conditions and related mitigation measures.[FOOTNOTE 46] These are quantitative projections and are neither predictions nor forecasts. Around half of all modelled global emission scenarios assume cost-effective approaches that rely on least-cost emission abatement options globally. The other half looks at existing policies and regionally and sectorally differentiated actions. Most do not make explicit assumptions about global equity, environmental justice or intra-regional income distribution. Global emission pathways, including those based on cost effective approaches contain regionally differentiated assumptions and outcomes, and have to be assessed with the careful recognition of these assumptions. This assessment focuses on their global characteristics. The majority of the assessed scenarios (about 80%) have become available since the SR1.5, but some were assessed in that report. Scenarios with and without mitigation were categorised based on their projected global warming over the 21st century, following the same scheme as in the SR1.5 for warming up to and including 2°C. {1.5, 3.2, 3.3, Annex III.II.2, Annex III.II.3}

FOOTNOTE 45: In the literature, the terms pathways and scenarios are used interchangeably, with the former more frequently used in relation to climate goals. For this reason, this SPM uses mostly the term (emissions and mitigation) pathways. {Annex III.II.1.1}

FOOTNOTE 46: Key assumptions relate to technology development in agriculture and energy systems and socio-economic development, including demographic and economic projections. IPCC is neutral with regard to the assumptions underlying the scenarios in the literature assessed in this report, which do not cover all possible futures. Additional scenarios may be developed. The underlying population assumptions range from 8.5 to 9.7 billion in 2050 and 7.4 to 10.9 billion in 2100 (5-95th percentile) starting from 7.6 billion in 2019. The underlying assumptions on global GDP growth (ppp) range from 2.5 to 3.5% per year in the 2019-2050 period and 1.3 to 2.1% per year in the 2050-2100 (5-95th percentile). Many underlying assumptions are regionally differentiated. {1.5; 3.2; 3.3; Figure 3.9; Annex III.II.1.4; Annex III.II.3}

Scenario categories are defined by their likelihood of exceeding global warming levels (at peak and in 2100) and referred to in this report as follows [FOOTNOTE 47, 48]:

- Category C1 comprises modelled scenarios that limit warming to 1.5°C in 2100 with a likelihood of greater than 50%, and reach or exceed warming of 1.5°C during the 21st century with a likelihood of 67% or less. In this report, these scenarios are referred to as scenarios that limit warming to 1.5°C (>50%) with no or limited overshoot. Limited overshoot refers to exceeding 1.5°C global warming by up to about 0.1°C and for up to several decades. [FOOTNOTE 49]
- Category C2 comprises modelled scenarios that limit warming to 1.5°C in 2100 with a likelihood of greater than 50%, and exceed warming of 1.5°C during the 21st century with a likelihood of greater than 67%. In this report, these scenarios are also referred to as scenarios

that return warming to 1.5°C (>50%) after a high overshoot. High overshoot refers to temporarily exceeding 1.5°C global warming by 0.1-0.3°C for up to several decades.

- Category C3 comprises modelled scenarios that limit peak warming to 2°C throughout the 21st century with a likelihood of greater than 67%. In this report, these scenarios are also referred to as scenarios that limit warming to 2°C (>67%).
- Categories C4-C7 comprise modelled scenarios that limit warming to 2°C, 2.5°C, 3°C, 4°C, respectively, throughout the 21st century with a likelihood of greater than 50%. In some scenarios in C4 and many scenarios in C5-C7, warming continues beyond the 21st century.
- Category C8 comprises modelled scenarios that exceed warming of 4°C during the 21st century with a likelihood of 50% or greater. In these scenarios warming continues to rise beyond the 21st century.

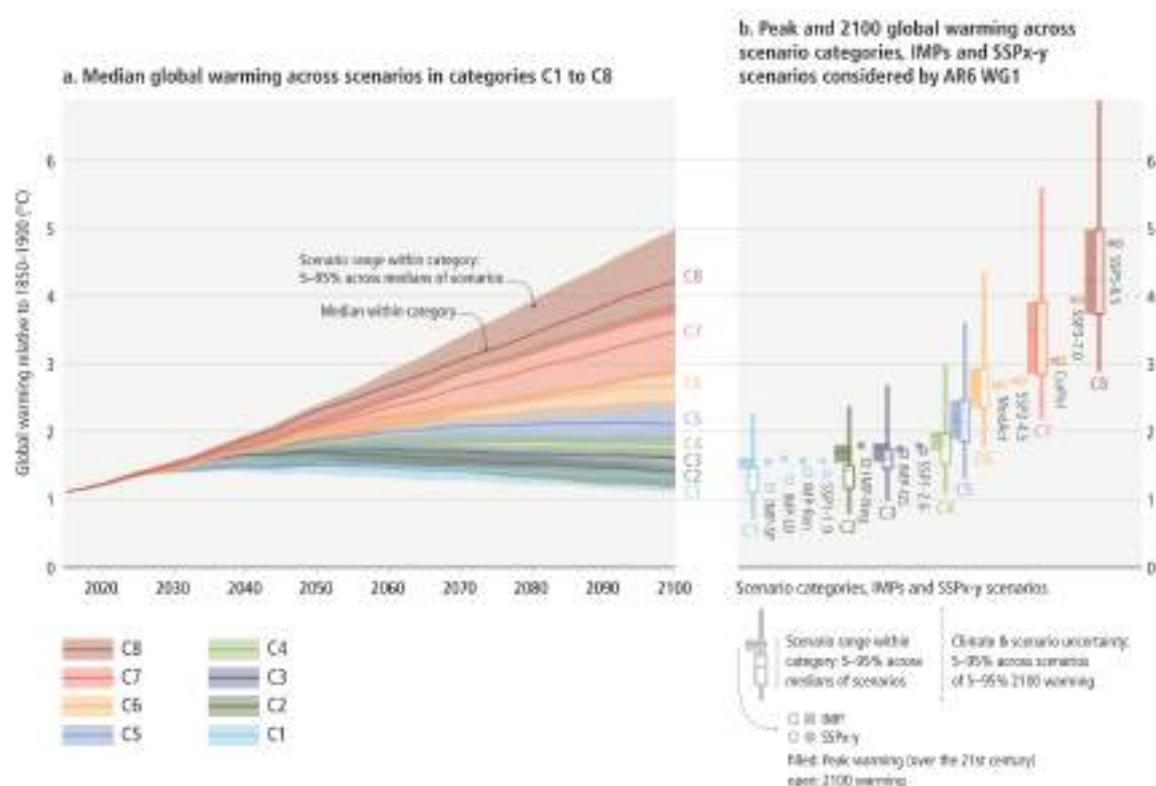

Categories of modelled scenarios are distinct and do not overlap; they do not contain categories consistent with lower levels of global warming, e.g., the category of C3 scenarios that limit warming to 2°C (>67%) does not include the C1 and C2 scenarios that limit or return warming to 1.5°C (>50%). Where relevant, scenarios belonging to the group of categories C1-C3 are referred to in this report as scenarios that limit warming to 2°C (>67%) or lower.

FOOTNOTE 47: The future scenario projections presented here are consistent with the total observed increase in global surface temperature between 1850-1900 and 1995-2014 as well as to 2011-2020 (with best estimates of 0.85 and 1.09°C, respectively) assessed in WGI. The largest contributor to historical human-induced warming is CO₂, with historical cumulative CO₂ emissions from 1850 to 2019 being 2400 ± 240 (GtCO₂). {WGI SPM A.1.2, WGI Table SPM.2, WGI Table 5.1, Section B}

FOOTNOTE 48: In case no explicit likelihood is provided, the reported warming levels are associated with a likelihood of >50%.

FOOTNOTE 49: Scenarios in this category are found to have simultaneous likelihood to limit peak global warming to 2°C throughout the 21st century of close to and more than 90%.

The range of assessed scenarios results in a range of 21st century projected global warming.

Box SPM.1, Figure 1

Projected global mean warming of the ensemble of modelled scenarios included in the climate categories C1-C8 and IMPs (based on emulators calibrated to the WGI assessment), as well as five illustrative scenarios (SSPx-y) as considered by AR6 WG I. The left panel shows the p5-p95 range of projected median warming across global modelled pathways within a category, with the category medians (line). The right panel shows the peak and 2100 emulated temperature outcomes for the categories C1 to C8 and for IMPs, and the five illustrative scenarios (SSPx-y) as considered by AR6 WG I. The boxes show the p5-p95 range within each scenario category as in panel-a. The combined p5-p95 range across scenarios and the climate uncertainty for each category C1- C8 is also shown for 2100 warming (thin vertical lines). {Table SPM.1, Figure 3.11, WGI Figure SPM.8}

Methods to project global warming associated with the scenarios were updated to ensure consistency with the AR6 WG1 assessment of physical climate science [FOOTNOTE 50]: {3.2, Annex III.II.2.5, WG I Cross-chapter box 7.1}

FOOTNOTE 50: This involved improved methodologies to use climate emulators (MAGICC7 and FAIR v1.6), which were evaluated and calibrated to closely match the global warming response to emissions as assessed in AR6 WGI. It included harmonisation of global GHG emissions in 2015 in modelled scenarios (51-56 GtCO₂-eq; 5th to 95th percentiles) with the corresponding emission value underlying the CMIP6 projected climate response assessed by WG I (54 GtCO₂-eq), based on similar data sources of historical emissions that are updated over time. The assessment of past GHG emissions in Chapter 2 of the report is based on a more recent dataset providing emissions of 57 [±6.3] GtCO₂-eq in 2015 (B.1). Differences are well within the assessed uncertainty range, and arise mainly from differences in estimated CO₂-LULUCF emissions, which are subject to large uncertainties, high annual variability and revisions over time. Projected rates of global emission reduction in mitigation scenarios

are reported relative to modelled global emissions in 2019 rather than the global emissions reported in Chapter 2; this ensures internal consistency in assumptions about emission sources and activities, as well as consistency with temperature projections based on the physical climate science assessment by WG I. {Annex III.II.2.5}

These updated methods affect the categorisation of some scenarios. On average across scenarios, peak global warming is projected to be lower by up to about $0.05[\pm 0.1]^{\circ}\text{C}$ than if the same scenarios were evaluated using the SR1.5 methodology, and global warming in 2100 is projected to be lower by about $0.1[\pm 0.1]^{\circ}\text{C}$. {Annex III.II.2.5.1, Annex III, Figure II.3}

Resulting changes to the emission characteristics of scenario categories described in Table SPM.1 interact with changes in the characteristics of the wider range of emission scenarios published since the SR1.5. Proportionally more scenarios assessed in AR6 are designed to limit temperature overshoot and more scenarios limit large-scale net negative CO₂ emissions than in SR1.5. As a result, AR6 scenarios in the lowest temperature category (C1) generally reach net zero GHG emissions later in the 21st century than scenarios in the same category assessed in SR1.5, and about half do not reach net zero GHG by 2100. The rate of decline of GHG emissions in the near term by 2030 in category C1 scenarios is very similar to the assessed rate in SR1.5, but absolute GHG emissions of category C1 scenarios in AR6 are slightly higher in 2030 than in SR1.5, since the reductions start from a higher emissions level in 2020. (Table SPM.1) {Annex III 2.5, 3.2, 3.3}

The large number of global emissions scenarios assessed, including 1202 scenarios with projected global warming outcomes using climate emulators, come from a wide range of modelling approaches. They include the five illustrative scenarios (Shared Socioeconomic Pathways; SSPs) assessed by WG I for their climate outcomes but cover a wider and more varied set in terms of assumptions and modelled outcomes. For this assessment, Illustrative Mitigation Pathways (IMPs) were selected from this larger set to illustrate a range of different mitigation strategies that would be consistent with different warming levels. The IMPs illustrate pathways that achieve deep and rapid emissions reductions through different combinations of mitigation strategies. The IMPs are not intended to be comprehensive and do not address all possible themes in the underlying report. They differ in terms of their focus, for example, placing greater emphasis on renewables (IMP-Ren), deployment of carbon dioxide removal that result in net negative global GHG emissions (IMP-Neg) and efficient resource use as well as shifts in consumption patterns globally, leading to low demand for resources, while ensuring a high level of services and satisfying basic needs (IMP-LD) (Figure SPM.5). Other IMPs illustrate the implications of a less rapid introduction of mitigation measures followed by a subsequent gradual strengthening (IMP-GS), and how shifting global pathways towards sustainable development, including by reducing inequality, can lead to mitigation (IMP-SP). The IMPs reach different climate goals as indicated in Table SPM.1 and Figure Box SPM.1. {1.5, 3.1, 3.2, 3.3, 3.6, Figure 3.7, Figure 3.8, Box 3.4, Annex III.II.2.4}

<END BOX SPM.1 HERE>

C.2 Global net zero CO₂ emissions are reached in the early 2050s in modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, and around the early 2070s in modelled pathways that limit warming to 2°C (>67%). Many of these pathways continue to net negative CO₂ emissions after the point of net zero. These pathways also include deep reductions in other GHG emissions. The level of peak warming depends on cumulative CO₂ emissions until the time of net zero CO₂ and the change in non-CO₂ climate forcings by the time of peaking. Deep

GHG emissions reductions by 2030 and 2040, particularly reductions of methane emissions, lower peak warming, reduce the likelihood of overshooting warming limits and lead to less reliance on net negative CO₂ emissions that reverse warming in the latter half of the century. Reaching and sustaining global net zero GHG emissions results in a gradual decline in warming. (*high confidence*) (Table SPM.1) {3.3, 3.5, Box 3.4, Cross-Chapter Box 3 in Chapter 3, AR6 WG I SPM D1.8}

C.2.1 Modelled global pathways limiting warming to 1.5°C (>50%) with no or limited overshoot are associated with projected cumulative net CO₂ emissions [FOOTNOTE 51] until the time of net zero CO₂ of 510 [330–710] GtCO₂. Pathways limiting warming to 2°C (>67%) are associated with 890 [640–1160] GtCO₂ (Table SPM.1). (*high confidence*). {3.3, Box 3.4}

FOOTNOTE 51: Cumulative net CO₂ emissions from the beginning of the year 2020 until the time of net zero CO₂ in assessed pathways are consistent with the remaining carbon budgets assessed by WG I, taking account of the ranges in the WG III temperature categories and warming from non-CO₂ gases. {Box 3.4}

C.2.2 Modelled global pathways that limit warming to 1.5°C (>50%) with no or limited overshoot involve more rapid and deeper near-term GHG emissions reductions through to 2030, and are projected to have less net negative CO₂ emissions and less carbon dioxide removal (CDR) in the longer term, than pathways that return warming to 1.5°C (>50%) after a high overshoot (C2 category). Modelled pathways that limit warming to 2°C (>67%) have on average lower net negative CO₂ emissions compared to pathways that limit warming to 1.5°C (>50%) with no or limited overshoot and pathways that return warming to 1.5°C (>50%) after a high overshoot (C1 and C2 categories respectively). Modelled pathways that return warming to 1.5°C (>50%) after a high overshoot (C2 category) show near-term GHG emissions reductions similar to pathways that limit warming to 2°C (>67%) (C3 category). For a given peak global warming level, greater and more rapid near-term GHG emissions reductions are associated with later net zero CO₂ dates. (*high confidence*) (Table SPM.1) {3.3, Table 3.5, Cross-Chapter Box 3 in Chapter 3, Annex I: Glossary}

C.2.3 Future non-CO₂ warming depends on reductions in non-CO₂ GHG, aerosol and their precursor, and ozone precursor emissions. In modelled global low emission pathways, the projected reduction of cooling and warming aerosol emissions over time leads to net warming in the near- to mid-term. In these mitigation pathways, the projected reductions of cooling aerosols are mostly due to reduced fossil fuel combustion that was not equipped with effective air pollution controls. Non-CO₂ GHG emissions at the time of net zero CO₂ are projected to be of similar magnitude in modelled pathways that limit warming to 2°C (>67%) or lower. These non-CO₂ GHG emissions are about 8 [5–11] GtCO₂-eq per year, with the largest fraction from CH₄ (60% [55–80%]), followed by N₂O (30% [20–35%]) and F-gases (3% [2–20%]). [FOOTNOTE 52] Due to the short lifetime of CH₄ in the atmosphere, projected deep reduction of CH₄ emissions up until the time of net zero CO₂ in modelled mitigation pathways effectively reduces peak global warming. (*high confidence*) {3.3, AR6 WG I SPM D1.7}

FOOTNOTE 52: All numbers here rounded to the closest 5%, except values below 5% (for F-gases).

C.2.4 At the time of global net zero GHG emissions, net negative CO₂ emissions counterbalance metric-weighted non-CO₂ GHG emissions. Typical emissions pathways that reach and sustain global net zero GHG emissions based on the 100 year global warming potential (GWP100) [FOOTNOTE 7] are projected to result in a gradual decline of global warming. About half of the assessed pathways that limit warming to 1.5°C (>50%) with no or limited overshoot (C1 category) reach net zero GHG emissions during the second half of the 21st century. These pathways show greater reduction in global warming after the peak to 1.2 [1.1–1.4]°C by 2100 than modelled pathways in the same category that

do not reach net zero GHG emissions before 2100 and that result in warming of 1.4 [1.3–1.5]°C by 2100. In modelled pathways that limit warming to 2°C (>67%) (C3 category), there is no significant difference in warming by 2100 between those pathways that reach net zero GHGs (around 30%) and those that do not (*high confidence*). In pathways that limit warming to 2°C (>67%) or lower and that do reach net zero GHG, net zero GHG occurs around 10–40 years later than net zero CO₂ emissions (*medium confidence*). {3.3, Cross-Chapter Box 3 in Chapter 3, Cross-Chapter Box 2 in Chapter 2; AR6 WG I SPM D1.8}

C.3 All global modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, and those that limit warming to 2°C (>67%) involve rapid and deep and in most cases immediate GHG emission reductions in all sectors. Modelled mitigation strategies to achieve these reductions include transitioning from fossil fuels without CCS to very low- or zero-carbon energy sources, such as renewables or fossil fuels with CCS, demand side measures and improving efficiency, reducing non-CO₂ emissions, and deploying carbon dioxide removal (CDR) methods to counterbalance residual GHG emissions. Illustrative Mitigation Pathways (IMPs) show different combinations of sectoral mitigation strategies consistent with a given warming level. (*high confidence*) (Figure SPM.5) {3.2, 3.3, 3.4, 6.4, 6.6}

C.3.1 There is a variation in the contributions of different sectors in modelled mitigation pathways, as illustrated by the Illustrative Mitigation Pathways. However, modelled pathways that limit warming to 2°C (>67%) or lower share common characteristics, including rapid and deep GHG emission reductions. Doing less in one sector needs to be compensated by further reductions in other sectors if warming is to be limited. (*high confidence*) (Figure SPM.5) {3.2, 3.3, 3.4}

C.3.2 In modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot, the global use of coal, oil and gas in 2050 is projected to decline with median values of about 95%, 60% and 45% compared to 2019. The interquartile ranges are (80 to 100%), (40 to 75%) and (20 to 60%) and the p5-p95 ranges are [60 to 100%], [25 to 90%] and [-30 to 85%], respectively. In modelled pathways that limit warming to 2°C (>67%), these projected declines have a median value and interquartile range of 85% (65 to 95%), 30% (15 to 50%) and 15% (-10 to 40%) respectively by 2050. The use of coal, oil and gas without CCS in modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot is projected to be reduced to a greater degree, with median values of about 100%, 60% and 70% in 2050 compared to 2019. The interquartile ranges are (95 to 100%), (45 to 75%) and (60 to 80%) and the p5-p95 range of about [85 to 100%], [25 to 90%], and [35 to 90%] for coal, oil and gas respectively. In these global modelled pathways, in 2050 almost all electricity is supplied from zero or low-carbon sources, such as renewables or fossil fuels with CCS, combined with increased electrification of energy demand. As indicated by the ranges, choices in one sector can be compensated for by choices in another while being consistent with assessed warming levels. [FOOTNOTE 53] (*high confidence*) {3.4, 3.5, Table 3.6, Figure 3.22, Figure 6.35}

FOOTNOTE 53: Most but not all models include the use of fossil fuels for feedstock with varying underlying standards.

C.3.3 In modelled pathways that reach global net zero CO₂ emissions, at the point they reach net zero, 5-16 GtCO₂ of emissions from some sectors are compensated for by net negative CO₂ emissions in other sectors. In most global modelled pathways that limit warming to 2°C (>67%) or lower, the AFOLU sector, via reforestation and reduced deforestation, and the energy supply sector reach net zero CO₂ emissions earlier than the buildings, industry and transport sectors. (*high confidence*) (Figure SPM.5, panel e and f) {3.4}

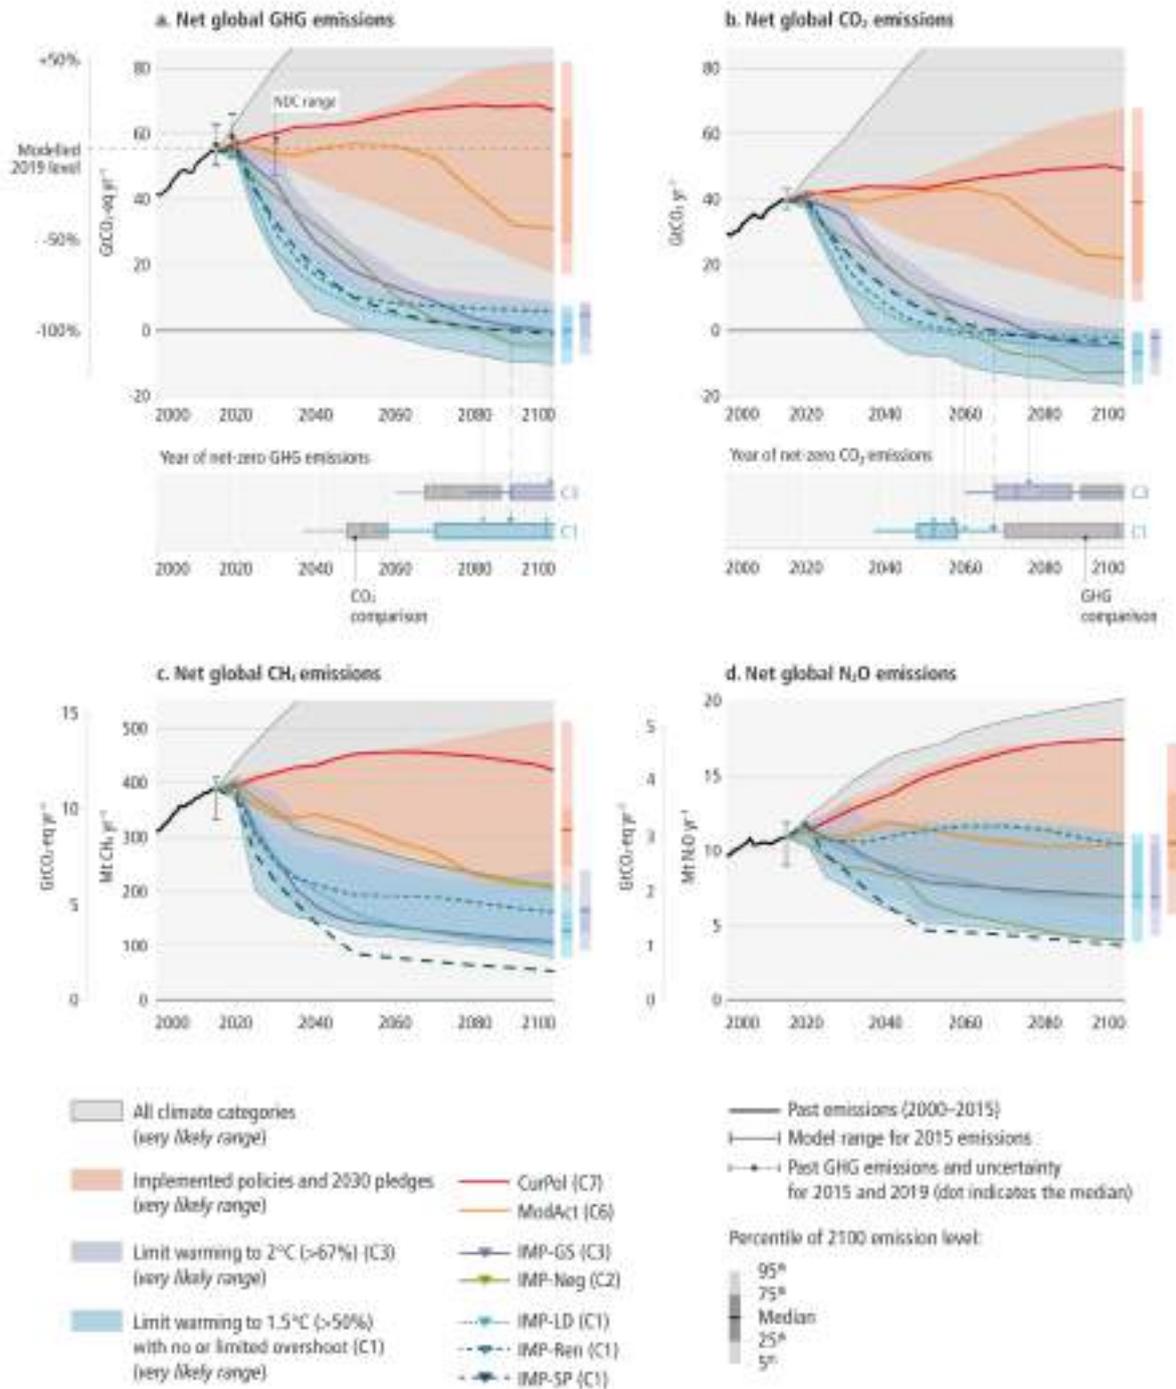

C.3.4 In modelled pathways that reach global net zero GHG emissions, at the point they reach net zero GHG, around 74% [54 to 90%] of global emissions reductions are achieved by CO₂ reductions in energy supply and demand, 13% [4 to 20%] by CO₂ mitigation options in the AFOLU sector, and 13% [10 to 18%] through the reduction of non-CO₂ emissions from land-use, energy and industry (*medium confidence*). (Figure SPM.5f) {3.3, 3.4}

C.3.5 Methods and levels of CDR deployment in global modelled mitigation pathways vary depending on assumptions about costs, availability and constraints. [FOOTNOTE 54] In modelled pathways that report CDR and that limit warming to 1.5°C (>50%) with no or limited overshoot, global cumulative CDR during 2020–2100 from Bioenergy with Carbon Dioxide Capture and Storage (BECCS) and Direct Air Carbon Dioxide Capture and Storage (DACCS) is 30–780 GtCO₂ and 0–310 GtCO₂, respectively. In these modelled pathways, the AFOLU sector contributes 20–400 GtCO₂ net negative emissions. Total cumulative net negative CO₂ emissions including CDR deployment across all options represented in these modelled pathways are 20–660 GtCO₂. In modelled pathways that limit warming to 2°C (>67%), global cumulative CDR during 2020–2100 from BECCS and DACCS is 170–650 and 0–250 GtCO₂ respectively, the AFOLU sector contributes 10–250 GtCO₂ net negative emissions, and total cumulative net negative CO₂ emissions are around 40 [0–290] GtCO₂. (Table SPM.1) (*high confidence*) {Table 3.2, 3.3, 3.4}

FOOTNOTE 54: Aggregate levels of CDR deployment are higher than total net negative CO₂ emissions given that some of the deployed CDR is used to counterbalance remaining gross emissions. Total net negative CO₂ emissions in modelled pathways might not match the aggregated net negative CO₂ emissions attributed to individual CDR methods. Ranges refer to the 5–95th percentile across modelled pathways that include the specific CDR method. Cumulative levels of CDR from AFOLU cannot be quantified precisely given that: a) some pathways assess CDR deployment relative to a baseline; and b) different models use different reporting methodologies that in some cases combine gross emissions and removals in AFOLU. Total CDR from AFOLU equals or exceeds the net negative emissions mentioned.

C.3.6 All mitigation strategies face implementation challenges, including technology risks, scaling, and costs. Many challenges, such as dependence on CDR, pressure on land and biodiversity (e.g., bioenergy) and reliance on technologies with high upfront investments (e.g., nuclear), are significantly reduced in modelled pathways that assume using resources more efficiently (e.g., IMP-LD) or shift global development towards sustainability (e.g., IMP-SP). (*high confidence*) (Figure SPM 5) {3.2, 3.4, 3.7, 3.8, 4.3, 5.1}

Modelled mitigation pathways that limit warming to 1.5°C, and 2°C, involve deep, rapid and sustained emissions reductions.

Net zero CO₂ and net zero GHG emissions are possible through different modelled mitigation pathways.

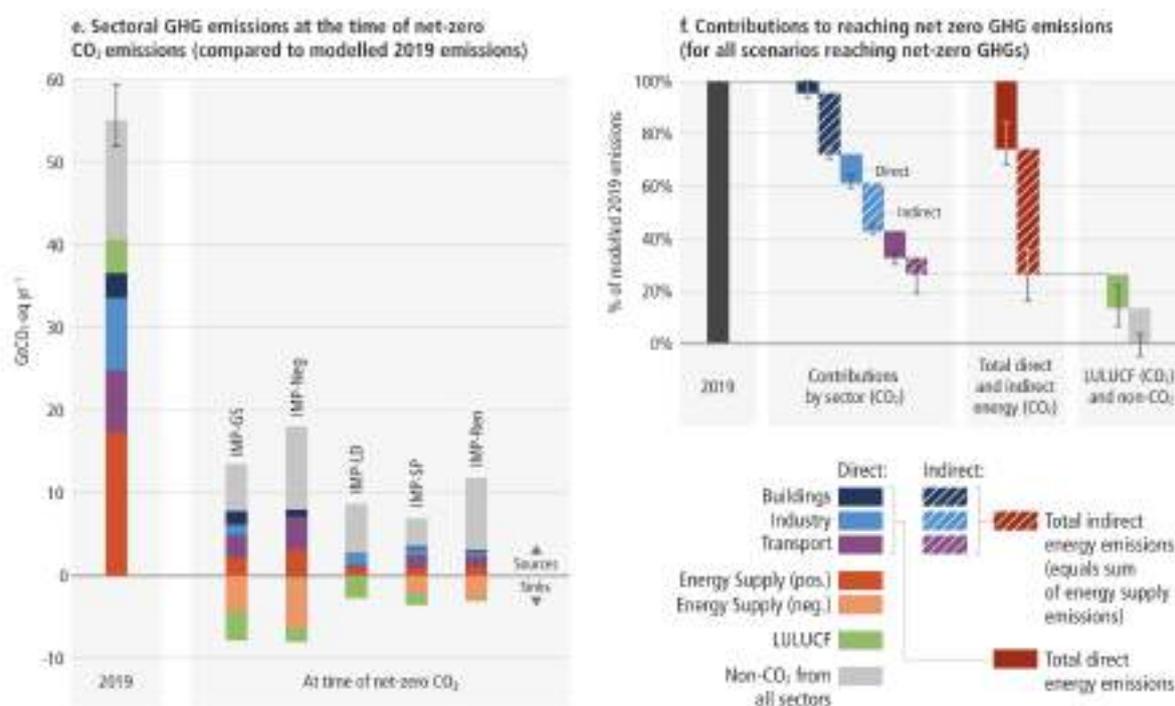

Figure SPM.5: Illustrative Mitigation Emissions Pathways (IMPs) and net zero CO₂ and GHG emissions strategies

Panel a and b show the development of global GHG and CO₂ emissions in modelled global pathways (upper sub-panels) and the associated timing of when GHG and CO₂ emissions reach net zero (lower sub-panels). Panels c and d show the development of global CH₄ and N₂O emissions, respectively. Coloured ranges denote the 5th to 95th percentile across pathways. The red ranges depict emissions pathways assuming policies that were implemented by the end of 2020 and pathways assuming implementation of NDCs (announced prior to COP26). Ranges of modelled pathways that limit warming to 1.5°C (>50%) with no or limited overshoot are shown in light blue (category C1) and pathways that limit warming to 2°C (>67%) are shown in light purple (category C3). The grey range comprises all assessed pathways (C1-C8) from the 5th percentile of the lowest warming category (C1) to the 95th percentile of the highest warming category (C8). The modelled pathway ranges are compared to the emissions from two pathways illustrative of high emissions (CurPol and ModAct) and five Illustrative Mitigation Pathways (IMPs): IMP-LD, IMP-Ren, IMP-SP, IMP-Neg and IMP-GS. Emissions are harmonised to the same 2015 base year. The vertical error bars in 2015 show the 5-95th percentile uncertainty range of the non-harmonised emissions across the pathways, and the uncertainty range, and median value, in emission estimates for 2015 and 2019. The vertical error bars in 2030 (panel a) depict the assessed range of the NDCs, as announced prior to COP26 (see Figure SPM.4, FOOTNOTE 24).

Panel e shows the sectoral contributions of CO₂ and non-CO₂ emissions sources and sinks at the time when net zero CO₂ emissions are reached in the IMPs. Positive and negative emissions for different IMPs are compared to the GHG emissions from the year 2019. Energy supply (neg.) includes BECCS and DACCS. DACCS features in only two of the five IMPs (IMP-REN, IMP-GS) and contributes <1 % and 64%, respectively, to the net negative emissions in Energy Supply (neg.).

Panel f shows the contribution of different sectors and sources to the emissions reductions from a 2019 baseline for reaching net zero GHG emissions. Bars denote the median emissions reductions for all pathways that reach net zero GHG emissions. The whiskers indicate the p5-p95 range. The contributions of the service sectors (transport, buildings, industry) are split into direct (demand-side) as well as indirect (supply-side) CO₂ emissions

reductions. Direct emissions represent demand-side emissions due to the fuel use in the respective demand sector. Indirect emissions represent upstream emissions due to industrial processes and energy conversion, transmission and distribution. In addition, the contributions from the LULUCF sector and reductions from non-CO₂ emissions sources (green and grey bars) are displayed.

{3.3, 3.4}

C.4 Reducing GHG emissions across the full energy sector requires major transitions, including a substantial reduction in overall fossil fuel use, the deployment of low-emission energy sources, switching to alternative energy carriers, and energy efficiency and conservation. The continued installation of unabated fossil fuel [FOOTNOTE 55] infrastructure will ‘lock-in’ GHG emissions. (*high confidence*) {2.7, 6.6, 6.7, 16.4}

C.4.1 Net-zero CO₂ energy systems entail: a substantial reduction in overall fossil fuel use, minimal use of unabated fossil fuels, and use of CCS in the remaining fossil system [FOOTNOTE 55]; electricity systems that emit no net CO₂; widespread electrification of the energy system including end uses; energy carriers such as sustainable biofuels, low-emissions hydrogen, and derivatives in applications less amenable to electrification; energy conservation and efficiency; and greater physical, institutional, and operational integration across the energy system. CDR will be needed to counter-balance residual emissions in the energy sector. The most appropriate strategies depend on national and regional circumstances, including enabling conditions and technology availability. (*high confidence*) {3.4, 6.6, 11.3, 16.4}

FOOTNOTE 55: In this context, ‘unabated fossil fuels’ refers to fossil fuels produced and used without interventions that substantially reduce the amount of GHG emitted throughout the life-cycle; for example, capturing 90% or more from power plants, or 50-80% of fugitive methane emissions from energy supply. {Box 6.5, 11.3}

C.4.2 Unit cost reductions in key technologies, notably wind power, solar power, and storage, have increased the economic attractiveness of low-emission energy sector transitions through 2030. Maintaining emission-intensive systems may, in some regions and sectors, be more expensive than transitioning to low emission systems. Low-emission energy sector transitions will have multiple co-benefits, including improvements in air quality and health. The long-term economic attractiveness of deploying energy system mitigation options depends, *inter alia*, on policy design and implementation, technology availability and performance, institutional capacity, equity, access to finance, and public and political support. (*high confidence*) {Figure SPM3, 3.4, 6.4, 6.6, 6.7, 13.7}

C.4.3 Electricity systems powered predominantly by renewables are becoming increasingly viable. Electricity systems in some countries and regions are already predominantly powered by renewables. It will be more challenging to supply the entire energy system with renewable energy. Even though operational, technological, economic, regulatory, and social challenges remain, a variety of systemic solutions to accommodate large shares of renewables in the energy system have emerged. A broad portfolio of options such as, integrating systems, coupling sectors, energy storage, smart grids, demand-side management, sustainable biofuels, electrolytic hydrogen and derivatives, and others will ultimately be needed to accommodate large shares of renewables in energy systems. (*high confidence*) {Box 6.8, 6.4, 6.6}

C.4.4 Limiting global warming to 2°C or below will leave a substantial amount of fossil fuels unburned and could strand considerable fossil fuel infrastructure (*high confidence*). Depending on its availability, CCS could allow fossil fuels to be used longer, reducing stranded assets (*high confidence*). The combined global discounted value of the unburned fossil fuels and stranded fossil fuel infrastructure

has been projected to be around 1–4 trillion dollars from 2015 to 2050 to limit global warming to approximately 2°C, and it will be higher if global warming is limited to approximately 1.5°C (*medium confidence*). In this context, coal assets are projected to be at risk of being stranded before 2030, while oil and gas assets are projected to be more at risk of being stranded toward mid-century. A low-emission energy sector transition is projected to reduce international trade in fossil fuels. (*high confidence*) {6.7, Figure 6.35}

C.4.5 Global methane emissions from energy supply, primarily fugitive emissions from production and transport of fossil fuels, accounted for about 18% [13%-23%] of global GHG emissions from energy supply, 32% [22%-42%] of global methane emissions, and 6% [4%-8%] of global GHG emissions in 2019 (*high confidence*). About 50–80% of CH₄ emissions from these fossil fuels could be avoided with currently available technologies at less than USD50 tCO₂-eq⁻¹ (*medium confidence*). {6.3, 6.4.2, Box 6.5, 11.3, 2.2.2, Table 2.1, Figure 2.5; Annex1 Glossary}

C.4.6 CCS is an option to reduce emissions from large-scale fossil-based energy and industry sources, provided geological storage is available. When CO₂ is captured directly from the atmosphere (DACCS), or from biomass (BECCS), CCS provides the storage component of these CDR methods. CO₂ capture and subsurface injection is a mature technology for gas processing and enhanced oil recovery. In contrast to the oil and gas sector, CCS is less mature in the power sector, as well as in cement and chemicals production, where it is a critical mitigation option. The technical geological CO₂ storage capacity is estimated to be on the order of 1000 gigatonnes of CO₂, which is more than the CO₂ storage requirements through 2100 to limit global warming to 1.5°C, although the regional availability of geological storage could be a limiting factor. If the geological storage site is appropriately selected and managed, it is estimated that the CO₂ can be permanently isolated from the atmosphere. Implementation of CCS currently faces technological, economic, institutional, ecological-environmental and socio-cultural barriers. Currently, global rates of CCS deployment are far below those in modelled pathways limiting global warming to 1.5°C or 2°C. Enabling conditions such as policy instruments, greater public support and technological innovation could reduce these barriers. (*high confidence*) {2.5, 6.3, 6.4, 6.7, 11.3, 11.4, Cross-Chapter Box 8 in Chapter 12, Figure TS.31, SRCCS Chapter 5}

C.5 Net-zero CO₂ emissions from the industrial sector are challenging but possible. Reducing industry emissions will entail coordinated action throughout value chains to promote all mitigation options, including demand management, energy and materials efficiency, circular material flows, as well as abatement technologies and transformational changes in production processes. Progressing towards net zero GHG emissions from industry will be enabled by the adoption of new production processes using low and zero GHG electricity, hydrogen, fuels, and carbon management. (*high confidence*) {11.2, 11.3, 11.4, Box TS.4}

C.5.1 The use of steel, cement, plastics, and other materials is increasing globally, and in most regions. There are many sustainable options for demand management, materials efficiency, and circular material flows that can contribute to reduced emissions, but how these can be applied will vary across regions and different materials. These options have a potential for being more used in industrial practice and would need more attention from industrial policy. These options, as well as new production technologies, are generally not considered in recent global scenarios nor in national economy-wide scenarios due to relative newness. As a consequence, the mitigation potential in some scenarios is underestimated compared to bottom-up industry-specific models. (*high confidence*) {3.4, 5.3, Figure 5.7, 11.2, Box 11.2, 11.3, 11.4, 11.5.2, 11.6}

C.5.2 For almost all basic materials – primary metals [FOOTNOTE 56], building materials and chemicals – many low- to zero- GHG intensity production processes are at the *pilot to near-commercial* and in some cases *commercial* stage but not yet established industrial practice. Introducing new sustainable basic materials production processes could increase production costs but, given the small fraction of consumer cost based on materials, are expected to translate into minimal cost increases for final consumers. Hydrogen direct reduction for primary steelmaking is *near-commercial* in some regions. Until new chemistries are mastered, deep reduction of cement process emissions will rely on already commercialised cementitious material substitution and the availability of CCS. Reducing emissions from the production and use of chemicals would need to rely on a life cycle approach, including increased plastics recycling, fuel and feedstock switching, and carbon sourced through biogenic sources, and, depending on availability, CCU, direct air CO₂ capture, as well as CCS. Light industry, mining and manufacturing have the potential to be decarbonised through available abatement technologies (e.g., material efficiency, circularity), electrification (e.g., electrothermal heating, heat pumps) and low- or zero- GHG emitting fuels (e.g., hydrogen, ammonia, and bio-based & other synthetic fuels). (*high confidence*) {Table 11.4, Box 11.2, 11.3, 11.4}

FOOTNOTE 56: Primary metals refers to virgin metals produced from ore.

C.5.3 Action to reduce industry sector emissions may change the location of GHG intensive industries and the organisation of value chains. Regions with abundant low GHG energy and feedstocks have the potential to become exporters of hydrogen-based chemicals and materials processed using low-carbon electricity and hydrogen. Such reallocation will have global distributional effects on employment and economic structure. (*medium confidence*) {Box 11.1}

C.5.4 Emissions intensive and highly traded basic materials industries are exposed to international competition, and international cooperation and coordination may be particularly important in enabling change. For sustainable industrial transitions, broad and sequential national and sub-national policy strategies reflecting regional contexts will be required. These may combine policy packages including: transparent GHG accounting and standards; demand management; materials and energy efficiency policies; R&D and niche markets for commercialisation of low emission materials and products; economic and regulatory instruments to drive market uptake; high quality recycling, low-emissions energy and other abatement infrastructure (e.g., for CCS); and socially inclusive phase-out plans of emissions intensive facilities within the context of just transitions. The coverage of mitigation policies

could be expanded nationally and sub-nationally to include all industrial emission sources, and both available and emerging mitigation options. (*high confidence*) {11.6}

C.6 Urban areas can create opportunities to increase resource efficiency and significantly reduce GHG emissions through the systemic transition of infrastructure and urban form through low-emission development pathways towards net-zero emissions. Ambitious mitigation efforts for established, rapidly growing and emerging cities will encompass 1) reducing or changing energy and material consumption, 2) electrification, and 3) enhancing carbon uptake and storage in the urban environment. Cities can achieve net-zero emissions, but only if emissions are reduced within and outside of their administrative boundaries through supply chains, which will have beneficial cascading effects across other sectors. (*very high confidence*) {8.2, 8.3, 8.4, 8.5, 8.6, Figure 8.21, 13.2}

C.6.1 In modelled scenarios, global consumption-based urban CO₂ and CH₄ emissions [FOOTNOTE 15] are projected to rise from 29 GtCO₂-eq in 2020 to 34 GtCO₂-eq in 2050 with moderate mitigation efforts (intermediate GHG emissions, SSP2-4.5), and up to 40 GtCO₂-eq in 2050 with low mitigation efforts (high GHG emissions, SSP 3-7.0). With ambitious and immediate mitigation efforts, including high levels of electrification and improved energy and material efficiency, global consumption-based urban CO₂ and CH₄ emissions could be reduced to 3 GtCO₂-eq in 2050 in the modelled scenario with very low GHG emissions (SSP1-1.9). [FOOTNOTE 57] (*medium confidence*) {8.3}

FOOTNOTE 15: This estimate is based on consumption-based accounting, including both direct emissions from within urban areas, and indirect emissions from outside urban areas related to the production of electricity, goods and services consumed in cities. These estimates include all CO₂ and CH₄ emission categories except for aviation and marine bunker fuels, land-use change, forestry and agriculture. {8.1, Annex I: Glossary}

FOOTNOTE 57: These scenarios have been assessed by WGI to correspond to intermediate, high and very low GHG emissions.

C.6.2 The potential and sequencing of mitigation strategies to reduce GHG emissions will vary depending on a city's land use, spatial form, development level, and state of urbanisation (*high confidence*). Strategies for established cities to achieve large GHG emissions savings include efficiently improving, repurposing or retrofitting the building stock, targeted infilling, and supporting non-motorised (e.g., walking, bicycling) and public transport. Rapidly growing cities can avoid future emissions by co-locating jobs and housing to achieve compact urban form, and by leapfrogging or transitioning to low-emissions technologies. New and emerging cities will have significant infrastructure development needs to achieve high quality of life, which can be met through energy efficient infrastructures and services, and people-centred urban design. (*high confidence*). For cities, three broad mitigation strategies have been found to be effective when implemented concurrently: i) reducing or changing energy and material use towards more sustainable production and consumption; ii) electrification in combination with switching to low-emission energy sources; and iii) enhancing carbon uptake and storage in the urban environment, for example through bio-based building materials, permeable surfaces, green roofs, trees, green spaces, rivers, ponds and lakes [FOOTNOTE 58]. (*very high confidence*) {5.3, Figure 5.7, Table SM5.2, 8.2, 8.4, 8.6, Figure 8.21, 9.4, 9.6, 10.2}

FOOTNOTE 58: These examples are considered to be a subset of nature-based solutions or ecosystem-based approaches.

C.6.3 The implementation of packages of multiple city-scale mitigation strategies can have cascading effects across sectors and reduce GHG emissions both within and outside a city's administrative boundaries. The capacity of cities to develop and implement mitigation strategies varies with the broader regulatory and institutional settings, as well as enabling conditions, including access to financial and technological resources, local governance capacity, engagement of civil society, and municipal budgetary powers. (*very high confidence*). {Figure 5.7, Table SM5.2, 8.4, 8.5, 8.6, 13.2, 13.3, 13.5, 13.7, Cross-Chapter Box 9}

C.6.4 A growing number of cities are setting climate targets, including net-zero GHG targets. Given the regional and global reach of urban consumption patterns and supply chains, the full potential for reducing consumption-based urban emissions to net-zero GHG can be met only when emissions beyond cities' administrative boundaries are also addressed. The effectiveness of these strategies depends on cooperation and coordination with national and sub-national governments, industry, and civil society, and whether cities have adequate capacity to plan and implement mitigation strategies. Cities can play a positive role in reducing emissions across supply chains that extend beyond cities' administrative boundaries, for example through building codes and the choice of construction materials. (*very high confidence*) {8.4, Box 8.4, 8.5, 9.6, 9.9, 13.5, 13.9}

C.7. In modelled global scenarios, existing buildings, if retrofitted, and buildings yet to be built, are projected to approach net zero GHG emissions in 2050 if policy packages, which combine ambitious sufficiency, efficiency, and renewable energy measures, are effectively implemented and barriers to decarbonisation are removed. Low ambitious policies increase the risk of lock-in buildings in carbon for decades while well-designed and effectively implemented mitigation interventions, in both new buildings and existing ones if retrofitted, have significant potential to contribute to achieving SDGs in all regions while adapting buildings to future climate. (*high confidence*) {9.1, 9.3, 9.4, 9.5, 9.6, 9.9}

C.7.1 In 2019, global direct and indirect GHG emissions from buildings and emissions from cement and steel use for building construction and renovation were 12 GtCO₂-eq. These emissions include indirect emissions from offsite generation of electricity and heat, direct emissions produced onsite and emissions from cement and steel used for building construction and renovation. In 2019, global direct and indirect emissions from non-residential buildings increased by about 55% and those from residential buildings increased by about 50% compared to 1990. The latter increase, according to the decomposition analysis, was mainly driven by the increase of the floor area per capita, population growth and the increased use of emission-intensive electricity and heat while efficiency improvements have partly decreased emissions. There are great differences in the contribution of each of these drivers to regional emissions. (*high confidence*) {9.3}

C.7.2 Integrated design approaches to the construction and retrofit of buildings have led to increasing examples of zero energy or zero carbon buildings in several regions. However, the low renovation rates and low ambition of retrofitted buildings have hindered the decrease of emissions. Mitigation interventions at the design stage include buildings typology, form, and multi-functionality to allow for adjusting the size of buildings to the evolving needs of their users and repurposing unused existing buildings to avoid using GHG-intensive materials and additional land. Mitigation interventions include: at the construction phase, low-emission construction materials, highly efficient building envelope and the integration of renewable energy solutions[FOOTNOTE 59]; at the use phase, highly efficient appliances/ equipment, the optimisation of the use of buildings and the supply with low-emission energy

sources; and at the disposal phase, recycling and re-using construction materials. (*high confidence*) {9.4, 9.5, 9.6, 9.7}

FOOTNOTE 59: Integration of renewable energy solutions refers to the integration of solutions such as solar photovoltaics, small wind turbines, solar thermal collectors, and biomass boilers.

C.7.3 By 2050, bottom-up studies show that up to 61% (8.2 GtCO₂) of global building emissions could be mitigated. Sufficiency policies [FOOTNOTE 60] that avoid the demand for energy and materials contribute 10% to this potential, energy efficiency policies contribute 42%, and renewable energy policies 9%. The largest share of the mitigation potential of new buildings is available in developing countries while in developed countries the highest mitigation potential is within the retrofit of existing buildings. The 2020-2030 decade is critical for accelerating the learning of know-how, building the technical and institutional capacity, setting the appropriate governance structures, ensuring the flow of finance, and in developing the skills needed to fully capture the mitigation potential of buildings. (*high confidence*) {9.3, 9.4, 9.5, 9.6, 9.7, 9.9}

FOOTNOTE 60: Sufficiency policies are a set of measures and daily practices that avoid demand for energy, materials, land and water while delivering human wellbeing for all within planetary boundaries.

C.8 Demand-side options and low-GHG emissions technologies can reduce transport sector emissions in developed countries and limit emissions growth in developing countries (*high confidence*). Demand-focused interventions can reduce demand for all transport services and support the shift to more energy efficient transport modes (*medium confidence*). Electric vehicles powered by low emissions electricity offer the largest decarbonisation potential for land-based transport, on a life cycle basis (*high confidence*). Sustainable biofuels can offer additional mitigation benefits in land-based transport in the short and medium term (*medium confidence*). Sustainable biofuels, low emissions hydrogen, and derivatives (including synthetic fuels) can support mitigation of CO₂ emissions from shipping, aviation, and heavy-duty land transport but require production process improvements and cost reductions (*medium confidence*). Many mitigation strategies in the transport sector would have various co-benefits, including air quality improvements, health benefits, equitable access to transportation services, reduced congestion, and reduced material demand (*high confidence*). {10.2, 10.4, 10.5, 10.6, 10.7}

C.8.1 In scenarios that limit warming to 1.5°C (>50%) with no or limited overshoot, global transport-related CO₂ emissions fall by 59% [42–68% interquartile range] by 2050 relative to modelled 2020 emissions, but with regionally differentiated trends (*high confidence*). In global modelled scenarios that limit warming to 2°C (>67%), transport related CO₂ emissions are projected to decrease by 29% [14–44% interquartile range] by 2050 compared to modelled 2020 emissions. In both categories of scenarios, the transport sector *likely* does not reach zero CO₂ emissions by 2100 so negative emissions are *likely* needed to counterbalance residual CO₂ emissions from the sector (*high confidence*). {3.4, 10.7}

C.8.2 Changes in urban form (e.g., density, land use mix, connectivity, and accessibility) in combination with programmes that encourage changes in consumer behaviour (e.g., transport pricing) could reduce transport related greenhouse gas emissions in developed countries and slow growth in emissions in developing countries (*high confidence*). Investments in public inter- and intra-city transport and active transport infrastructure (e.g., bike and pedestrian pathways) can further support the shift to less GHG-intensive transport modes (*high confidence*). Combinations of systemic changes including, teleworking, digitalisation, dematerialisation, supply chain management, and smart and

shared mobility may reduce demand for passenger and freight services across land, air, and sea (*high confidence*). Some of these changes could lead to induced demand for transport and energy services, which may decrease their GHG emissions reduction potential (*medium confidence*). {5.3, 10.2, 10.8}

C.8.3 Electric vehicles powered by low-GHG emissions electricity have large potential to reduce land-based transport GHG emissions, on a life cycle basis (*high confidence*). Costs of electrified vehicles, including automobiles, two and three wheelers, and buses are decreasing and their adoption is accelerating, but they require continued investments in supporting infrastructure to increase scale of deployment (*high confidence*). Advances in battery technologies could facilitate the electrification of heavy-duty trucks and complement conventional electric rail systems (*medium confidence*). There are growing concerns about critical minerals needed for batteries. Material and supply diversification strategies, energy and material efficiency improvements, and circular material flows can reduce the environmental footprint and material supply risks for battery production (*medium confidence*). Sourced sustainably and with low-GHG emissions feedstocks, bio-based fuels, blended or unblended with fossil fuels, can provide mitigation benefits, particularly in the short- and medium-term (*medium confidence*). Low-GHG emissions hydrogen and hydrogen derivatives, including synthetic fuels, can offer mitigation potential in some contexts and land-based transport segments (*medium confidence*). {3.4, 6.3, 10.3, 10.4, 10.7, 10.8, Box 10.6}

C.8.4 While efficiency improvements (e.g., optimised aircraft and vessel designs, mass reduction, and propulsion system improvements) can provide some mitigation potential, additional CO₂ emissions mitigation technologies for aviation and shipping will be required (*high confidence*). For aviation, such technologies include high energy density biofuels (*high confidence*), and low-emission hydrogen and synthetic fuels (*medium confidence*). Alternative fuels for shipping include low-emission hydrogen, ammonia, biofuels, and other synthetic fuels (*medium confidence*). Electrification could play a niche role for aviation and shipping for short trips (*medium confidence*) and can reduce emissions from port and airport operations (*high confidence*). Improvements to national and international governance structures would further enable the decarbonisation of shipping and aviation (*medium confidence*). Such improvements could include, for example, the implementation of stricter efficiency and carbon intensity standards for the sectors (*medium confidence*). {10.3, 10.5, 10.6, 10.7, 10.8, Box 10.5}

C.8.5 Substantial potential for GHG reductions, both direct and indirect, for the transport sector largely depends on power sector decarbonisation, and low emissions feedstocks and production chains (*high confidence*). Integrated transport and energy infrastructure planning and operations can enable sectoral synergies and reduce the environmental, social, and economic impacts of decarbonising the transport and energy sectors (*high confidence*). Technology transfer and financing can support developing countries leapfrogging or transitioning to low emissions transport systems thereby providing multiple co-benefits (*high confidence*). {10.2, 10.3, 10.4, 10.5, 10.6, 10.7, 10.8}

C.9 **AFOLU mitigation options, when sustainably implemented, can deliver large-scale GHG emission reductions and enhanced removals, but cannot fully compensate for delayed action in other sectors. In addition, sustainably sourced agricultural and forest products can be used instead of more GHG intensive products in other sectors. Barriers to implementation and trade-offs may result from the impacts of climate change, competing demands on land, conflicts with food security and livelihoods, the complexity of land ownership and management systems, and cultural aspects. There are many country-specific opportunities to provide co-benefits (such as biodiversity conservation, ecosystem services, and livelihoods) and avoid risks (for example, through adaptation to climate change). (*high confidence*) {7.4, 7.6, 7.7, 12.5, 12.6}**

C.9.1 The projected economic mitigation potential of AFOLU options between 2020 and 2050, at costs below USD100 tCO₂-eq⁻¹, is 8-14 GtCO₂-eq yr⁻¹ [FOOTNOTE 61] (*high confidence*). 30-50% of this potential is available at less than USD20/tCO₂-eq and could be upscaled in the near term across most regions (*high confidence*). The largest share of this economic potential [4.2-7.4 GtCO₂-eq yr⁻¹] comes from the conservation, improved management, and restoration of forests and other ecosystems (coastal wetlands, peatlands, savannas and grasslands), with reduced deforestation in tropical regions having the highest total mitigation. Improved and sustainable crop and livestock management, and carbon sequestration in agriculture, the latter includes soil carbon management in croplands and grasslands, agroforestry and biochar, can contribute 1.8-4.1 GtCO₂-eq yr⁻¹ reduction. Demand-side and material substitution measures, such as shifting to balanced, sustainable healthy diets [FOOTNOTE 62], reducing food loss and waste, and using bio-materials, can contribute 2.1 [1.1-3.6]GtCO₂-eq yr⁻¹ reduction. In addition, demand-side measures together with the sustainable intensification of agriculture can reduce ecosystem conversion and CH₄ and N₂O emissions, and free-up land for reforestation and restoration, and the producing of renewable energy. The improved and expanded use of wood products sourced from sustainably managed forests also has potential through the allocation of harvested wood to longer-lived products, increasing recycling or material substitution. AFOLU mitigation measures cannot compensate for delayed emission reductions in other sectors. Persistent and region-specific barriers continue to hamper the economic and political feasibility of deploying AFOLU mitigation options. Assisting countries to overcome barriers will help to achieve significant mitigation (*medium confidence*). (Figure SPM.6) {7.1, 7.4, 7.5, 7.6}

FOOTNOTE 61: The global top-down estimates and sectoral bottom-up estimates described here do not include the substitution of emissions from fossil fuels and GHG-intensive materials. 8-14 GtCO₂-eq yr⁻¹ represents the mean of the AFOLU economic mitigation potential estimates from top-down estimates (lower bound of range) and global sectoral bottom-up estimates (upper bound of range). The full range from top-down estimates is 4.1-17.3 GtCO₂-eq yr⁻¹ using a “no policy” baseline. The full range from global sectoral studies is 6.7-23.4 GtCO₂-eq yr⁻¹ using a variety of baselines. (*high confidence*)

FOOTNOTE 62: ‘Sustainable healthy diets’ promote all dimensions of individuals’ health and wellbeing; have low environmental pressure and impact; are accessible, affordable, safe and equitable; and are culturally acceptable, as described in FAO and WHO. The related concept of balanced diets refers to diets that feature plant-based foods, such as those based on coarse grains, legumes, fruits and vegetables, nuts and seeds, and animal-sourced food produced in resilient, sustainable and low-GHG emission systems, as described in SRCCCL.

C.9.2 AFOLU carbon sequestration and GHG emission reduction options have both co-benefits and risks in terms of biodiversity and ecosystem conservation, food and water security, wood supply, livelihoods and land tenure and land-use rights of Indigenous Peoples, local communities and small land owners. Many options have co-benefits but those that compete for land and land-based resources can pose risks. The scale of benefit or risk largely depends on the type of activity undertaken, deployment strategy (e.g., scale, method), and context (e.g., soil, biome, climate, food system, land ownership) that vary geographically and over time. Risks can be avoided when AFOLU mitigation is pursued in response to the needs and perspectives of multiple stakeholders to achieve outcomes that maximize co-benefits while limiting trade-offs. (*high confidence*) {7.4, 7.6, 12.3}

C.9.3 Realising the AFOLU potential entails overcoming institutional, economic and policy constraints and managing potential trade-offs (*high confidence*). Land-use decisions are often spread across a wide range of landowners; demand-side measures depend on billions of consumers in diverse contexts. Barriers to the implementation of AFOLU mitigation include insufficient institutional and financial support, uncertainty over long-term additionality and trade-offs, weak governance, insecure land ownership, the low incomes and the lack of access to alternative sources of income, and the risk of reversal. Limited access to technology, data, and know-how is a barrier to implementation. Research and development are key for all measures. For example, measures for the mitigation of agricultural CH₄ and N₂O emissions with emerging technologies show promising results. However the mitigation of agricultural CH₄ and N₂O emissions is still constrained by cost, the diversity and complexity of agricultural systems, and by increasing demands to raise agricultural yields, and increasing demand for livestock products. (*high confidence*) {7.4, 7.6}

C.9.4 Net costs of delivering 5-6 Gt CO₂ yr⁻¹ of forest related carbon sequestration and emission reduction as assessed with sectoral models are estimated to reach to ~USD400 billion yr⁻¹ by 2050. The costs of other AFOLU mitigation measures are highly context specific. Financing needs in AFOLU, and in particular in forestry, include both the direct effects of any changes in activities as well as the opportunity costs associated with land use change. Enhanced monitoring, reporting and verification capacity and the rule of law are crucial for land-based mitigation, in combination with policies also recognising interactions with wider ecosystem services, could enable engagement by a wider array of actors, including private businesses, NGOs, and Indigenous Peoples and local communities. (*medium confidence*) {7.6, 7.7}

C.9.5 Context specific policies and measures have been effective in demonstrating the delivery of AFOLU carbon sequestration and GHG emission reduction options but the above-mentioned constraints hinder large scale implementation (*medium confidence*). Deploying land-based mitigation can draw on lessons from experience with regulations, policies, economic incentives, payments (e.g., for biofuels, control of nutrient pollution, water regulations, conservation and forest carbon, ecosystem services, and rural livelihoods), and from diverse forms of knowledge such as Indigenous knowledge, local knowledge and scientific knowledge. Indigenous Peoples, private forest owners, local farmers and communities manage a significant share of global forests and agricultural land and play a central role in land-based mitigation options. Scaling successful policies and measures relies on governance that emphasises integrated land use planning and management framed by SDGs, with support for implementation. (*high confidence*) {7.4, Box 7.2, 7.6}

C.10 Demand-side mitigation encompasses changes in infrastructure use, end-use technology adoption, and socio-cultural and behavioural change. Demand-side measures and new ways of end-use service provision can reduce global GHG emissions in end use sectors by 40-70% by 2050 compared to baseline scenarios, while some regions and socioeconomic groups require additional energy and resources. Demand side mitigation response options are consistent with improving basic wellbeing for all. (*high confidence*) (Figure SPM.6) {5.3, 5.4, Figure 5.6, Figure 5.14, 8.2, 9.4, 10.2, 11.3, 11.4, 12.4, Figure TS.22}

C.10.1 Infrastructure design and access, and technology access and adoption, including information and communication technologies, influence patterns of demand and ways of providing services, such as mobility, shelter, water, sanitation, and nutrition. Illustrative global low demand scenarios, accounting for regional differences, indicate that more efficient end-use energy conversion can improve services while reducing the need for upstream energy by 45% by 2050 compared to 2020. Demand-side mitigation potential differs between and within regions, and some regions and populations require additional energy, capacity, and resources for human wellbeing. The lowest population quartile by

income worldwide faces shortfalls in shelter, mobility, and nutrition. (*high confidence*) {5.2, 5.3, 5.4, 5.5, Figure 5.6, Figure 5.10, Figure TS.20, Figure TS.22, Table 5.2}

C.10.2 By 2050, comprehensive demand-side strategies across all sectors could reduce CO₂ and non-CO₂ GHG emissions globally by 40–70% compared to the 2050 emissions projection of two scenarios consistent with policies announced by national governments until 2020. With policy support, socio-cultural options, and behavioural change can reduce global GHG emissions of end-use sectors by at least 5% rapidly, with most of the potential in developed countries, and more until 2050, if combined with improved infrastructure design and access. Individuals with high socio-economic status contribute disproportionately to emissions and have the highest potential for emissions reductions, e.g., as citizens, investors, consumers, role models, and professionals. (*high confidence*) (Figure SPM.6){5.2, 5.3, 5.4, 5.5, 5.6, Table SM5.2, 8.4, 9.9, 13.2, 13.5, 13.8, Figure TS.20}

C.10.3 A range of 5-30% of global annual GHG emissions from end-use sectors are avoidable by 2050, compared to 2050 emissions projection of two scenarios consistent with policies announced by national governments until 2020, through changes in the built environment, new and repurposed infrastructures and service provision through compact cities, co-location of jobs and housing, more efficient use of floor space and energy in buildings, and reallocation of street space for active mobility (*high confidence*). (Figure SPM.6) {5.3.1, 5.3.3, 5.4, Figure 5.7, Figure 5.13, Table 5.1, Table 5.5, Table SM5.2, 8.4, 9.5, 10.2, 11.3, 11.4, Table 11.6, Box TS.12}

C.10.4 Choice architecture [FOOTNOTE 63] can help end-users adopt, as relevant to consumers, culture and country contexts, low GHG intensive options such as balanced, sustainable healthy diets[FOOTNOTE 62] acknowledging nutritional needs; food waste reduction; adaptive heating and cooling choices for thermal comfort; integrated building renewable energy; and electric light-duty vehicles, and shifts to walking, cycling, shared pooled and public transit; sustainable consumption by intensive use of longer-lived repairable products (*high confidence*). Addressing inequality and many forms of status consumption [FOOTNOTE 64] and focusing on wellbeing supports climate change mitigation efforts (*high confidence*). (Figure SPM.6) {2.4.3, 2.6.2, 4.2.5, 5.1, 5.2, 5.3, 5.4, Figure 5.4, Figure 5.10, Table 5.2, Table SM5.2, 7.4.5, 8.2, 8.4, 9.4, 10.2, 12.4, Figure TS.20}

FOOTNOTE 63: Choice architecture describes the presentation of choices to consumers, and the impact that presentation has on consumer decision-making.

FOOTNOTE 64: Status consumption refers to the consumption of goods and services which publicly demonstrates social prestige.

Demand-side mitigation can be achieved through changes in socio-cultural factors, infrastructure design and use, and end-use technology adoption by 2050.

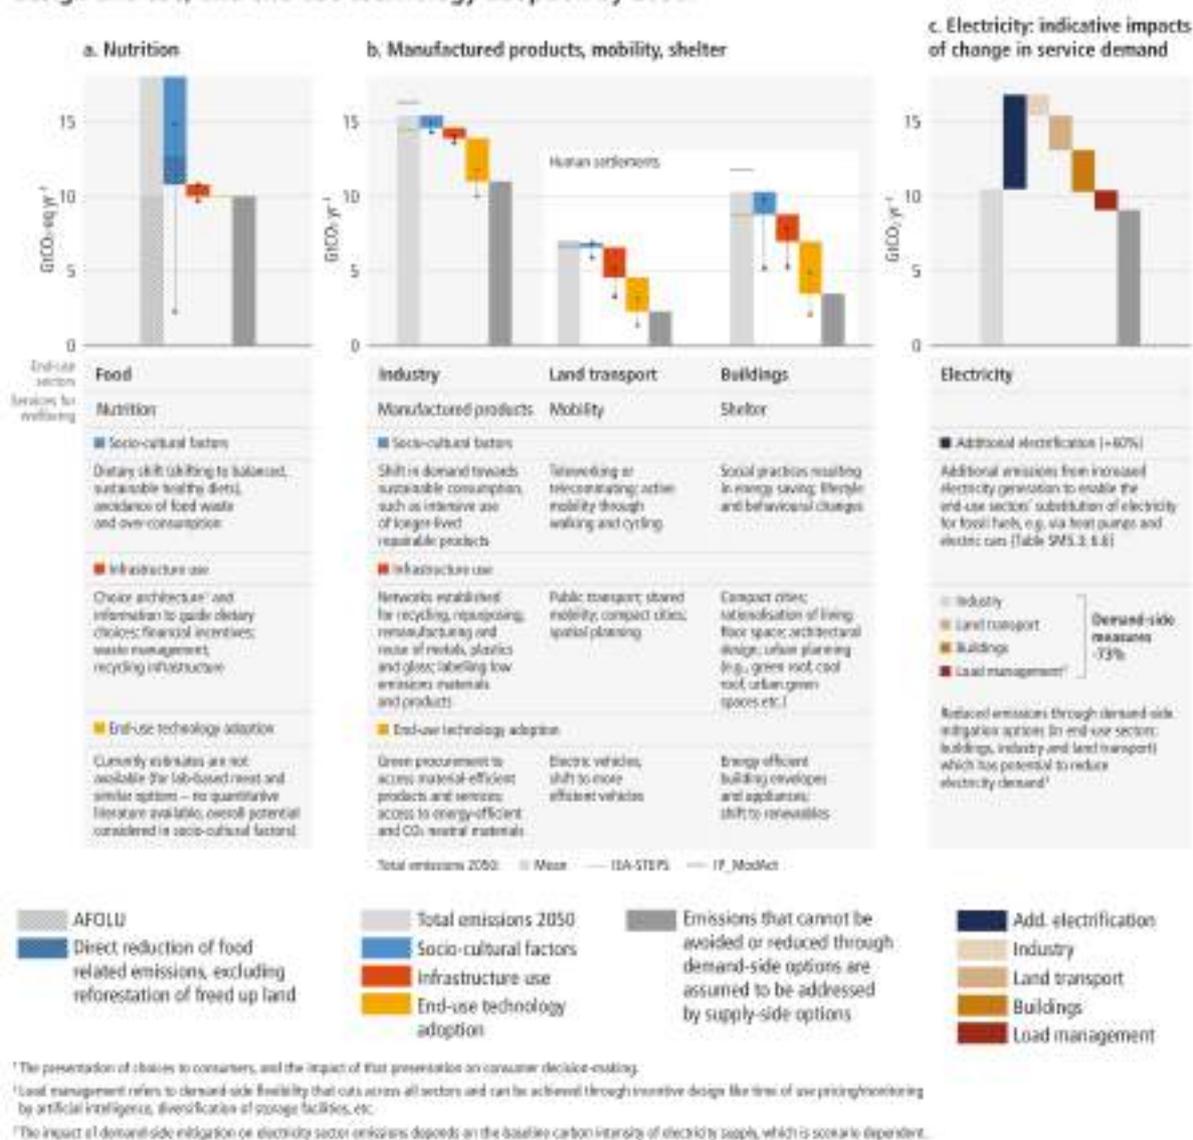

Figure SPM.6 Indicative potential of demand-side mitigation options by 2050

Figure SPM.6 covers the indicative potential of demand-side options for the year 2050. Figure SPM.7 covers cost and potentials for the year 2030. Demand-side mitigation response options are categorised into three broad domains: ‘socio-cultural factors’, associated with individual choices, behaviour; and lifestyle changes, social norms and culture; ‘infrastructure use’, related to the design and use of supporting hard and soft infrastructure that enables changes in individual choices and behaviour; and ‘end-use technology adoption’, refers to the uptake of technologies by end-users. Demand side mitigation is a central element of the IMP-LD and IMP-SP scenarios (Figure SPM.5).

Panel (a) (Nutrition) demand-side potentials in 2050 assessment is based on bottom-up studies and estimated following the 2050 baseline for the food sector presented in peer-reviewed literature (more information in Supplementary Material 5.II, and 7.4.5). Panel (b) (Manufactured products, mobility, shelter) assessment of potentials for total emissions in 2050 are estimated based on approximately 500 bottom up studies representing all global regions (detailed list is in Table SM5.2). Baseline is provided by the sectoral mean GHG emissions in 2050 of the two scenarios consistent with policies announced by national governments until 2020. The heights of the coloured columns represent the potentials represented by the median value. These are based on a range of values available in the case studies from literature shown in Chapter 5 Supplementary Material II. The range is

shown by the dots connected by dotted lines representing the highest and the lowest potentials reported in the literature.

Panel (a) shows the demand side potential of socio-cultural factors and infrastructure use. The median value of direct emissions (mostly non-CO₂) reduction through socio-cultural factors is 1.9 GtCO₂-eq without considering land-use change through reforestation of freed up land. If changes in land use pattern enabled by this change in food demand are considered, the indicative potential could reach 7 GtCO₂-eq. Panel (b) illustrates mitigation potential in industry, land transport and buildings end-use sectors through demand-side options. Key options are presented in the summary table below the figure and the details are in Table SM5.2.

Panel (c) visualizes how sectoral demand-side mitigation options (presented in Panel (b)) change demand on the electricity distribution system. Electricity accounts for an increasing proportion of final energy demand in 2050 (additional electricity bar) in line with multiple bottom-up studies (detailed list is in Table SM5.3), and Chapters 6 (6.6). These studies are used to compute the impact of end-use electrification which increases overall electricity demand. Some of the projected increase in electricity demand can be avoided through demand-side mitigation options in the domains of socio-cultural factors and infrastructure use in end-use electricity use in buildings, industry, and land transport found in literature based on bottom-up assessments. Dark grey columns show the emissions that cannot be avoided through demand-side mitigation options. {5.3, Figure 5.7, Supplementary Material 5.II}

C.11 The deployment of CDR to counterbalance hard-to-abate residual emissions is unavoidable if net zero CO₂ or GHG emissions are to be achieved. The scale and timing of deployment will depend on the trajectories of gross emission reductions in different sectors. Upscaling the deployment of CDR depends on developing effective approaches to address feasibility and sustainability constraints especially at large scales. (*high confidence*) {3.4, 7.4, 12.3, Cross-Chapter Box 8 in Chapter 12}

C.11.1 CDR refers to anthropogenic activities that remove CO₂ from the atmosphere and store it durably in geological, terrestrial, or ocean reservoirs, or in products. CDR methods vary in terms of their maturity, removal process, timescale of carbon storage, storage medium, mitigation potential, cost, co-benefits, impacts and risks, and governance requirements (*high confidence*). Specifically, maturity ranges from lower maturity (e.g., ocean alkalisation) to higher maturity (e.g., reforestation); removal and storage potential ranges from lower potential (<1 Gt CO₂ yr⁻¹, e.g., blue carbon management) to higher potential (>3 Gt CO₂ yr⁻¹, e.g., agroforestry); costs range from lower cost (e.g., 45-100 USD/tCO₂ for soil carbon sequestration) to higher cost (e.g., 100-300 USD/tCO₂ for DACCS) (*medium confidence*). Estimated storage timescales vary from decades to centuries for methods that store carbon in vegetation and through soil carbon management, to ten thousand years or more for methods that store carbon in geological formations (*high confidence*). The processes by which CO₂ is removed from the atmosphere are categorised as biological, geochemical or chemical. Afforestation, reforestation, improved forest management, agroforestry and soil carbon sequestration are currently the only widely practiced CDR methods (*high confidence*). {7.4, 7.6, 12.3, Table 12.6, Table TS.7, Cross-Chapter Box 8 in Chapter 12, WG I 5.6}

C.11.2 The impacts, risks and co-benefits of CDR deployment for ecosystems, biodiversity and people will be highly variable depending on the method, site-specific context, implementation and scale (*high confidence*). Reforestation, improved forest management, soil carbon sequestration, peatland restoration and blue carbon management are examples of methods that can enhance biodiversity and ecosystem functions, employment and local livelihoods, depending on context (*high confidence*). In contrast, afforestation or production of biomass crops for BECCS or biochar, when poorly implemented, can have adverse socio-economic and environmental impacts, including on biodiversity, food and water security, local livelihoods and on the rights of Indigenous Peoples, especially if implemented at large scales and where land tenure is insecure (*high confidence*). Ocean fertilisation, if implemented, could

lead to nutrient redistribution, restructuring of ecosystems, enhanced oxygen consumption and acidification in deeper waters (*medium confidence*). {7.4, 7.6, 12.3, 12.5}

C.11.3 The removal and storage of CO₂ through vegetation and soil management can be reversed by human or natural disturbances; it is also prone to climate change impacts. In comparison, CO₂ stored in geological and ocean reservoirs (via BECCS, DACCS, ocean alkalisation) and as carbon in biochar is less prone to reversal. (*high confidence*) {6.4, 7.4, 12.3}

C11.4 In addition to deep, rapid, and sustained emission reductions CDR can fulfil three different complementary roles globally or at country level: lowering net CO₂ or net GHG emissions in the near-term; counterbalancing ‘hard-to-abate’ residual emissions (e.g., emissions from agriculture, aviation, shipping, industrial processes) in order to help reach net zero CO₂ or net zero GHG emissions in the mid-term; achieving net negative CO₂ or GHG emissions in the long-term if deployed at levels exceeding annual residual emissions (*high confidence*) {3.3, 7.4, 11.3, 12.3, Cross-Chapter Box 8 in Chapter 12}

C.11.5 Rapid emission reductions in all sectors interact with future scale of deployment of CDR methods, and their associated risks, impacts and co-benefits. Upscaling the deployment of CDR methods depends on developing effective approaches to address sustainability and feasibility constraints, potential impacts, co-benefits and risks. Enablers of CDR include accelerated research, development and demonstration, improved tools for risk assessment and management, targeted incentives and development of agreed methods for measurement, reporting and verification of carbon flows. (*high confidence*) {3.4, 7.6, 12.3}

C.12 Mitigation options costing USD100 tCO₂-eq⁻¹ or less could reduce global GHG emissions by at least half the 2019 level by 2030 (*high confidence*). Global GDP continues to grow in modelled pathways [FOOTNOTE 65] but, without accounting for the economic benefits of mitigation action from avoided damages from climate change nor from reduced adaptation costs, it is a few percent lower in 2050 compared to pathways without mitigation beyond current policies. The global economic benefit of limiting warming to 2°C is reported to exceed the cost of mitigation in most of the assessed literature. (*medium confidence*) (Figure SPM.7) {3.6, 3.8, Cross-Working Group Box 1 in Chapter 3, 12.2, Box TS.7}

FOOTNOTE 65: In modelled pathways that limit warming to 2°C (>67%) or lower.

C.12.1 Based on a detailed sectoral assessment of mitigation options, it is estimated that mitigation options costing USD100 tCO₂-eq⁻¹ or less could reduce global GHG emissions by at least half of the 2019 level by 2030 (options costing less than USD20 tCO₂-eq⁻¹ are estimated to make up more than half of this potential) [FOOTNOTE 66]. For a smaller part of the potential, deployment leads to net cost savings. Large contributions with costs less than USD20 tCO₂-eq⁻¹ come from solar and wind energy, energy efficiency improvements, reduced conversion of natural ecosystems, and CH₄ emissions reductions (coal mining, oil and gas, waste). The mitigation potentials and mitigation costs of individual technologies in a specific context or region may differ greatly from the provided estimates. The assessment of the underlying literature suggests that the relative contribution of the various options could change beyond 2030. (*medium confidence*) (Figure SPM.7) {12.2}

FOOTNOTE 66. The methodology underlying the assessment is described in the caption to Figure SPM.7.

C.12.2 The aggregate effects of climate change mitigation on global GDP are small compared to global projected GDP growth in assessed modelled global scenarios that quantify the macroeconomic implications of climate change mitigation, but that do not account for damages from climate change nor adaptation costs (*high confidence*). For example, compared to pathways that assume the continuation of policies implemented by the end of 2020, assessed global GDP reached in 2050 is reduced by 1.3–2.7% in modelled pathways assuming coordinated global action starting between now and 2025 at the latest to limit warming to 2°C (>67%). The corresponding average reduction in annual global GDP growth over 2020-2050 is 0.04–0.09 percentage points. In assessed modelled pathways, regardless of the level of mitigation action, global GDP is projected to at least double (increase by at least 100%) over 2020-2050. For modelled global pathways in other temperature categories, the reductions in global GDP in 2050 compared to pathways that assume the continuation of policies implemented by the end of 2020 are as follows: 2.6 - 4.2% (C1), 1.6 - 2.8% (C2), 0.8 - 2.1% (C4), 0.5 - 1.2% (C5). The corresponding reductions in average annual global GDP growth over 2020-2050, in percentage points, are as follows: 0.09 - 0.14 (C1), 0.05 - 0.09 (C2), 0.03 - 0.07 (C4), 0.02 - 0.04 (C5) [FOOTNOTE 67]. There are large variations in the modelled effects of mitigation on GDP across regions, depending notably on economic structure, regional emissions reductions, policy design and level of international cooperation [FOOTNOTE 68] (*high confidence*). Country level studies also show large variations in the effect of mitigation on GDP depending notably on the level of mitigation and on the way it is achieved (*high confidence*). Macroeconomic implications of mitigation co-benefits and trade-offs are not quantified comprehensively across the above scenarios and depend strongly on mitigation strategies (*high confidence*). {3.6, 4.2, Box TS.7, Annex III I.2, I.9, I.10 and II.3}

FOOTNOTE 67: These estimates are based on 311 pathways that report effects of mitigation on GDP and that could be classified in temperature categories, but that do not account for damages from climate change nor adaptation costs and that mostly do not reflect the economic impacts of mitigation co-benefits and trade-offs. The ranges given are interquartile ranges. The macroeconomic implications quantified vary largely depending on technology assumptions, climate/emissions target formulation, model structure and assumptions, and the extent to which pre-existing inefficiencies are considered. Models that produced the pathways classified in temperature categories do not represent the full diversity of existing modelling paradigms, and there are in the literature models that find higher mitigation costs, or conversely lower mitigation costs and even gains. {1.7, 3.2, 3.6, Annex III I.2 I.9 I.10 and II.3}

FOOTNOTE 68: In modelled cost-effective pathways with a globally uniform carbon price, without international financial transfers or complementary policies, carbon intensive and energy exporting countries are projected to bear relatively higher mitigation costs because of a deeper transformation of their economies and changes in international energy markets. {3.6}

C.12.3 Estimates of aggregate economic benefits from avoiding damages from climate change, and from reduced adaptation costs, increase with the stringency of mitigation (*high confidence*). Models that incorporate the economic damages from climate change find that the global cost of limiting warming to 2°C over the 21st century is lower than the global economic benefits of reducing warming, unless: i) climate damages are towards the low end of the range; or, ii) future damages are discounted at high rates (*medium confidence*) [FOOTNOTE 69]. Modelled pathways with a peak in global emissions between now and 2025 at the latest, compared to modelled pathways with a later peak in global emissions, entail more rapid near-term transitions and higher up-front investments, but bring long-term gains for the economy, as well as earlier benefits of avoided climate change impacts (*high confidence*). The precise magnitude of these gains and benefits is difficult to quantify. {1.7, 3.6, Cross-Working Group Box 1 in Chapter 3 Box TS.7, WGII SPM B.4}

FOOTNOTE 69: The evidence is too limited to make a similar robust conclusion for limiting warming to 1.5°C.

Many options available now in all sectors are estimated to offer substantial potential to reduce net emissions by 2030. Relative potentials and costs will vary across countries and in the longer term compared to 2030.

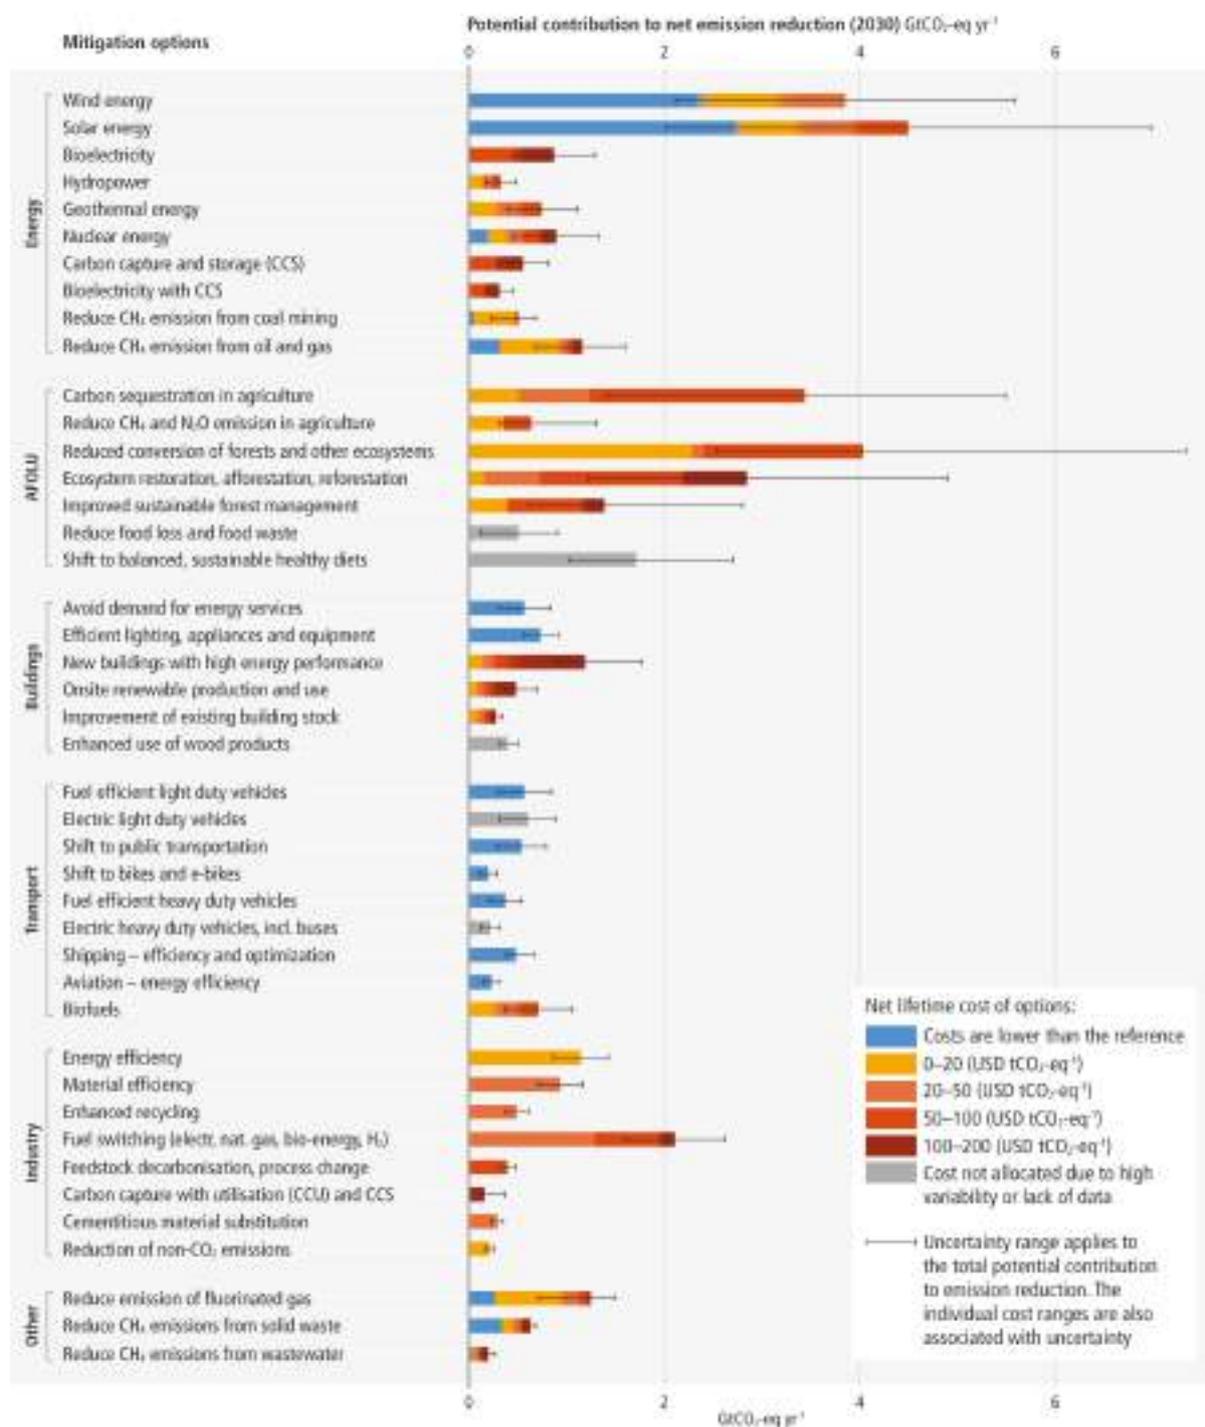

Figure SPM.7: Overview of mitigation options and their estimated ranges of costs and potentials in 2030.

Costs shown are net lifetime costs of avoided greenhouse gas emissions. Costs are calculated relative to a reference technology. The assessments per sector were carried out using a common methodology, including definition of potentials, target year, reference scenarios, and cost definitions. The mitigation potential (shown in the horizontal axis) is the quantity of net greenhouse gas emission reductions that can be achieved by a given mitigation option relative to a specified emission baseline. Net greenhouse gas emission reductions are the sum of reduced emissions and/or enhanced sinks. The baseline used consists of current policy (~ 2019) reference scenarios from the AR6 scenarios database (25/75 percentile values). The assessment relies on approximately 175 underlying sources, that together give a fair representation of emission reduction potentials across all regions. The mitigation potentials are assessed independently for each option and are not necessarily additive. {12.2.1, 12.2.2}

The length of the solid bars represents the mitigation potential of an option. The error bars display the full ranges of the estimates for the total mitigation potentials. Sources of uncertainty for the cost estimates include assumptions on the rate of technological advancement, regional differences, and economies of scale, among others. Those uncertainties are not displayed in the figure.

Potentials are broken down into cost categories, indicated by different colours (see legend). Only discounted lifetime monetary costs are considered. Where a gradual colour transition is shown, the breakdown of the potential into cost categories is not well known or depends heavily on factors such as geographical location, resource availability, and regional circumstances, and the colours indicate the range of estimates. Costs were taken directly from the underlying studies (mostly in the period 2015-2020) or recent datasets. No correction for inflation was applied, given the wide cost ranges used. The cost of the reference technologies were also taken from the underlying studies and recent datasets. Cost reductions through technological learning are taken into account (FOOTNOTE 70).

When interpreting this figure, the following should be taken into account:

- The mitigation potential is uncertain, as it will depend on the reference technology (and emissions) being displaced, the rate of new technology adoption, and several other factors.
- Cost and mitigation potential estimates were extrapolated from available sectoral studies. Actual costs and potentials would vary by place, context and time.
- Beyond 2030, the relative importance of the assessed mitigation options is expected to change, in particular while pursuing long-term mitigation goals, recognising also that the emphasis for particular options will vary across regions (for specific mitigation options see sections C4.1, C5.2, C7.3, C8.3 and C9.1).
- Different options have different feasibilities beyond the cost aspects, which are not reflected in the figure (cf. section E.1).
- The potentials in the cost range 100 to 200 USD tCO₂-eq⁻¹ may be underestimated for some options.
- Costs for accommodating the integration of variable renewable energy sources in electricity systems are expected to be modest until 2030, and are not included because of complexities in attributing such costs to individual technology options.
- Cost range categories are ordered from low to high. This order does not imply any sequence of implementation.
- Externalities are not taken into account.

{12.2, Table 12.3, 6.4, Table 7.3, Supplementary Material Table 9.2, Supplementary Material Table 9.3, 10.6, 11.4, Fig 11.13, Supplementary Material 12.A.2.3}

FOOTNOTE 70: For nuclear energy, modelled costs for long-term storage of radio-active waste are included.

D. Linkages between mitigation, adaptation, and sustainable development

D.1 Accelerated and equitable climate action in mitigating, and adapting to, climate change impacts is critical to sustainable development. Climate change actions can also result in some trade-offs. The trade-offs of individual options could be managed through policy design. The Sustainable Development Goals (SDGs) adopted under the UN 2030 Agenda for Sustainable Development can be used as a basis for evaluating climate action in the context of sustainable development. (*high confidence*) (Figure SPM.8) {1.6, 3.7, 17.3, Figure TS.29}

D.1.1 Human-induced climate change is a consequence of more than a century of net GHG emissions from unsustainable energy use, land-use and land use change, lifestyle and patterns of consumption and production. Without urgent, effective and equitable mitigation actions, climate change increasingly threatens the health and livelihoods of people around the globe, ecosystem health and biodiversity. There are both synergies and trade-offs between climate action and the pursuit of other SDGs. Accelerated and equitable climate action in mitigating, and adapting to, climate change impacts is critical to sustainable development. (*high confidence*) {1.6, Cross-Chapter Box 5 in Chapter 4, 7.2, 7.3, 17.3, WGI, WGII}

D.1.2 Synergies and trade-offs depend on the development context including inequalities, with consideration of climate justice. They also depend on means of implementation, intra- and inter-sectoral interactions, cooperation between countries and regions, the sequencing, timing and stringency of mitigation actions, governance, and policy design. Maximising synergies and avoiding trade-offs pose particular challenges for developing countries, vulnerable populations, and Indigenous Peoples with limited institutional, technological and financial capacity, and with constrained social, human, and economic capital. Trade-offs can be evaluated and minimized by giving emphasis to capacity building, finance, governance, technology transfer, investments, and development and social equity considerations with meaningful participation of Indigenous Peoples and vulnerable populations. (*high confidence*) {1.6, 1.7, 3.7, 5.2, 5.6, 7.4, 7.6, 17.4}

D.1.3 There are potential synergies between sustainable development and energy efficiency and renewable energy, urban planning with more green spaces, reduced air pollution, and demand side mitigation including shifts to balanced, sustainable healthy diets (*high confidence*). Electrification combined with low GHG energy, and shifts to public transport can enhance health, employment, and can elicit energy security and deliver equity (*high confidence*). In industry, electrification and circular material flows contribute to reduced environmental pressures and increased economic activity and employment. However, some industrial options could impose high costs (*medium confidence*). (Figure SPM.8) {5.2, 8.2, 11.3, 11.5, 17.3, Figure TS.29}

D.1.4 Land-based options such as reforestation and forest conservation, avoided deforestation and restoration and conservation of natural ecosystems and biodiversity, improved sustainable forest management, agroforestry, soil carbon management and options that reduce CH₄ and N₂O emissions in agriculture from livestock and soil, can have multiple synergies with the SDGs. These include enhancing sustainable agricultural productivity and resilience, food security, providing additional biomass for human use, and addressing land degradation. Maximising synergies and managing trade-offs depend on specific practices, scale of implementation, governance, capacity building, integration with existing land-use, and the involvement of local communities and Indigenous Peoples and through benefit sharing supported by frameworks such as Land Degradation Neutrality within the UNCCD. (*high confidence*) {3.7, 7.4, 12.5, 17.3}

D.1.5 Trade-offs in terms of employment, water use, land use competition and biodiversity, as well as access to, and the affordability of, energy, food, and water can be avoided by well-implemented land-based mitigation options, especially those that do not threaten existing sustainable land uses and land rights, though more frameworks for integrated policy implementation are required. The sustainability of bioenergy and other biobased products is influenced by feedstock, land management practice, climatic region, the context of existing land management, and the timing, scale and speed of deployment. (*medium confidence*) {3.5, 3.7, 7.4, 12.4, 12.5, 17.1}

D.1.6 CDR methods such as soil carbon sequestration and biochar [FOOTNOTE 71] can improve soil quality and food production capacity. Ecosystem restoration and reforestation sequester carbon in plants and soil, and can enhance biodiversity and provide additional biomass, but can displace food production and livelihoods, which calls for integrated approaches to land use planning, to meet multiple objectives including food security. However, due to limited application of some of the options today, there are some uncertainties about potential benefits (*high confidence*) {3.7, 7.4, 7.6, 12.5, 17.3, Table TS.7}

FOOTNOTE 71: Potential risks, knowledge gaps due to the relative immaturity of use of biochar as soil amendment and unknown impacts of widespread application, and co-benefits of biochar are reviewed in 7.4.3.2.

Mitigation options have synergies with many Sustainable Development Goals, but some options can also have trade-offs. The synergies and trade-offs vary dependent on context and scale.

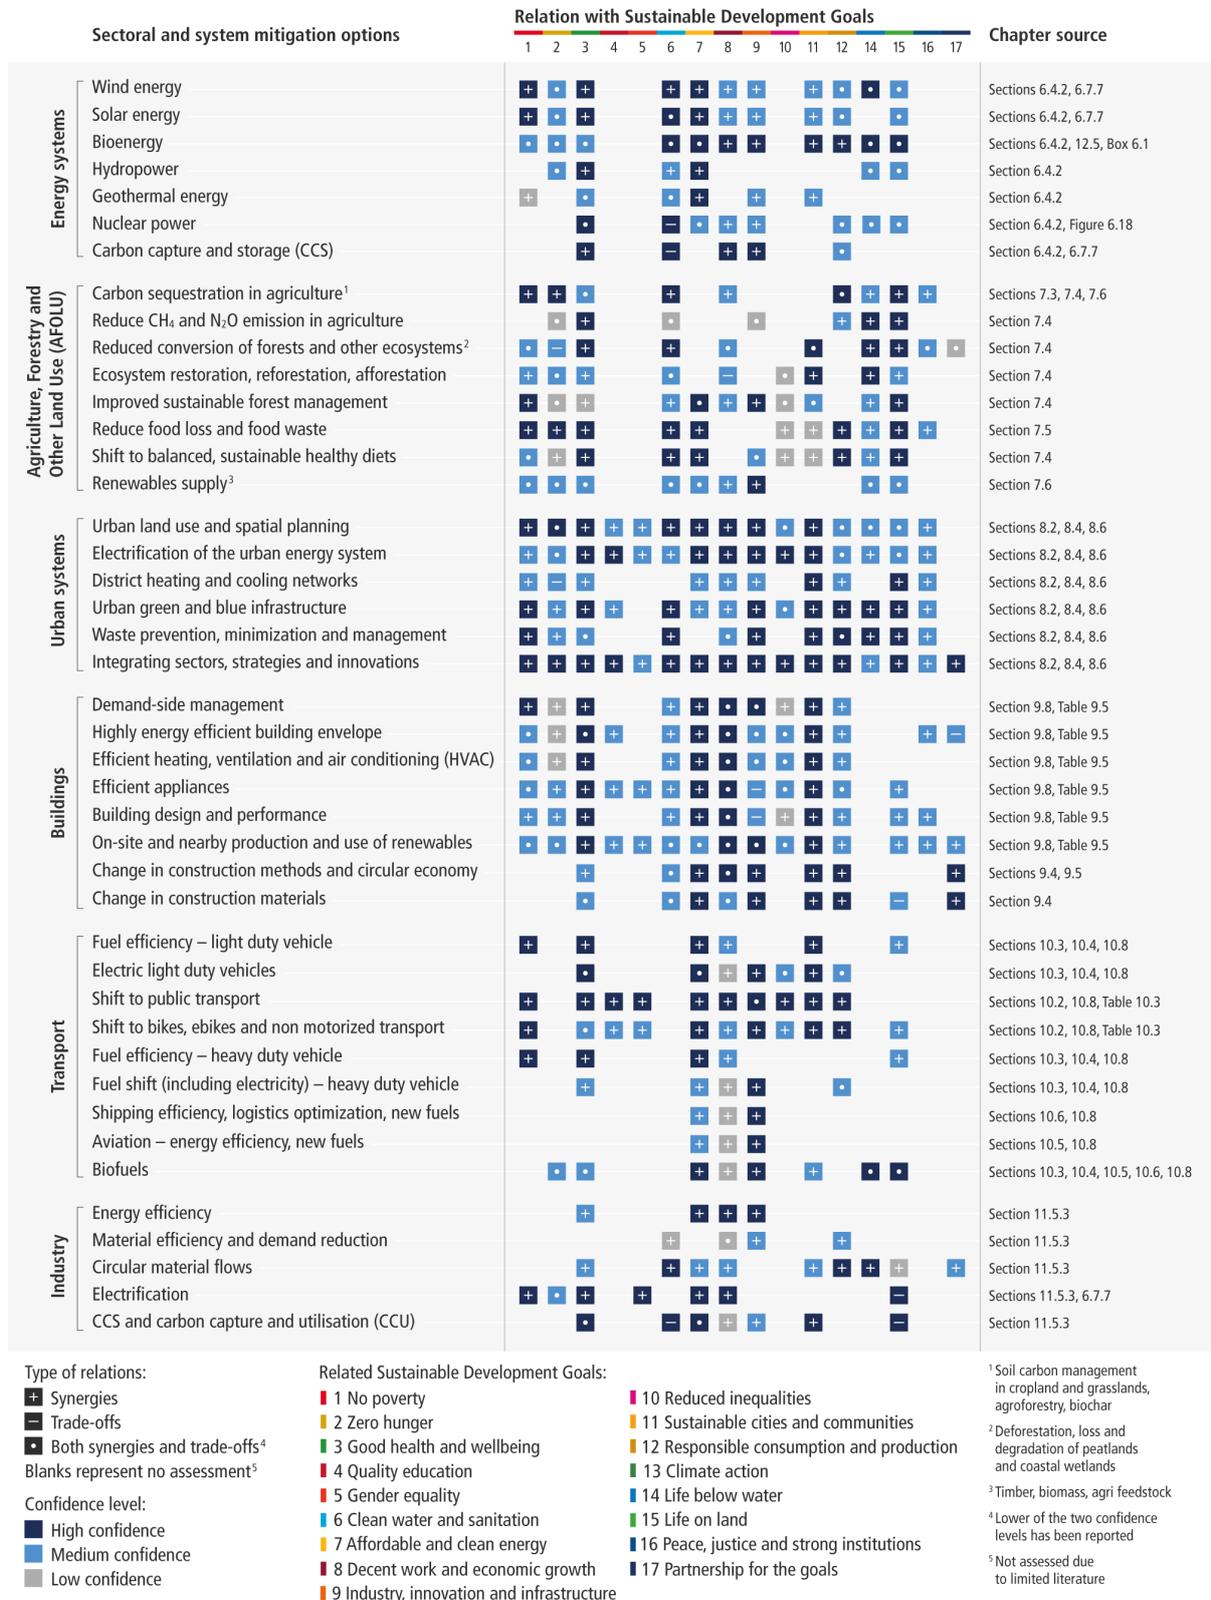

Figure SPM.8 Synergies and trade-offs between sectoral and system mitigation options and the SDGs

The sectoral chapters (Chapters 6–11) include qualitative assessments of synergies and trade-offs between sectoral mitigation options and the SDGs. Figure SPM.8 presents a summary of the chapter-level assessment for selected mitigation options (see Supplementary Material Table 17.1 for the underlying assessment). The last column provides a line of sight to the sectoral chapters, which provide details on context specificity and dependence of interactions on the scale of implementation. Blank cells indicate that interactions have not been assessed due to limited literature. They do not indicate the absence of interactions between mitigation options and the SDGs. Confidence levels depend on the quality of evidence and level of agreement in the underlying literature assessed by the sectoral chapters. Where both synergies and trade-offs exist, the lower of the confidence levels for these interactions is used.

Some mitigation options may have applications in more than one sector or system. The interactions between mitigation options and the SDGs might differ depending on the sector or system, and also on the context and the scale of implementation. Scale of implementation particularly matters when there is competition for scarce resources.

{6.3, 6.4, 6.7, 7.3, 7.4, 7.5, 7.6, 8.2, 8.4, 8.6, Figure 8.4, Table SM8.1, Table SM8.2, 9.4, 9.5, 9.8, Table 9.5, 10.3, 10.4, 10.5, 10.6, 10.8, Table 10.3, 11.5, 12.5, 17.3, Figure 17.1, Table SM17.1, Annex II Part IV Section 12}

D.2 There is a strong link between sustainable development, vulnerability and climate risks. Limited economic, social and institutional resources often result in high vulnerability and low adaptive capacity, especially in developing countries (*medium confidence*). Several response options deliver both mitigation and adaptation outcomes, especially in human settlements, land management, and in relation to ecosystems. However, land and aquatic ecosystems can be adversely affected by some mitigation actions, depending on their implementation (*medium confidence*). Coordinated cross-sectoral policies and planning can maximise synergies and avoid or reduce trade-offs between mitigation and adaptation (*high confidence*). {3.7, 4.4, 13.8, 17.3, WG II}

D.2.1 Sustainable urban planning and infrastructure design including green roofs and facades, networks of parks and open spaces, management of urban forests and wetlands, urban agriculture, and water-sensitive design can deliver both mitigation and adaptation benefits in settlements (*medium confidence*). These options can also reduce flood risks, pressure on urban sewer systems, urban heat island effects, and can deliver health benefits from reduced air pollution (*high confidence*). There could also be trade-offs. For example, increasing urban density to reduce travel demand, could imply high vulnerability to heat waves and flooding (*high confidence*). (Figure SPM.8) {3.7, 8.2, 8.4, 12.5, 13.8, 17.3}

D.2.2 Land-related mitigation options with potential co-benefits for adaptation include agroforestry, cover crops, intercropping, and perennial plants, thus restoring natural vegetation and rehabilitating degraded land. These can enhance resilience by maintaining land productivity and protecting and diversifying livelihoods. Restoration of mangroves and coastal wetlands sequester carbon, while also reducing coastal erosion and protecting against storm surges, thus, reduce the risks from sea level rise and extreme weather. (*high confidence*) {4.4, 7.4, 7.6, 12.5, 13.8}

D.2.3 Some mitigation options can increase competition for scarce resources including land, water and biomass. Consequently, these can also reduce adaptive capacity, especially if deployed at larger scale and with high expansion rates thus exacerbating existing risks in particular where land and water resources are very limited. Examples include the large-scale or poorly planned deployment of bioenergy, biochar, and afforestation of naturally unforested land. (*high confidence*) {12.5, 17.3}

D.2.4 Coordinated policies, equitable partnerships and integration of adaptation and mitigation within and across sectors can maximise synergies and minimise trade-offs and thereby enhance the support for climate action (*medium confidence*). Even if extensive global mitigation efforts are implemented, there

will be a large need for financial, technical, and human resources for adaptation. Absence or limited resources in social and institutional systems can lead to poorly coordinated responses, thus reducing the potential for maximising mitigation and adaptation benefits, and increasing risk (*high confidence*). {12.6, 13.8, 17.1, 17.3}

D.3 Enhanced mitigation and broader action to shift development pathways towards sustainability will have distributional consequences within and between countries. Attention to equity and broad and meaningful participation of all relevant actors in decision-making at all scales can build social trust, and deepen and widen support for transformative changes. (*high confidence*) {3.6, 4.2, 4.5, 5.2, 13.2, 17.3, 17.4}

D.3.1 Countries at all stages of economic development seek to improve the well-being of people, and their development priorities reflect different starting points and contexts. Different contexts include social, economic, environmental, cultural, or political conditions, resource endowment, capabilities, international environment, and history. The enabling conditions for shifting development pathways towards increased sustainability will therefore also differ, giving rise to different needs. (*high confidence*) (Figure SPM.2) {1.6, 1.7, 2.4, 2.6, Cross-Chapter Box 5 in Chapter 4, 4.3.2, 17.4}

D.3.2 Ambitious mitigation pathways imply large and sometimes disruptive changes in economic structure, with significant distributional consequences, within and between countries. Equity remains a central element in the UN climate regime, notwithstanding shifts in differentiation between states over time and challenges in assessing fair shares. Distributional consequences within and between countries include shifting of income and employment during the transition from high to low emissions activities. While some jobs may be lost, low-emissions development can also open more opportunities to enhance skills and create more jobs that last, with differences across countries and sectors. Integrated policy packages can improve the ability to integrate considerations of equity, gender equality and justice. (*high confidence*). {1.4, 1.6, 3.6, 4.2, 5.2, Box 11.1, 14.3, 15.2, 15.5, 15.6}

D.3.3 Inequalities in the distribution of emissions and in the impacts of mitigation policies within countries affect social cohesion and the acceptability of mitigation and other environmental policies. Equity and just transitions can enable deeper ambitions for accelerated mitigation. Applying just transition principles and implementing them through collective and participatory decision-making processes is an effective way of integrating equity principles into policies at all scales, in different ways depending on national circumstances. (*medium confidence*) This is already taking place in many countries and regions, as national just transition commissions or task forces, and related national policies, have been established in several countries. A multitude of actors, networks, and movements are engaged. (*high confidence*) {1.6, 1.7, 2.4, 2.6, 4.5, 13.2, 13.9, 14.3, 14.5}

D.3.4 Broadening equitable access to domestic and international finance, technologies that facilitate mitigation, and capacity, while explicitly addressing needs can further integrate equity and justice into national and international policies and act as a catalyst for accelerating mitigation and shifting development pathways (*medium confidence*). The consideration of ethics and equity can help address the uneven distribution of adverse impacts associated with 1.5°C and higher levels of global warming, in all societies (*high confidence*). Consideration of climate justice can help to facilitate shifting development pathways towards sustainability, including through equitable sharing of benefits and burdens of mitigation, increasing resilience to the impacts of climate change, especially for vulnerable countries and communities, and equitably supporting those in need (*high confidence*). {1.4, 1.6, 1.7,

3.6, 4.2, 4.5, Box 5.10, 13.4, 13.8, 13.9, 14.3, 14.5, 15.2, 15.5, 15.6, 16.5, 17.3, 17.4, SR1.5 SPM, WGII CH18}

E. Strengthening the response

E.1 There are mitigation options which are feasible [FOOTNOTE 72] to deploy at scale in the near term. Feasibility differs across sectors and regions, and according to capacities and the speed and scale of implementation. Barriers to feasibility would need to be reduced or removed, and enabling conditions [FOOTNOTE 73] strengthened to deploy mitigation options at scale. These barriers and enablers include geophysical, environmental-ecological, technological, and economic factors, and especially institutional and socio-cultural factors. Strengthened near-term action beyond the NDCs (announced prior to UNFCCC COP26) can reduce and/or avoid long-term feasibility challenges of global modelled pathways that limit warming to 1.5 °C (>50%) with no or limited overshoot. (*high confidence*) {3.8, 6.4, 8.5, 9.9, 10.8, 12.3, Figure TS.31, Annex II Part IV Section 11}

FOOTNOTE 72: In this report, the term ‘feasibility’ refers to the potential for a mitigation or adaptation option to be implemented. Factors influencing feasibility are context-dependent and may change over time. Feasibility depends on geophysical, environmental-ecological, technological, economic, socio-cultural and institutional factors that enable or constrain the implementation of an option. The feasibility of options may change when different options are combined and increase when enabling conditions are strengthened.

FOOTNOTE 73: In this report, the term ‘enabling conditions’ refers to conditions that enhance the feasibility of adaptation and mitigation options. Enabling conditions include finance, technological innovation, strengthening policy instruments, institutional capacity, multi-level governance and changes in human behaviour and lifestyles.

E.1.1 Several mitigation options, notably solar energy, wind energy, electrification of urban systems, urban green infrastructure, energy efficiency, demand side management, improved forest- and crop/grassland management, and reduced food waste and loss, are technically viable, are becoming increasingly cost effective, and are generally supported by the public. This enables deployment in many regions. (*high confidence*) While many mitigation options have environmental co-benefits, including improved air quality and reducing toxic waste, many also have adverse environmental impacts, such as reduced biodiversity, when applied at very large scale, for example very large scale bioenergy or large scale use of battery storage, that would have to be managed (*medium confidence*). Almost all mitigation options face institutional barriers that need to be addressed to enable their application at scale (*medium confidence*). {6.4, Figure 6.19, 7.4, 8.5, Figure 8.19, 9.9, Figure 9.20, 10.8, Figure 10.23, 12.3, Figure 12.4, Figure TS.31}

E.1.2 The feasibility of mitigation options varies according to context and time. For example, the institutional capacity to support deployment varies across countries; the feasibility of options that involve large-scale land use changes varies across regions; spatial planning has a higher potential at early stages of urban development; the potential of geothermal is site specific; and capacities, cultural and local conditions can either inhibit or enable demand-side responses. The deployment of solar and wind energy has been assessed to become increasingly feasible over time. The feasibility of some options can increase when combined or integrated, such as using land for both agriculture and

centralised solar production. (*high confidence*) {6.4, 6.6, 7.4, 8.5, 9.9, 10.8, 12.3, Appendix 10.3, Table SM6, Table SM8.2, Table SM9.1, Table SM12.B}

E.1.3 Feasibility depends on the scale and speed of implementation. Most options face barriers when they are implemented rapidly at a large scale, but the scale at which barriers manifest themselves varies. Strengthened and coordinated near-term actions in cost-effective modelled global pathways that limit warming to 2°C (>67%) or lower, reduce the overall risks to the feasibility of the system transitions, compared to modelled pathways with relatively delayed or uncoordinated action.[FOOTNOTE 74] (*high confidence*) {3.8, 6.4, 10.8, 12.3}

FOOTNOTE 74: The future feasibility challenges described in the modelled pathways may differ from the real-world feasibility experiences of the past.

E.2 In all countries, mitigation efforts embedded within the wider development context can increase the pace, depth and breadth of emissions reductions (*medium confidence*). Policies that shift development pathways towards sustainability can broaden the portfolio of available mitigation responses, and enable the pursuit of synergies with development objectives (*medium confidence*). Actions can be taken now to shift development pathways and accelerate mitigation and transitions across systems (*high confidence*). {4.3, 4.4, Cross-Chapter Box 5 in Chapter 4, 5.2, 5.4, 13.9, 14.5, 15.6, 16.3, 16.4, 16.5}

E.2.1 Current development pathways may create behavioural, spatial, economic and social barriers to accelerated mitigation at all scales (*high confidence*). Choices made by policymakers, citizens, the private sector and other stakeholders influence societies' development pathways (*high confidence*). Actions that steer, for example, energy and land systems transitions, economy-wide structural change, and behaviour change, can shift development pathways towards sustainability [FOOTNOTE 75] (*medium confidence*). {4.3, Cross-Chapter Box 5 in Chapter 4, 5.4, 13.9}

FOOTNOTE 75: Sustainability may be interpreted differently in various contexts as societies pursue a variety of sustainable development objectives.

E.2.2 Combining mitigation with policies to shift development pathways, such as broader sectoral policies, policies that induce lifestyle or behaviour changes, financial regulation, or macroeconomic policies can overcome barriers and open up a broader range of mitigation options (*high confidence*). It can also facilitate the combination of mitigation and other development goals (*high confidence*). For example, measures promoting walkable urban areas combined with electrification and renewable energy can create health co-benefits from cleaner air and benefits from enhanced mobility (*high confidence*). Coordinated housing policies that broaden relocation options can make mitigation measures in transport more effective (*medium confidence*). {3.2, 4.3, 4.4, Cross-Chapter Box 5 in Chapter 4, 5.3, 8.2, 8.4}

E.2.3 Institutional and regulatory capacity, innovation, finance, improved governance and collaboration across scales, and multi-objective policies enable enhanced mitigation and shifts in development pathways. Such interventions can be mutually reinforcing and establish positive feedback mechanisms, resulting in accelerated mitigation. (*high confidence*) {4.4, 5.4, Figure 5.14, 5.6, 9.9, 13.9, 14.5, 15.6, 16.3, 16.4, 16.5, Cross-Chapter Box 12 in Chapter 16}

E.2.4 Enhanced action on all the above enabling conditions can be taken now (*high confidence*). In some situations, such as with innovation in technology at an early stage of development and some changes in behaviour towards low-emissions, because the enabling conditions may take time to be established, action in the near-term can yield accelerated mitigation in the mid-term (*medium*

confidence). In other situations, the enabling conditions can be put in place and yield results in a relatively short time frame, for example the provision of energy related information, advice and feedback to promote energy saving behaviour (*high confidence*). {4.4, 5.4, Figure 5.14, 5.6, 6.7, 9.9, 13.9, 14.5, 15.6, 16.3, 16.4, 16.5, Cross-Chapter Box 12 in Chapter 16}

E.3 Climate governance, acting through laws, strategies and institutions, based on national circumstances, supports mitigation by providing frameworks through which diverse actors interact, and a basis for policy development and implementation (*medium confidence*). Climate governance is most effective when it integrates across multiple policy domains, helps realise synergies and minimize trade-offs, and connects national and sub-national policy-making levels (*high confidence*). Effective and equitable climate governance builds on engagement with civil society actors, political actors, businesses, youth, labour, media, Indigenous Peoples and local communities (*medium confidence*). {5.4, 5.6, 8.5, 9.9, 13.2, 13.7, 13.9}

E.3.1 Climate governance enables mitigation by providing an overall direction, setting targets, mainstreaming climate action across policy domains, enhancing regulatory certainty, creating specialised organisations and creating the context to mobilise finance (*medium confidence*). These functions can be promoted by climate-relevant laws, which are growing in number, or climate strategies, among others, based on national and sub-national context (*medium confidence*). Framework laws set an overarching legal basis, either operating through a target and implementation approach, or a sectoral mainstreaming approach, or both, depending on national circumstance (*medium confidence*). Direct national and sub-national laws that explicitly target mitigation and indirect laws that impact emissions through mitigation related policy domains have both been shown to be relevant to mitigation outcomes (*medium confidence*). {13.2}

E.3.2 Effective national climate institutions address coordination across sectors, scales and actors, build consensus for action among diverse interests, and inform strategy setting (*medium confidence*). These functions are often accomplished through independent national expert bodies, and high-level coordinating bodies that transcend departmental mandates. Complementary sub-national institutions tailor mitigation actions to local context and enable experimentation but can be limited by inequities and resource and capacity constraints (*high confidence*). Effective governance requires adequate institutional capacity at all levels (*high confidence*). {4.4, 8.5, 9.9, 11.3, 11.5, 11.6, 13.2, 13.5, 13.7, 13.9}

E.3.3 The extent to which civil society actors, political actors, businesses, youth, labour, media, Indigenous Peoples, and local communities are engaged influences political support for climate change mitigation and eventual policy outcomes. Structural factors of national circumstances and capabilities (e.g., economic and natural endowments, political systems and cultural factors and gender considerations) affect the breadth and depth of climate governance. Mitigation options that align with prevalent ideas, values and beliefs are more easily adopted and implemented. Climate-related litigation, for example by governments, private sector, civil society and individuals is growing, with a large number of cases in some developed countries, and with a much smaller number in some developing countries, and in some cases, has influenced the outcome and ambition of climate governance. (*medium confidence*) {5.2, 5.4, 5.5, 5.6, 9.9, 13.3, 13.4}

E.4 Many regulatory and economic instruments have already been deployed successfully. Instrument design can help address equity and other objectives. These instruments could support deep emissions reductions and stimulate innovation if scaled up and applied more widely (*high confidence*). Policy packages that enable innovation and build capacity are better able to support

a shift towards equitable low-emission futures than are individual policies (*high confidence*). Economy-wide packages, consistent with national circumstances, can meet short-term economic goals while reducing emissions and shifting development pathways towards sustainability (*medium confidence*). {13.6, 13.7, 13.9, 16.3, 16.4, 16.6, Cross-Chapter Box 5 in Chapter 4}

E.4.1 A wide range of regulatory instruments at the sectoral level have proven effective in reducing emissions. These instruments, and broad-based approaches including relevant economic instruments[FOOTNOTE 76], are complementary. (*high confidence*) Regulatory instruments that are designed to be implemented with flexibility mechanisms can reduce costs (*medium confidence*). Scaling up and enhancing the use of regulatory instruments, consistent with national circumstances, could improve mitigation outcomes in sectoral applications, including but not limited to renewable energy, land-use and zoning, building codes, vehicle and energy efficiency, fuel standards, and low-emissions industrial processes and materials (*high confidence*). {6.7, 7.6, 8.4, 9.9, 10.4, 11.5, 11.6, 13.6}

FOOTNOTE 76: Economic instruments are structured to provide a financial incentive to reduce emissions and include, among others, market- and price-based instruments.

E.4.2 Economic instruments have been effective in reducing emissions, complemented by regulatory instruments mainly at the national and also sub-national and regional level (*high confidence*). Where implemented, carbon pricing instruments have incentivized low-cost emissions reduction measures, but have been less effective, on their own and at prevailing prices during the assessment period, to promote higher-cost measures necessary for further reductions (*medium confidence*). Equity and distributional impacts of such carbon pricing instruments can be addressed by using revenue from carbon taxes or emissions trading to support low-income households, among other approaches (*high confidence*). Practical experience has informed instrument design and helped to improve predictability, environmental effectiveness, economic efficiency, distributional goals and social acceptance (*high confidence*). Removing fossil fuel subsidies would reduce emissions, improve public revenue and macroeconomic performance, and yield other environmental and sustainable development benefits; subsidy removal may have adverse distributional impacts especially on the most economically vulnerable groups which, in some cases can be mitigated by measures such as re-distributing revenue saved, all of which depend on national circumstances (*high confidence*); fossil fuel subsidy removal is projected by various studies to reduce global CO₂ emissions by 1-4%, and GHG emissions by up to 10% by 2030, varying across regions (*medium confidence*). {6.3, 13.6}

E.4.3 Low-emission technological innovation is strengthened through the combination of dedicated technology-push policies and investments (e.g., for scientific training, R&D, demonstration), with tailored demand-pull policies (e.g., standards, feed-in tariffs, taxes), which create incentives and market opportunities. Developing countries' abilities to deploy low-emission technologies, seize socio-economic benefits and manage trade-offs would be enhanced with increased financial resources and capacity for innovation which are currently concentrated in developed countries, alongside technology transfer. (*high confidence*) {16.2, 16.3, 16.4, 16.5}

E.4.4 Effective policy packages would be comprehensive in coverage, harnessed to a clear vision for change, balanced across objectives, aligned with specific technology and system needs, consistent in terms of design and tailored to national circumstances. They are better able to realise synergies and avoid trade-offs across climate and development objectives. Examples include: emissions reductions from buildings through a mix of efficiency targets, building codes, appliance performance standards, information provision, carbon pricing, finance and technical assistance; and industrial GHG emissions reductions through innovation support, market creation and capacity building. (*high confidence*) {4.4, 6.7, 9.9, 11.6, 13.7, 13.9, 16.3, 16.4}

E.4.5 Economy-wide packages that support mitigation and avoid negative environmental outcomes include: long-term public spending commitments, pricing reform; and investment in education and training, natural capital, R&D and infrastructure (*high confidence*). They can meet short-term economic goals while reducing emissions and shifting development pathways towards sustainability (*medium confidence*). Infrastructure investments can be designed to promote low-emissions futures that meet development needs (*medium confidence*). {Cross Chapter Box 7 in Chapter 4, 5.4, 5.6, 8.5, 13.6, 13.9, 16.3, 16.5, 16.6}

E.4.6 National policies to support technology development and diffusion, and participation in international markets for emission reduction, can bring positive spill-over effects for other countries (*medium confidence*), although reduced demand for fossil fuels could result in costs to exporting countries (*high confidence*). There is no consistent evidence that current emission trading systems have led to significant emissions leakage, which can be attributed to design features aimed at minimising competitiveness effects among other reasons (*medium confidence*). {13.6, 13.7, 13.8, 16.2, 16.3, 16.4}

E.5 **Tracked financial flows fall short of the levels needed to achieve mitigation goals across all sectors and regions. The challenge of closing gaps is largest in developing countries as a whole. Scaling up mitigation financial flows can be supported by clear policy choices and signals from governments and the international community. (*high confidence*) Accelerated international financial cooperation is a critical enabler of low-GHG and just transitions, and can address inequities in access to finance and the costs of, and vulnerability to, the impacts of climate change (*high confidence*).** {15.2, 15.3, 15.4, 15.5, 15.6}

E.5.1 Average annual modelled investment requirements for 2020 to 2030 in scenarios that limit warming to 2°C or 1.5°C are a factor of three to six greater than current levels, and total mitigation investments (public, private, domestic and international) would need to increase across all sectors and regions (*medium confidence*). Mitigation investment gaps are wide for all sectors, and widest for the AFOLU sector in relative terms and for developing countries [FOOTNOTE 77] (*high confidence*). Financing and investment requirements for adaptation, reduction of losses and damages, general infrastructure, regulatory environment and capacity building, and climate-responsive social protection further exacerbate the magnitude of the challenges for developing countries to attract financing (*high confidence*). {3.2, 14.4, 15.1, 15.2, 15.3, 15.4, 15.5}

FOOTNOTE 77: In modelled pathways, regional investments are projected to occur when and where they are most cost-effective to limit global warming. The model quantifications help to identify high-priority areas for cost-effective investments, but do not provide any indication on who would finance the regional investments.

E.5.2 There is sufficient global capital and liquidity to close global investment gaps, given the size of the global financial system, but there are barriers to redirect capital to climate action both within and outside the global financial sector, and in the macroeconomic headwinds facing developing regions. Barriers to the deployment of commercial finance from within the financial sector as well as macroeconomic considerations include: inadequate assessment of climate-related risks and investment opportunities, regional mismatch between available capital and investment needs, home bias factors, country indebtedness levels, economic vulnerability, and limited institutional capacities (*high confidence*). Challenges from outside the financial sector include: limited local capital markets; unattractive risk-return profiles, in particular due to missing or weak regulatory environments consistent with ambition levels; limited institutional capacity to ensure safeguards; standardization, aggregation,

scalability and replicability of investment opportunities and financing models; and, a pipeline ready for commercial investments. (*high confidence*) {15.2, 15.3, 15.5, 15.6}

E.5.3 Accelerated financial support for developing countries from developed countries and other sources is a critical enabler to enhance mitigation action and address inequities in access to finance, including its costs, terms and conditions and economic vulnerability to climate change for developing countries (*high confidence*). Scaled-up public grants for mitigation and adaptation funding for vulnerable regions, especially in Sub-Saharan Africa, would be cost-effective and have high social returns in terms of access to basic energy (*high confidence*). Options for scaling up mitigation in developing regions include: increased levels of public finance and publicly mobilised private finance flows from developed to developing countries in the context of the USD100 billion-a-year goal; increase the use of public guarantees to reduce risks and leverage private flows at lower cost; local capital markets development; and building greater trust in international cooperation processes (*high confidence*). A coordinated effort to make the post-pandemic recovery sustainable and increased flows of financing over the next decade can accelerate climate action, including in developing regions and countries facing high debt costs, debt distress and macro-economic uncertainty (*high confidence*). {15.2, 15.3, 15.4, 15.5, 15.6, Box 15.6}

E.5.4 Clear signalling by governments and the international community, including a stronger alignment of public sector finance and policy, and higher levels of public sector climate finance, reduces uncertainty and transition risks for the private sector. Depending on national contexts, investors and financial intermediaries, central banks, and financial regulators can support climate action and can shift the systemic underpricing of climate-related risk by increasing awareness, transparency and consideration of climate-related risk, and investment opportunities. Financial flows can also be aligned with funding needs through: greater support for technology development; a continued role for multilateral and national climate funds and development banks; lowering financing costs for underserved groups through entities such as green banks existing in some countries, funds and risk-sharing mechanisms; economic instruments which consider economic and social equity and distributional impacts; gender-responsive and women-empowerment programs as well as enhanced access to finance for local communities and Indigenous Peoples and small landowners; and greater public-private cooperation. (*high confidence*) {15.2, 15.5, 15.6}

E.6 International cooperation is a critical enabler for achieving ambitious climate change mitigation goals. The UNFCCC, Kyoto Protocol, and Paris Agreement are supporting rising levels of national ambition and encouraging development and implementation of climate policies, although gaps remain. Partnerships, agreements, institutions and initiatives operating at the sub-global and sectoral levels and engaging multiple actors are emerging, with mixed levels of effectiveness. (*high confidence*) {8.5, 14.2, 14.3, 14.5, 14.6, 15.6, 16.5}

E.6.1 Internationally agreed processes and goals, such as those in the UNFCCC, Kyoto Protocol, and Paris Agreement, including transparency requirements for national reporting on emissions, actions and support, and tracking progress towards the achievement of nationally determined contributions, are enhancing international cooperation, national ambition and policy development. International financial, technology and capacity building support to developing countries will enable greater implementation and encourage ambitious nationally determined contributions over time. (*medium confidence*) {14.3}

E.6.2 International cooperation on technology development and transfer accompanied by capacity building, knowledge sharing, and technical and financial support can accelerate the global diffusion of mitigation technologies, practices and policies at national and sub-national levels, and align these with

other development objectives (*high confidence*). Challenges in and opportunities to enhance innovation cooperation exist, including in the implementation of elements of the UNFCCC and the Paris Agreement as per the literature assessed, such as in relation to technology development and transfer, and finance (*high confidence*). International cooperation on innovation works best when tailored to specific institutional and capability contexts, when it benefits local value chains, when partners collaborate equitably and on voluntary and mutually agreed terms, when all relevant voices are heard, and when capacity building is an integral part of the effort (*medium confidence*). Support to strengthen technological innovation systems and innovation capabilities, including through financial support in developing countries would enhance engagement in and improve international cooperation on innovation (*high confidence*). {4.4, 14.2, 14.4, 16.3, 16.5, 16.6}

E.6.3 Transnational partnerships can stimulate policy development, low-emissions technology diffusion and emission reductions by linking sub-national and other actors, including cities, regions, non-governmental organisations and private sector entities, and by enhancing interactions between state and non-state actors. While this potential of transnational partnerships is evident, uncertainties remain over their costs, feasibility, and effectiveness. Transnational networks of city governments are leading to enhanced ambition and policy development and a growing exchange of experience and best practices (*medium confidence*). {8.5, 11.6, 14.5, 16.5, Cross-Chapter Box 12 in Chapter 16}

E.6.4 International environmental and sectoral agreements, institutions, and initiatives are helping, and in some cases may help, to stimulate low GHG emissions investment and reduce emissions. Agreements addressing ozone depletion and transboundary air pollution are contributing to mitigation, and in other areas, such as atmospheric emissions of mercury, may contribute to mitigation (*high confidence*). Trade rules have the potential to stimulate international adoption of mitigation technologies and policies, but may also limit countries' ability to adopt trade-related climate policies (*medium confidence*). Current sectoral levels of ambition vary, with emission reduction aspirations in international aviation and shipping lower than in many other sectors (*medium confidence*). {14.5, 14.6}

1 **TS. 1 Introduction**

2 The Working Group III (WG III) contribution to the IPCC's Sixth Assessment Report (AR6) assesses
3 the current state of knowledge on the scientific, technological, environmental, economic and social
4 aspects of climate change mitigation. It builds on previous IPCC reports, including the WG III
5 contribution to the IPCC's Fifth Assessment Report (AR5) and the three Special Reports of the Sixth
6 Assessment cycle on: *Global warming of 1.5°C (SR 1.5°C)*; *Climate Change and Land (SRCCL)*; and,
7 *the Ocean and Cryosphere in a Changing Climate (SROCC)*.¹

8 The report assesses new literature, methodological and recent developments, and changes in approaches
9 towards climate change mitigation since the IPCC AR5 report was published in 2014.

10 The global science and policy landscape on climate change mitigation has evolved since AR5. The
11 development of the literature reflects, among other factors, the UN Framework Convention on Climate
12 Change (UNFCCC), the outcomes of its Kyoto Protocol and the goals of the Paris Agreement {13, 14,
13 15}, and the UN 2030 Agenda for Sustainable Development {1, 4, 17}. Literature further highlights the
14 growing role of non-state and sub-national actors in the global effort to address climate change,
15 including cities, businesses, citizens, transnational initiatives and public-private entities {5, 8, 13}. It
16 draws attention to the decreasing cost of some low emission technologies {2, 6, 12} and the evolving
17 role of international cooperation {14}, finance {15} and innovation {16}. Emerging literature examines
18 the global spread of climate policies, strengthened mitigation actions in developing countries, sustained
19 reductions in greenhouse gas (GHG) emissions in some developed countries and the continuing
20 challenges for mitigation. {2, 13}

21 There are ever closer linkages between climate change mitigation, development pathways and the
22 pursuit of sustainable development goals. Development pathways largely drive GHG emissions and
23 hence shape the mitigation challenge and the portfolio of available responses {4}. The co-benefits and
24 risks of mitigation responses also differ according to stages of development and national capabilities
25 {1, 2, 3, 4, 13}. Climate change mitigation framed in the context of sustainable development, equity,
26 and poverty eradication, and rooted in the development aspirations of the society within which they
27 take place, will be more acceptable, durable and effective. {1, 4, 17}

28 This report includes new assessment approaches that go beyond those evaluated in the previous IPCC
29 WG III reports. In addition to sectoral and systems chapters {6, 7, 8, 9, 10, 11}, this report includes, for
30 the first time, chapters dedicated to cross-sectoral perspectives {12} demand, services and social aspects
31 of mitigation (Box TS.11) {5} and innovation, technology development and transfer {16}. The
32 assessment of future pathways combines a forward-looking assessment of near- to medium-term
33 perspectives up to 2050, including ways of shifting development pathways towards sustainability {4},
34 with an assessment of long-term outcome-oriented pathways up to 2100 {3}. Collaboration between
35 the IPCC Working Groups is reflected in Cross-Working Group boxes which address topics such as the
36 economic benefits from avoided impacts along mitigation pathways {Cross-Working Group Box 1 in
37 Chapter 3}, climate change and urban areas {Cross-Working Group Box 2 in Chapter 8}, mitigation
38 and adaptation through the bioeconomy {Cross-Working Group Box 3 in Chapter 12} and Solar
39 Radiation Modification {Cross-Working Group Box 4 in Chapter 14}. This assessment also gives

FOOTNOTE ¹ The three Special Reports are: *Global Warming of 1.5°C: an IPCC Special Report on the impacts of global warming of 1.5°C above pre-industrial levels and related global greenhouse gas emission pathways, in the context of strengthening the global response to the threat of climate change, sustainable development, and efforts to eradicate poverty* (2018); *Climate Change and Land: an IPCC Special Report on climate change, desertification, land degradation, sustainable land management, food security, and greenhouse gas fluxes in terrestrial ecosystems* (2019); *IPCC Special Report on the Ocean and Cryosphere in a Changing Climate* (2019).

1 greater attention than AR5 to social, economic and environmental dimensions of mitigation actions,
2 and institutional, legal and financial aspects {5, 13, 14, 15}.

3 The report draws from literature on broad and diverse analytic frameworks across multiple disciplines.
4 These include, inter alia: economic and environmental efficiency {1}; ethics and equity {4, 5, 17};
5 innovation and the dynamics of socio-technical transitions {16}; and, socio-political-institutional
6 frameworks {1, 5, 13, 14, 17}. These help to identify synergies and trade-offs with sustainable
7 development goals, challenges and windows of opportunity for action including co-benefits, and
8 equitable transitions at local, national and global scales. {1, 5, 13, 14, 16}.

9 This Technical Summary (TS) of the WG III contribution to the IPCC's Sixth Assessment Report
10 broadly follows the report chapter order and is structured as follows.

- 11 • TS Section 2 sets out how the global context for mitigation has changed and summarises signs of
12 progress and continuing challenges.
- 13 • TS Section 3 evaluates emission trends and drivers including recent sectoral, financial,
14 technological and policy developments.
- 15 • TS Section 4 identifies mitigation and development pathways in the near and medium- term to
16 2050, and in the longer term to 2100. This section includes an assessment of how mitigation
17 pathways deploying different portfolios of mitigation responses are consistent with limiting global
18 warming to different levels.
- 19 • TS Section 5 summarises recent advances in knowledge across sectors and systems including
20 energy, urban and other settlements, transport, buildings, industry, and agriculture, forestry and
21 other land use.
- 22 • TS Section 6 examines how enabling conditions including *behaviour and lifestyle, policy,*
23 *governance and institutional capacity, international cooperation, finance, and innovation and*
24 *technology* can accelerate mitigation in the context of sustainable development
- 25 • TS Section 7 evaluates how mitigation can be achieved in the context of sustainable development,
26 while maximising co-benefits and minimising risks.

27

28 *Throughout this Technical Summary the validity of findings, confidence in findings, and cross*
29 *references to Technical Summary sections, figures and tables are shown in () brackets.² References to*
30 *the underlying report are shown in { } brackets.*

31

32

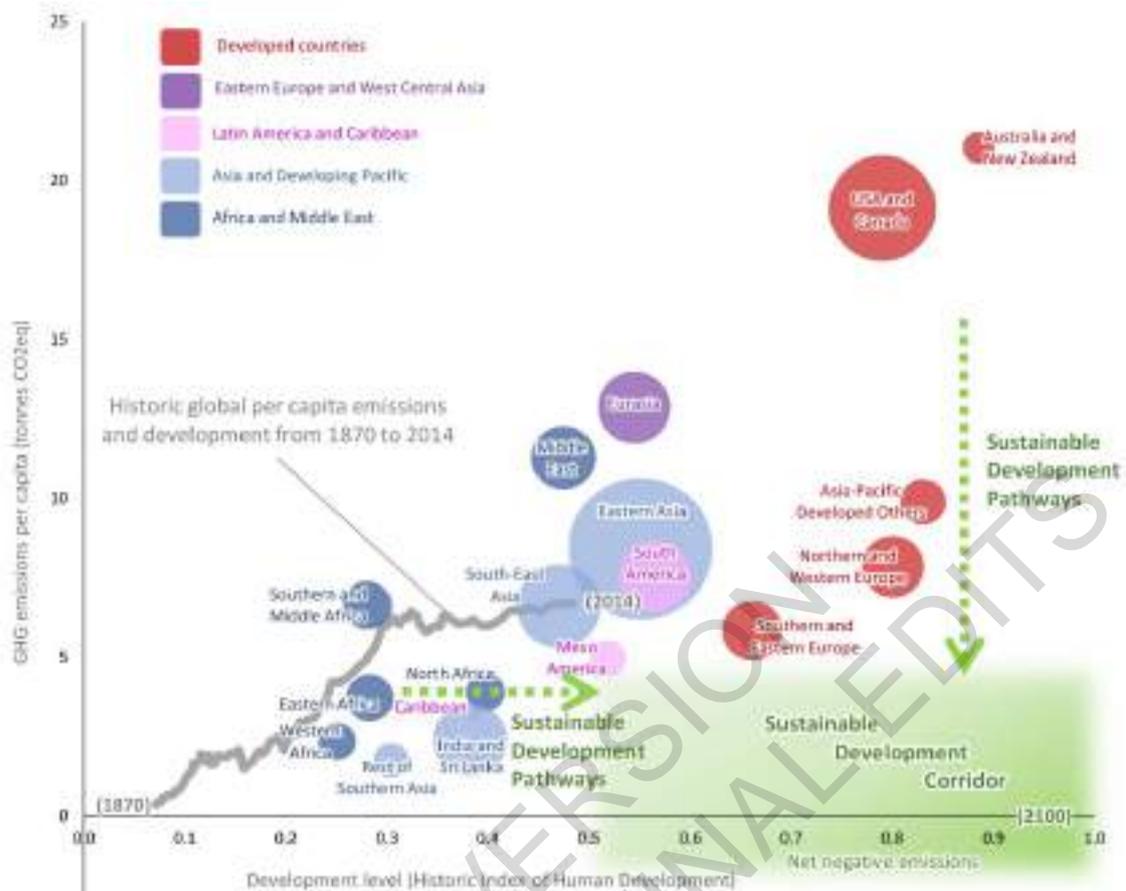

FOOTNOTE ² Each finding is grounded in an evaluation of the underlying evidence, typeset in italics. The validity of a finding is evaluated in terms of the evidence quality – *‘limited’*, *‘medium’*, *‘robust’* – and the degree of agreement between sources – *‘low’*, *‘medium’*, *‘high’*. A level of confidence is expressed using five qualifiers: *very low*, *low*, *medium*, *high* and *very high*. Generally, the level of confidence is highest where there is robust evidence from multiple sources and high agreement. For findings with, for example, *‘robust evidence, medium agreement’*, a confidence statement may not always be appropriate. The assessed likelihood of an outcome or a result is described as: *virtually certain* 99–100% probability, *very likely* 90–100%, *likely* 66–100%, *about as likely as not* 33–66%, *unlikely* 0–33%, *very unlikely* 0–10%, *exceptionally unlikely* 0–1%. Additional terms may also be used when appropriate, consistent with the IPCC uncertainty guidance: <https://www.ipcc.ch/site/assets/uploads/2018/05/uncertainty-guidance-note.pdf>.

1 **TS. 2 The changed global context, signs of progress and continuing**
2 **challenges**

3 **Since the IPCC's Fifth Assessment Report (AR5), important changes that have emerged include**
4 **the specific objectives established in the Paris Agreement of 2015 (for temperature, adaptation**
5 **and finance), rising climate impacts, and higher levels of societal awareness and support for**
6 **climate action (*high confidence*).** Meeting the long-term temperature goal in the Paris Agreement,
7 however, implies a rapid inflection in GHG emission trends and accelerating decline towards 'net zero'.
8 This is implausible without urgent and ambitious action at all scales. {1.2, 1.3, 1.5, 1.6, Chapters 3 and
9 4}

10 **Effective and equitable climate policies are largely compatible with the broader goal of**
11 **sustainable development and efforts to eradicate poverty as enshrined in the UN 2030 Agenda for**
12 **Sustainable Development and its 17 Sustainable Development Goals (SDGs), notwithstanding**
13 **trade-offs in some cases (*high confidence*).** Taking urgent action to combat climate change and its
14 impacts is one of the 17 SDGs (SDG13). However, climate change mitigation also has synergies and/or
15 trade-offs with many other SDGs. There has been a strong relationship between development and GHG
16 emissions, as historically both per capita and absolute emissions have risen with industrialisation.
17 However, recent evidence shows countries can grow their economies while reducing emissions.
18 Countries have different priorities in achieving the SDGs and reducing emissions as informed by their
19 respective national conditions and capabilities. Given the differences in GHG emissions contributions,
20 degree of vulnerability and impacts, as well as capacities within and between nations, equity and justice
21 are important considerations for effective climate policy and for securing national and international
22 support for deep decarbonisation. Achieving sustainable development and eradicating poverty would
23 involve effective and equitable climate policies at all levels from local to global scale. Failure to address
24 questions of equity and justice over time can undermine social cohesion and stability. International co-
25 operation can enhance efforts to achieve ambitious global climate mitigation in the context of
26 sustainable development pathways towards fulfilling the SDGs are illustrated in Figure TS.1. {1.4, 1.6,
27 Chapters 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 13 and 17}

28

1
2
3 **Figure TS.1: Sustainable development pathways towards fulfilling the Sustainable Development Goals**

4 Figure TS.1 legend: The graph shows how global average per capita GHG emissions (vertical axis) and relative
5 "Historic Index of Human Development" (HIHD) levels (horizontal axis) have increased globally since the
6 industrial revolution (grey line). The bubbles on the graph show regional per capita GHG emissions and human
7 development levels in the year 2015, illustrating large disparities. Pathways towards fulfilling the Paris
8 Agreement and SDG 13 (Climate Action) involve global average per capita GHG emissions below around 5
9 tCO₂eq by 2030. Likewise, HIHD levels need to be at least 0.5 or greater to fulfil SDGs 3 (Good Health &
10 Well-being), SDG 4 (Quality Education) and SDG 8 (Decent Work & Economic Growth). This suggests a
11 'sustainable development zone' for year 2030 (in green); the in-figure text also suggests a *sustainable*
12 *development corridor*, where countries limit per capita GHG emissions while improving levels of human
13 development over time. The emphasis of pathways into the sustainable development zone differ (green arrows)
14 but in each case transformations are needed in how human development is attained while limiting GHG
15 emissions. {Figure 1.6}

16
17 **The transition to a low carbon economy depends on a wide range of closely intertwined drivers**
18 **and constraints, including policies and technologies where notable advances over the past decade**
19 **have opened up new and large-scale opportunities for deep decarbonisation, and for alternative**
20 **development pathways which could deliver multiple social and developmental goals (*high***
21 ***confidence*).** Drivers for-, and constraints on-, low carbon societal transitions comprise *economic and*
22 *technological* factors (the means by which services such as food, heating and shelter are provided and
23 for whom, the emissions intensity of traded products, finance and investment), *socio-political issues*
24 (political economy, equity and fairness, social innovation and behaviour change), and *institutional*
25 *factors* (legal framework and institutions, and the quality of international cooperation). In addition to
26 being deeply intertwined, all the factors matter to varying degrees, depending on prevailing social,

1 economic, cultural and political context. They often both drive and inhibit transitions at the same time,
2 within and across different scales. The development and deployment of innovative technologies and
3 systems at scale are important for achieving deep decarbonisation, and in recent years, the cost of
4 several low carbon technologies has declined sharply as deployment has risen rapidly. (Figure TS.7)
5 {1.3, 1.4, Chapters 2, 4, 5, 13,14}

6 **Accelerating mitigation to prevent dangerous anthropogenic interference with the climate system**
7 **will require the integration of broadened assessment frameworks and tools that combine multiple**
8 **perspectives, applied in a context of multi-level governance (*high confidence*).** Analysing a
9 challenge on the scale of fully decarbonising our economies entails integration of multiple analytic
10 frameworks. Approaches to risk assessment and resilience, established across IPCC Working Groups,
11 are complemented by frameworks for probing the challenges in implementing mitigation. *Aggregate*
12 *frameworks* include cost-effectiveness analysis towards given objectives, and cost-benefit analysis,
13 both of which have been developing to take fuller account of advances in understanding risks and
14 innovation, the dynamics of sectors and systems and of climate impacts, and welfare economic theory
15 including growing consensus on long-term discounting. *Ethical frameworks* consider the fairness of
16 processes and outcomes which can help ameliorate distributional impacts across income groups,
17 countries and generations. *Transition and transformation frameworks* explain and evaluate the
18 dynamics of transitions to low-carbon systems arising from interactions amongst levels. *Psychological,*
19 *behavioural and political frameworks* outline the constraints (and opportunities) arising from human
20 psychology and the power of incumbent interests. A comprehensive understanding of climate mitigation
21 must combine these multiple frameworks. Together with established risk frameworks, these collectively
22 help to explain potential synergies and trade-offs in mitigation, implying a need for a wide portfolio of
23 policies attuned to different actors and levels of decision-making, and underpin ‘just transition’
24 strategies in diverse contexts. {1.2.2, 1.7, 1.8, Figure 1.7}

25 **The speed, direction, and depth of any transition will be determined by choices in the**
26 **environmental, technological, economic, socio-cultural and institutional realms (*high confidence*).**
27 Transitions in specific systems can be gradual or can be rapid and disruptive. The pace of a transition
28 can be impeded by ‘lock-in’ generated by existing physical capital, institutions, and social norms. The
29 interaction between politics, economics and power relationships is central to explaining why broad
30 commitments do not always translate to urgent action. At the same time, attention to, and support for,
31 climate policies and low carbon societal transitions has generally increased, as the impacts have become
32 more salient. Both public and private financing and financial structures strongly affect the scale and
33 balance of high and low carbon investments. Societal and behavioural norms, regulations and
34 institutions are essential conditions to accelerate low carbon transitions in multiple sectors, whilst
35 addressing distributional concerns endemic to any major transition. The COVID-19 pandemic has also
36 had far-reaching impacts on the global economic and social system, and recovery will present both
37 challenges and opportunities for climate mitigation. (Box TS.1){ 1.3, Box 1.1, 1.4, 1.8, Chapters 2, 3, 4,
38 5, 15, 17}

39 **Achieving the global transition to a low-carbon, climate-resilient and sustainable world requires**
40 **purposeful and increasingly coordinated planning and decisions at many scales of governance**
41 **including local, subnational, national and global levels (*high confidence*).** Accelerating mitigation
42 globally would imply strengthening policies adopted to date, expanding the effort across options,
43 sectors, and countries, and broadening responses to include more diverse actors and societal processes
44 at multiple – including international – levels. The effective governance of climate change entails strong
45 action across multiple jurisdictions and decision-making levels, including regular evaluation and
46 learning. Choices that cause climate change as well as the processes for making and implementing
47 relevant decisions involve a range of non-nation state actors such as cities, businesses, and civil society
48 organisations. At global, national and subnational levels, climate change actions are interwoven with,

1 and embedded in, the context of much broader social, economic and political goals. Therefore, the
2 governance required to address climate change has to navigate power, political, economic, and social
3 dynamics at all levels of decision making. Effective climate-governing institutions, and openness to
4 experimentation on a variety of institutional arrangements, policies and programmes can play a vital
5 role in engaging stakeholders and building momentum for effective climate action. {1.4, 1.9, Chapters
6 8, 13, 15, 17}

7 **GHG emissions continued to rise to 2019, although the growth of global GHG emissions has**
8 **slowed over the past decade (*high confidence*)**. Delivering the updated Nationally Determined
9 Contributions (NDCs) to 2030 would turn this into decline, but the implied global emissions by 2030,
10 still exceed pathways consistent with 1.5°C by a large margin and are near the upper end of the range
11 of modelled pathways that *likely* limit warming to 2°C or below. In all chapters of this report there is
12 evidence of progress towards deeper mitigation, but there remain many obstacles to be overcome. Table
13 TS.1 summarises some of the key signs of progress in emission trends, sectors, policies and investment,
14 as well as the challenges that persist.

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1 **Table TS.1: Signs of Progress and Continuing Challenges**

Signs of progress	Continuing challenges
<i>Emissions trends</i>	
<p>The rate of global GHG emissions growth has slowed in recent years, from 2.1% per year between 2000 and 2009, to 1.3% per year in between 2010 and 2019. (TS.3) {2.2}</p>	<p>GHG emissions have continued to grow at high absolute rates. Emissions increased by 8.9 GtCO₂eq from 2000-2009 and by 6.5 GtCO₂eq 2010-2019, reaching 59 GtCO₂eq in 2019. (TS.3) {2.2}</p>
<p>At least 24 countries have reduced both territorial carbon dioxide (CO₂) and GHG emissions and consumption-based CO₂ emissions in absolute terms for at least 10 years, including consumption-based CO₂ emissions. Of these, six are Western and Northern European countries that started reducing in the 1970s, six are former Eastern Bloc countries with consistent reductions since the 1990s, and 12 more have reduced since the mid-2000s. Some have done so at rapid sustained CO₂ reduction rates of 4% per year. (TS.3) {2.2}</p>	<p>The combined emissions reductions of these 24 countries were outweighed by rapid emissions growth elsewhere, particularly among developing countries that have grown from a much lower base of per capita emissions. Uncertainties in emissions levels and changes over time prevents a precise assessment of reductions in some cases. The per capita emissions of developed countries remain high, particularly in Australia, Canada, and the United States. {2.2}</p>
<p>Lockdown policies in response to COVID-19 led to an estimated global drop of 5.8% in CO₂ emissions in 2020 relative to 2019. Energy demand reduction occurred across sectors, except in residential buildings due to teleworking and homeschooling. The transport sector was particularly impacted and international aviation emissions declined by 45%. (Box TS.1) {2.2}</p>	<p>Atmospheric CO₂ concentrations continued to rise in 2020 and emissions have already rebounded as lockdown policies are eased. Economic recovery packages currently include support for fossil fuel industries. (Box TS.1; Box TS.8)</p>
<i>Sectors</i>	
<p>Multiple low-carbon electricity generation and storage technologies have made rapid progress: costs have reduced, deployment has scaled up, and performance has improved. These include solar photovoltaics (PV), onshore and offshore wind, and batteries. In many contexts solar PV and onshore wind power are now competitive with fossil-based generation. (TS.3) {2.5, 6.3}</p>	<p>Although deployment is increasing rapidly, low-carbon electricity generation deployment levels and rates are currently insufficient to meet stringent climate goals. The combined market share of solar PV and wind generation technologies are still below 10%. Global low-carbon electricity generation will have to reach 100% by 2050, which is challenged by the continuous global increase in electricity demand. The contribution of biomass has absolute limits. (TS.5, 2.5)</p>
<p>The rate of emissions growth from coal slowed since 2010 as coal power plants were retired in the United States and Europe, fewer new plants were added in China,</p>	<p>Global coal emissions may not have peaked yet, and a few countries and international development banks continue to fund and develop new coal capacity,</p>

Signs of progress	Continuing challenges
and a large number of planned global plants were scrapped or converted to co-firing with biomass. (TS.3) {2.7, 6.3}	especially abroad. The lifetime emissions of current fossil-based energy infrastructures may already exceed the remaining carbon budget for keeping warming below 1.5°C. (TS.3) {2.2; 2.7, 6.7}
<p>Deforestation has declined since 2010 and net forest cover increased. Government initiatives and international moratoria were successful in reducing deforestation in the Amazon between 2004 and 2015, while regrowth and regeneration occurred in Europe, Eurasia and North America. (TS.5.6.1) {7.3.1}</p>	<p>The long-term maintenance of low deforestation rates is challenging. Deforestation in the Amazon has risen again over the past four years. Other parts of the world also face steady, or rapidly increasing, deforestation. {7.3.1}</p>
<p>Electrification of public transport services is demonstrated as a feasible, scalable and affordable mitigation option to decarbonise mass transportation. Electric vehicles (e-vehicles) are the fastest growing segment of the automobile industry, having achieved double-digit market share by 2020 in many countries. When charged with low-carbon electricity, these vehicles can significantly reduce emissions. {10.4}</p>	<p>Transport emissions have remained roughly constant, growing at an average of 2% per annum between 2010-2019 due to the persistence of high travel demand, heavier vehicles, low efficiencies, and car-centric development. The full decarbonisation of e-vehicles requires that they are charged with zero-carbon electricity, and that car production, shipping, aviation and supply chains are decarbonized. (TS.3) {2.4}</p>
<p>There has been a significant global transition from coal and biomass use in buildings towards modern energy carriers and efficient conversion technologies. This led to efficiency improvements and some emissions reductions in developed countries, as well as significant gains in health and well-being outcomes in developing regions. Nearly Zero Energy (NZE) Buildings or low-energy Buildings are achievable in all regions and climate zones for both new and existing buildings. {9.3; 9.8}</p>	<p>There is a significant lock-in risk in all regions given the long lifespans of buildings and the low ambition of building policies. This is the case for both existing buildings in developed countries, and also for new buildings in developing countries that are also challenged by the lack of technical capacity and effective governance. Emissions reductions in developed countries have been outweighed by the increase in population growth, floor area per capita and the demand for electricity and heat. {9.9; 9.3}</p>
<p>The decarbonisation of most industrial processes has been demonstrated using technologies that include electricity and hydrogen for energy and feedstocks, carbon capture and utilisation technologies, and innovation in circular material flows. (TS.5.5) {11.2}</p>	<p>Industry emissions continue to increase, driven by a strong global demand for basic materials. Without reductions in material demand growth and a very rapid scale-up of low-carbon innovations, the long lifetimes of industrial capital stock risks locking-in emissions for decades to come. (TS.5.5) {11.2}</p>
<i>Policies and investment</i>	

Signs of progress	Continuing challenges
<p>The Paris Agreement established a new global policy architecture to meet stringent climate goals, while avoiding many areas of deadlock that had arisen in trying to extend the Kyoto Protocol. (TS 6.3)</p>	<p>Current national pledges under the Paris Agreement³ are insufficient to limit warming to 1.5°C with no or limited overshoot, and would require an abrupt acceleration of mitigation efforts after 2030 to likely limit warming to 2°C. (TS 6.3)</p>
<p>Most wealthy countries, and a growing list of developing countries, have signaled an intention to achieve net zero GHG (or net zero CO₂) emissions by mid-century. National economy-wide GHG emissions targets covered 90% of global emissions in 2020 compared to 49% in 2010. Direct and indirect climate legislation has also steadily increased and this is supported by a growing list of financial investors. (TS.6.2)</p>	<p>Many net zero targets are ambiguously defined, and the policies needed to achieve them are not yet in place. Opposition from status quo interests, as well as insufficient low-carbon financial flows, act as barriers to establishing and implementing stringent climate policies covering all sectors. (Box TS.6) {13.4}</p>
<p>The global coverage of mandatory policies – pricing and regulation – has increased, and sectoral coverage of mitigation policies has expanded. Emission trading and carbon taxes now cover over 20% of global CO₂ emissions (TS 6). Allowance prices as of April 1, 2021 ranged from just over USD1 to USD50, covering between 9 and 80% of a jurisdiction’s emissions {13.6.3}. Many countries have introduced sectoral regulations that block new investment in fossil fuel technologies.</p>	<p>There is incomplete global policy coverage of non-CO₂ gases, CO₂ from industrial processes, and emissions outside the energy sector. Few of the world’s carbon prices are at a level consistent with various estimates of the carbon price needed to limit warming to 2°C or 1.5°C {13.6}</p>
<p>There has been a marked increase in civic and private engagement with climate governance. This includes business measures to limit emissions, invest in reforestation and develop carbon-neutral value chains such as using wood for construction. There is an upsurge in climate activism, and growing engagement of groups such as labour unions {1.3.3, 5.2.3}. The media coverage of climate change has also grown steadily across platforms and has generally become more accurate over time. (TS 6.2)</p>	<p>There is no conclusive evidence that an increase in engagement results in overall pro-mitigation outcomes. A broad group of actors influence how climate governance develop over time, including a range of civic organisations, encompassing both pro-and anti-climate action groups. Accurate transference of the climate science has been undermined significantly by climate change counter-movements, in both legacy and new/social media environments through misinformation. (TS 6.2)</p>

1

FOOTNOTE ³ Current NDCs refer to nationally determined contributions submitted to the UNFCCC, as well as publicly announced but not yet submitted mitigation pledges with sufficient detail on targets, reflected in studies published up to 11 October 2021. Revised NDCs submitted or announced after 11 October 2021 are not included. Intended nationally determined contributions (INDCs) were converted to NDCs as countries ratified the Paris Agreement. Original INDCs and NDCs refer to those submitted to the UNFCCC in 2015 and 2016

1 **TS. 3 Emission trends and drivers**

2 **Global net anthropogenic GHG emissions during the decade (2010-2019) were higher than any**
3 **previous time in human history (*high confidence*).** Since 2010, GHG emissions have continued to
4 grow reaching 59 ± 6.6 GtCO₂-eq in 2019,⁴ but the average annual growth in the last decade (1.3%,
5 2010-2019) was lower than in the previous decade (2.1%, 2000-2009) (*high confidence*). Average
6 annual GHG emissions were 56 GtCO₂-eq yr⁻¹ for 2010-2019 (the highest decadal average on record)
7 growing by about 9.1 GtCO₂-eq yr⁻¹ from the previous decade (2000-2009) (*high confidence*). (Figure
8 TS.2) {2.2.2, Table 2.1, Figure 2.5}

9 **Emissions growth has varied, but has persisted, across all groups of greenhouse gases (*high***
10 ***confidence*).** The average annual emission levels of the last decade (2010-2019) were higher than in
11 any previous decade for each group of greenhouse gases (*high confidence*). In 2019, CO₂ emissions
12 were 45 ± 5.5 GtCO₂,⁵ methane (CH₄) 11 ± 3.2 GtCO₂-eq, nitrous oxide (N₂O) 2.7 ± 1.6 GtCO₂-eq and
13 fluorinated gases (F-gases⁶) 1.4 ± 0.41 GtCO₂-eq. Compared to 1990, the magnitude and speed of these
14 increases differed across gases: CO₂ from fossil fuel and industry (FFI) grew by 15 GtCO₂-eq yr⁻¹
15 (67%), CH₄ by 2.4 GtCO₂-eq yr⁻¹ (29%), F-gases by 0.97 GtCO₂-eq yr⁻¹ (250%), N₂O by 0.65 GtCO₂-
16 eq yr⁻¹ (33%). CO₂ emissions from net land use, land-use change and forestry (LULUCF) have shown
17 little long-term change, with large uncertainties preventing the detection of statistically significant
18 trends. F-gases excluded from GHG emissions inventories such as *chlorofluorocarbons* and
19 *hydrochlorofluorocarbons* are about the same size as those included (*high confidence*). (Figure TS.2)
20 {2.2.1, 2.2.2, Table 2.1, Figure 2.2, Figure 2.3, Figure 2.5}

21 **Globally, Gross Domestic Product (GDP) per capita and population growth remained the**
22 **strongest drivers of CO₂ emissions from fossil fuel combustion in the last decade (*high confidence*).**
23 Trends since 1990 continued in the years 2010 to 2019 with GDP per capita and population growth
24 increasing emissions by 2.3% and 1.2% yr⁻¹, respectively. This growth outpaced the reduction in the
25 use of energy per unit of GDP (-2% yr⁻¹, globally) as well as improvements in the carbon intensity of
26 energy (-0.3% yr⁻¹). {2.4.1, Figure 2.19}

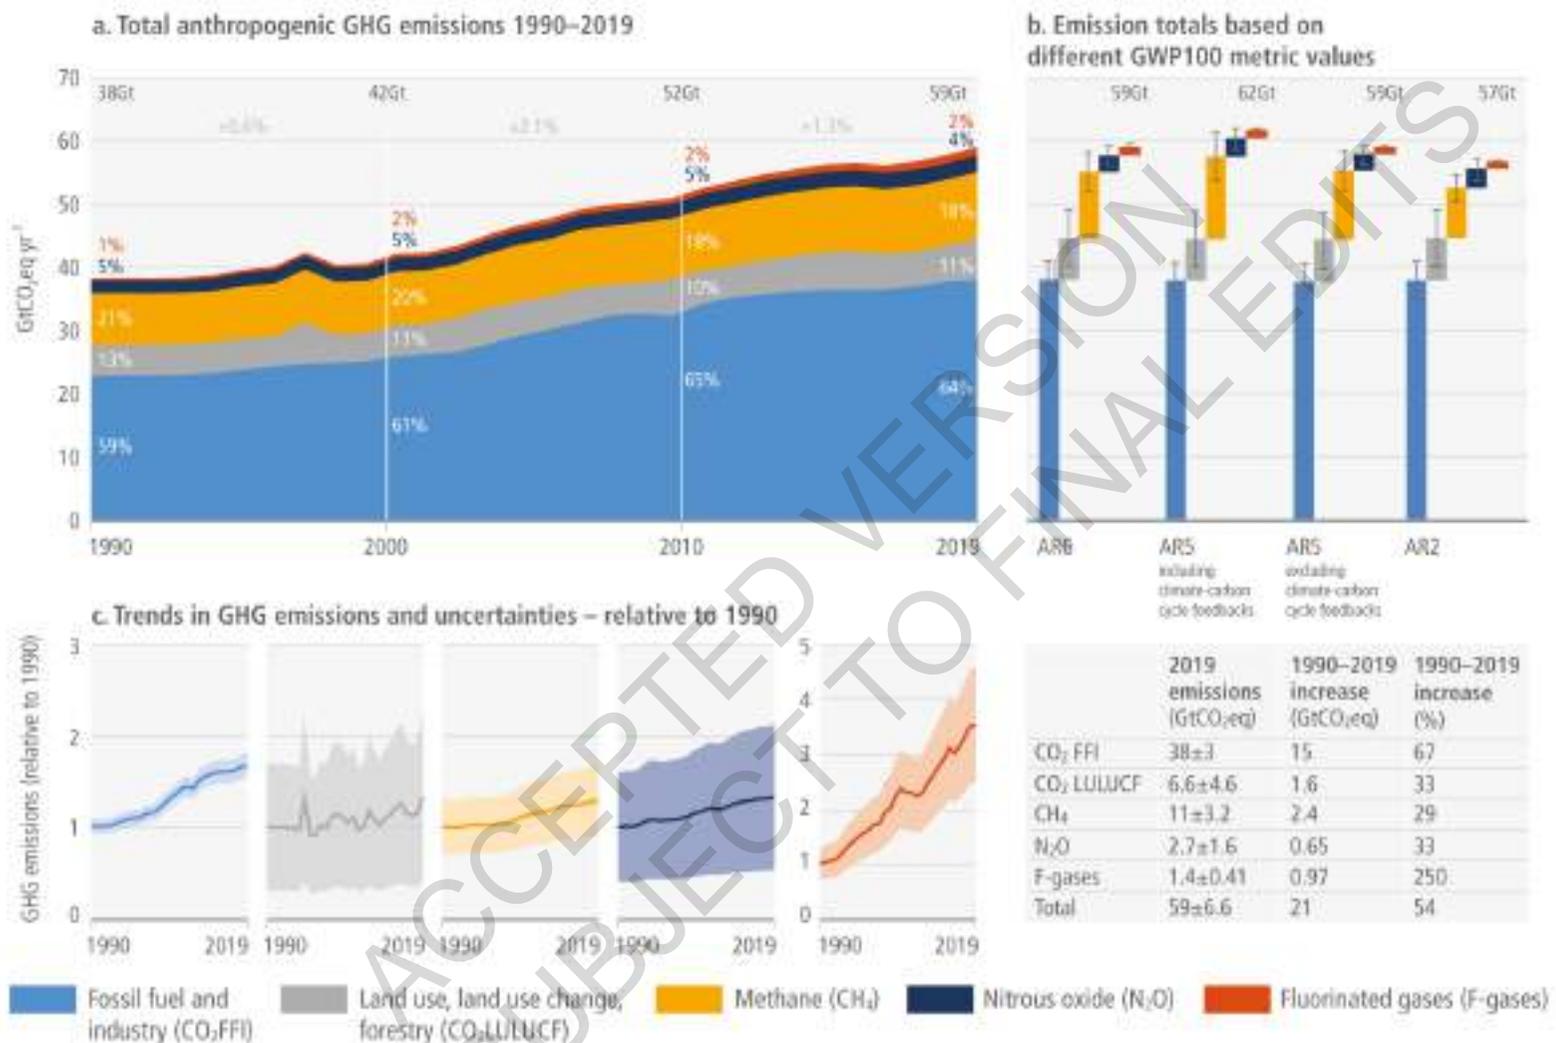

27

FOOTNOTE ⁴ Emissions of GHGs are weighed by Global Warming Potentials with a 100 year time horizon (GWP100) from the Sixth Assessment Report. GWP100 is commonly used in wide parts of the literature on climate change mitigation and is required for reporting emissions under the United Nations Framework Convention on Climate Change (UNFCCC). All metrics have limitations and uncertainties. {Cross-Chapter Box 2, Annex II Part II Section 8}

FOOTNOTE ⁵ In 2019, CO₂ from fossil fuel and industry (FFI) were 38 ± 3.0 Gt, CO₂ from net land use, land-use change and forestry (LULUCF) 6.6 ± 4.6 Gt.

FOOTNOTE ⁶ Fluorinated gases, also known as 'F-gases', include: hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulphur hexafluoride (SF₆), nitrogen trifluoride (NF₃).

1

2

3

Figure TS.2: Global anthropogenic emissions have continued to rise across all major groups of greenhouse gases (GtCO₂-eq yr⁻¹) 1990-2019

1 **Figure TS.2 Legend:** Total anthropogenic GHG emissions include CO₂ from fossil fuel combustion and
2 industrial processes (CO₂-FFI); CO₂ from Land use, land use change and forestry (CO₂-LULUCF); methane
3 (CH₄); nitrous oxide (N₂O); fluorinated gases (F-gases: HFCs; PFCs, SF₆, NF₃). CO₂-LULUCF emissions
4 include gross removals as well as emissions. F-gas emissions do not include some important species covered by
5 the Montreal Protocol such as (chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs).

6 Panel a: Aggregate GHG emission trends by groups of gases reported in GtCO₂-eq converted based on global
7 warming potentials with a 100-year time horizon (GWP100) from the IPCC Sixth Assessment Report Working
8 Group I (Chapter 7).

9 Panel b: GHG emissions for the year 2019 in Gt of CO₂-eq units using GWP100 values from the IPCC's Sixth,
10 Fifth and Second Assessment Reports, respectively. Error bars show emissions uncertainties at a 90%
11 confidence interval.

12 Panel c: Individual trends in CO₂-FFI, CO₂-LULUCF, CH₄, N₂O and F-gas emissions for the period 1990–2019,
13 normalised relative to 1 in 1990. Note the different scale for F-gas emissions compared to other gases,
14 highlighting its rapid growth from a low base. The table shows absolute emissions in 2019 as well as emissions
15 growth between 1990 and 2019, expressed as absolute change in CO₂-eq and as percentage change relative to
16 1990. Note that these changes therefore include interannual variability for these individual years as well as
17 longer term trends. {2.2, Figure 2.5}

19 START BOX TS.1 HERE

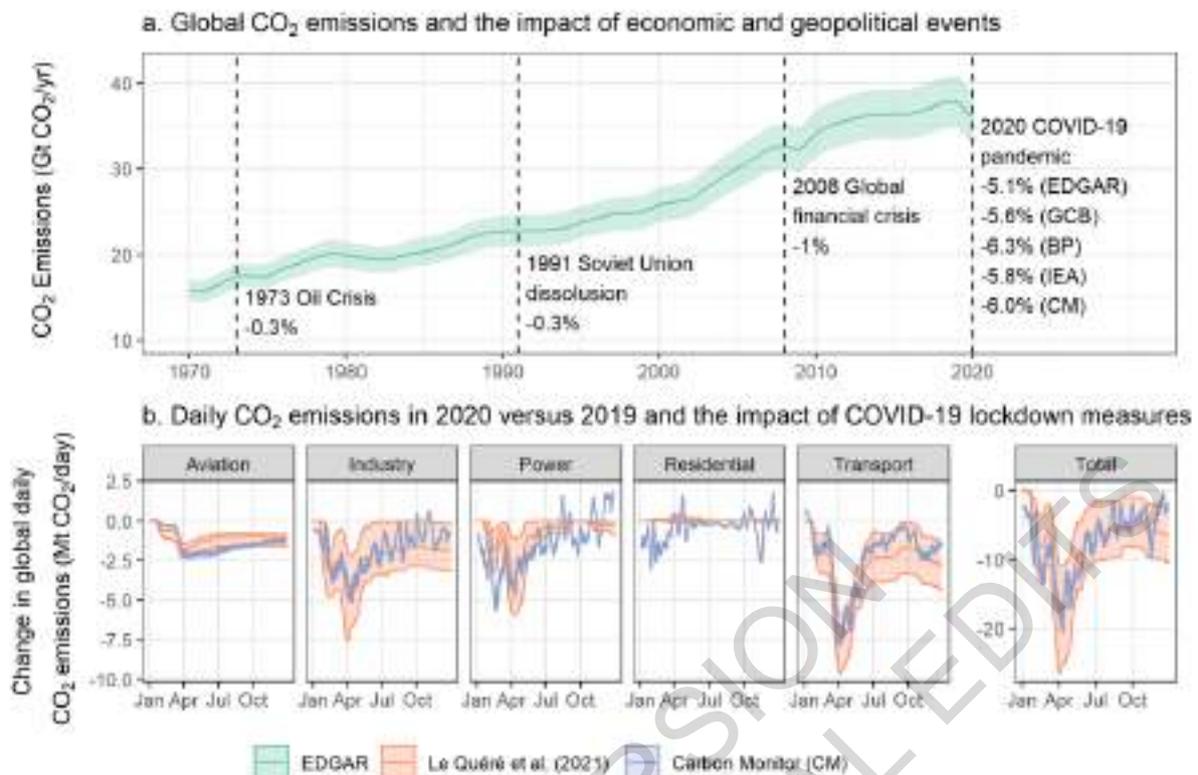

20 **Box TS.1: The COVID-19 pandemic: Impact on emissions and opportunities for mitigation**

21 The COVID-19 pandemic triggered the deepest global economic contraction as well as CO₂ emission
22 reductions since the Second World War {2.2.2}. While emissions and most economies rebounded in
23 2020, some impacts of the pandemic could last well beyond this. Owing to the very recent nature of this
24 event, it remains unclear what the exact short and long-term impacts on global emissions drivers, trends,
25 macroeconomics and finance will be.

26 Starting in the spring of 2020 a major break in global emissions trends was observed due to lockdown
27 policies implemented in response to the pandemic. Overall, global CO₂-FFI emissions are estimated to
28 have declined by 5.8% (5.1%-6.3%) in 2020, or about 2.2 (1.9-2.4) GtCO₂ in total. This exceeds any
29 previous global emissions decline since 1970 both in relative and absolute terms (Box TS.1 Figure 1).
30 During periods of economic lockdown, daily emissions, estimated based on activity and power-
31 generation data, declined substantially compared to 2019, particularly in April 2020 –as shown in Box
32 TS.1 Figure 1 – but rebounded by the end of 2020. Impacts were differentiated by sector, with road
33 transport and aviation particularly affected. Different databases estimate the total power sector CO₂
34 reduction from 2019 to 2020 at 3% (IEA⁷) and 4.5% (EDGAR⁸). Approaches that predict near real-time
35 estimates of the power sector reduction are more uncertain and estimates range more widely between
36 1.8%, 4.1% and 6.8%, the latter taking into account the over-proportional reduction of coal generation
37 due to low gas prices and merit order effects.

FOOTNOTE ⁷ IEA: International Energy Agency

FOOTNOTE ⁸ EDGAR: Emissions Database for Global Atmospheric Research

1

2

Box TS.1 Figure 1: Global carbon emissions in 2020 and the impact of COVID-19

3

4

5

6

7

Box TS.1 Figure 1 legend: Panel a depicts carbon emissions from fossil fuel and industry over the past five decades. The single year declines in emissions following major economic and geopolitical events are shown, as well as the decline recorded in five different datasets for emissions in 2020 compared to 2019. Panel b depicts the perturbation of daily carbon emissions in 2020 compared to 2019, showing the impact of COVID-19 lockdown policies. {Figure 2.6}

8

9

10

11

12

The lockdowns implemented in many countries accelerated some specific trends, such as the uptake in urban cycling. The acceptability of collective social change over a longer term towards less resource-intensive lifestyles, however, depends on the social mandate for change. This mandate can be built through public participation, discussion and debate, to produce recommendations that inform policymaking. {Box 5.2}

13

14

15

16

17

Most countries were forced to undertake unprecedented levels of short-term public expenditures in 2021. This is expected to slow economic growth and may squeeze financial resources for mitigation and relevant investments in the near future. Pandemic responses have increased sovereign debt across countries in all income bands and the sharp increase in most developing economies and regions has caused debt distress, widening the gap in developing countries' access to capital. {15.6.3}

18

19

20

21

22

23

The wider overall reduction in energy investment has prompted a relative shift towards low carbon investment particularly for major future investment decisions by the private sector {15.2.1, 15.3.1, 15.6.1}. Some countries and regions have prioritised green stimulus expenditures for example as part of a 'Green New Deal' {Box 13.1}. This is motivated by assessments that investing in new growth industries can boost the macroeconomic effectiveness ('multipliers') of public spending, crowd-in and revive private investment, whilst also delivering on mitigation commitments. {15.2.3}

24

25

26

The impacts of COVID-19 may have temporarily set back development and the delivery of many SDGs. It also distracts political and financial capacity away from efforts to accelerate climate change mitigation and shift development pathways to increased sustainability. Yet, studies of previous post-

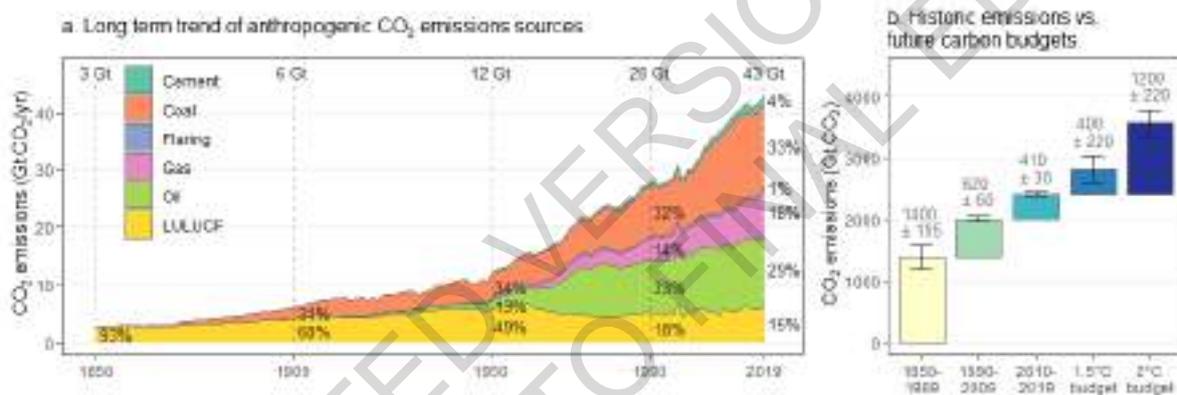

1 shock periods suggest that waves of innovation that are ready to emerge can be accelerated by crises,
2 which may prompt new behaviours, weaken incumbent systems, and initiate rapid reform. {1.6.5}

3 Institutional change can be slow but major economic dislocation can create significant opportunities for
4 new ways of financing and enabling ‘leapfrogging’ investment {10.8}. Given the unambiguous risks of
5 climate change, and consequent stranded asset risks from new fossil fuel investments {Box 6.11}, the
6 most robust recoveries may well be those which align with lower carbon and resilient development
7 pathways.

8 **END BOX TS.1 HERE**

9

10 **Cumulative net CO₂ emissions over the last decade (2010-2019) are about the same size as the**
11 **remaining carbon budget likely to limit warming to 1.5°C (medium confidence).** 62% of total
12 cumulative CO₂ emissions from 1850 to 2019 occurred since 1970 (1500±140 GtCO₂), about 43% since
13 1990 (1000±90 GtCO₂), and about 17% since 2010 (410±30 GtCO₂). For comparison, the remaining
14 carbon budget for keeping warming to 1.5°C with a 67% (50%) probability is about 400 (500) ±220
15 GtCO₂ (Figure TS.3). {2.2.2, Figure 2.7, WG I Chapter 5.5, WG I Chapter 5 Table 5.8}

16

17 **Figure TS.3: Historic anthropogenic CO₂ emission and cumulative CO₂ emissions (1850-2019) as well as**
18 **remaining carbon budgets for likely limiting warming to 1.5°C and 2°C**

19 **Figure TS.3 legend:** Panel a shows historic annual anthropogenic CO₂ emissions (GtCO₂ yr⁻¹) by fuel type and
20 process. Panel b shows historic cumulative anthropogenic CO₂ emissions for the periods 1850-1989, 1990-2009,
21 and 2010-2019 as well as remaining future carbon budgets as of 1 January 2020 to limit warming to 1.5°C and
22 2°C at the 67th percentile of the transient climate response to cumulative CO₂ emissions. The whiskers indicate
23 a budget uncertainty of ±220 GtCO₂-eq for each budget and the aggregate uncertainty range at one standard
24 deviation for historical cumulative CO₂ emissions, consistent with Working Group I. {Figure 2.7}

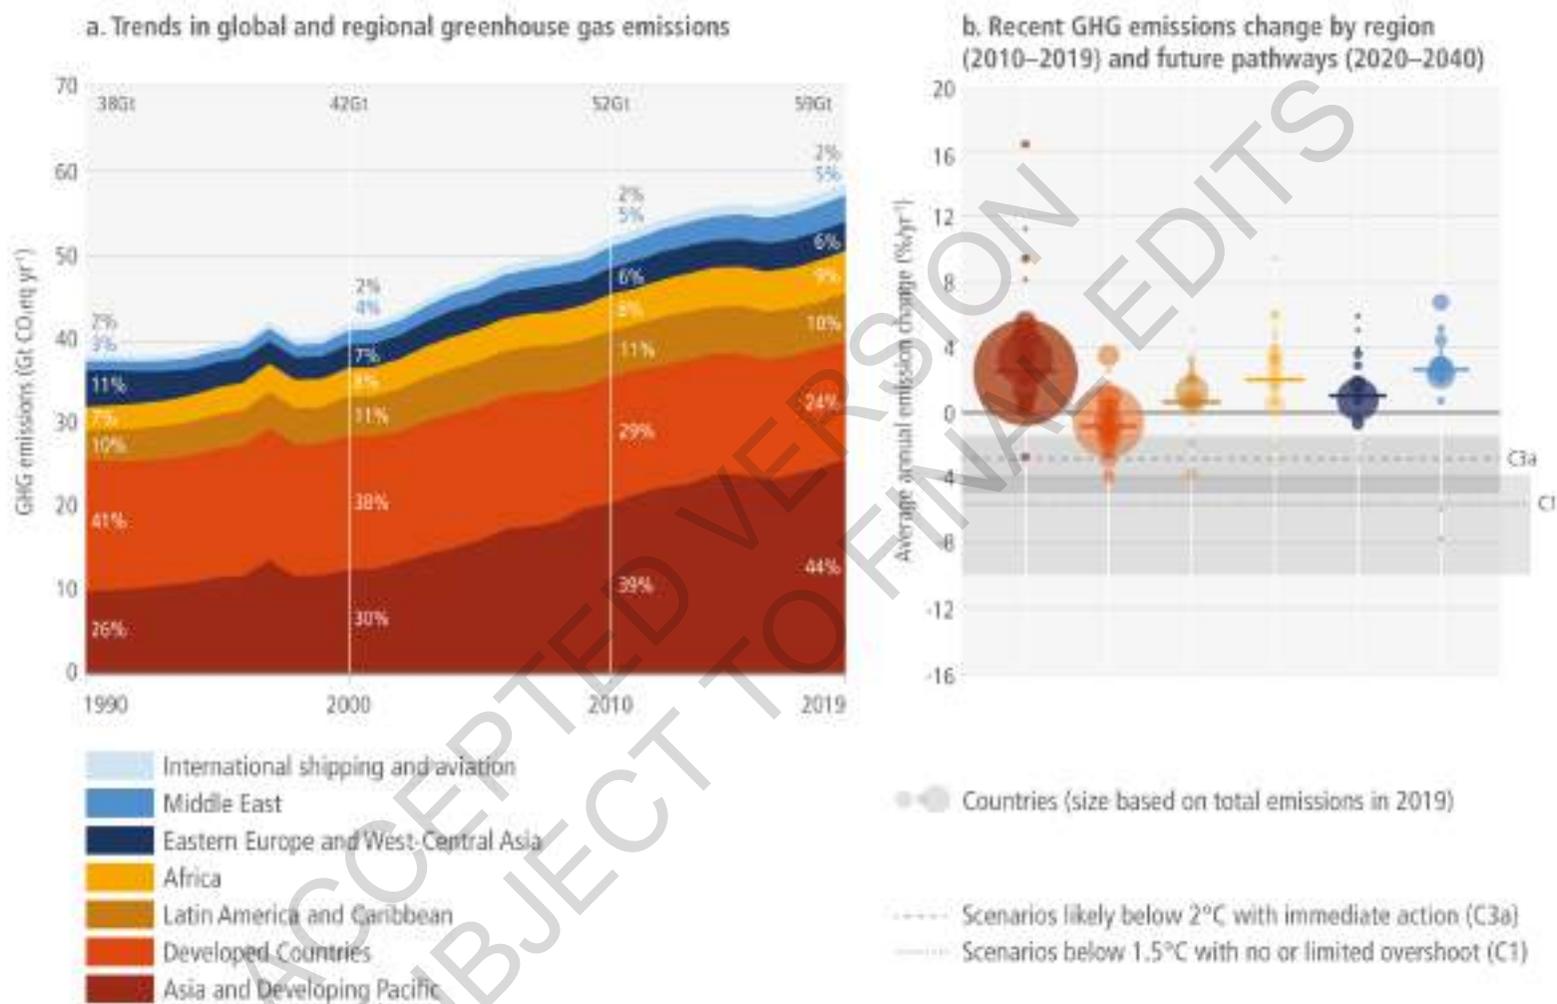

25

26 **A growing number of countries have achieved GHG emission reductions over periods longer than**
27 **10 years – a few at rates that are broadly consistent with the global rates described in climate**
28 **change mitigation scenarios that likely to limit warming to 2°C (high confidence).** At least 24
29 countries have reduced CO₂ and GHG emissions for longer than 10 years. Reduction rates in a few
30 countries have reached 4% in some years, in line with global rates observed in pathways that likely limit
31 warming to 2°C. However, the total reduction in annual GHG emissions of these countries is small
32 (about 3.2 GtCO₂-eq yr⁻¹) compared to global emissions growth observed over the last decades.
33 Complementary evidence suggests that countries have decoupled territorial CO₂ emissions from GDP,
34 but fewer have decoupled consumption-based emissions from GDP. Decoupling has mostly occurred

- 1 in countries with high per capita GDP and high per capita CO₂ emissions. (Figure TS.4, Box TS.2)
- 2 {2.2.3, 2.3.3, Figure 2.11, Table 2.3, Table 2.4}

Figure TS.4: Emissions have grown in most regions, although some countries have achieved sustained emission reductions in line with 2°C scenarios

1

2 **Figure TS.4 legend:** Change in regional GHG emissions and rates of change compatible with warming targets.

3 Panel a: Regional GHG emission trends (in GtCO₂-eq yr⁻¹ (GWP100 AR6)) for the time period 1990–2019.

4 Panel b: Historical GHG emissions change by region (2010–2019). Circles depict countries, scaled by total
5 emissions in 2019, short horizontal lines depict the average change by region. Also shown are global rates of
6 reduction over the period 2020–2040 in scenarios assessed in the AR6 that limit global warming to 1.5°C and
7 2°C with different probabilities. The 5th–95th percentile range of emissions changes for scenarios below 1.5°C
8 with no or limited overshoot (scenario category C1) and scenarios *likely* below 2°C with immediate action
9 (scenario category C3a) are shown as a shaded area with a horizontal line at the mean value. Panel b excludes
10 CO₂ LULUCF due to a lack of consistent historical national data, and International Shipping and Aviation,
11 which cannot be allocated to regions. Global rates of reduction in scenarios are shown for illustrative purposes
12 only and do not suggest rates of reduction at the regional or national level. {Figure 2.9, Figure 2.11}

13

14 **START BOX TS.2 HERE**

15 **Box TS.2: GHG emission metrics provide simplified information about the effects of different** 16 **greenhouse gases**

17 Comprehensive mitigation policy relies on consideration of all anthropogenic forcing agents, which
18 differ widely in their atmospheric lifetimes and impacts on the climate system. GHG emission metrics
19 provide simplified information about the effect that emissions of different gases have on global
20 temperature or other aspects of climate, usually expressed relative to the effect of emitting CO₂[‡]. This
21 information can support choices about priorities, trade-offs and synergies in mitigation policies and
22 emission targets for non-CO₂ gases relative to CO₂ as well as baskets of gases expressed in CO₂-eq.

23 The choice of metric can affect the timing and emphasis placed on reducing emissions of Short-Lived
24 Climate Forcers (SLCFs) relative to CO₂ within multi-gas abatement strategies as well as the costs of
25 such strategies. Different metric choices can also alter the time at which net zero GHG emissions are
26 calculated to be reached for any given emissions scenario. A wide range of GHG emission metrics has
27 been published in the scientific literature, which differ in terms of: (i) the key measure of climate change
28 they consider, (ii) whether they consider climate outcomes for a specified point in time or integrated
29 over a specified time horizon, (iii) the time horizon over which the metric is applied, (iv) whether they
30 apply to a single emission pulse, to emissions sustained over a period of time, or to a combination of
31 both, and (v) whether they consider the climate effect from an emission compared to the absence of that
32 emission, or compared to a reference emissions level or climate state {Annex I}.

33 Parties to the Paris Agreement decided to report aggregated emissions and removals (expressed as CO₂-
34 eq) based on the Global Warming Potential with a time horizon of 100 years (GWP100) using values
35 from IPCC AR5 or from a subsequent IPCC report as agreed upon by the CMA[†], and to account for
36 future nationally determined contributions (NDCs) in accordance with this approach. Parties may also
37 report supplemental information on aggregate emissions and removals, expressed as CO₂-eq, using
38 other GHG emission metrics assessed by the IPCC.

39 The WG III contribution to AR6 uses updated GWP100 values from AR6 WG I to report aggregate
40 emissions and removals unless stated otherwise. These reflect updated scientific understanding of the
41 response of the climate system to emissions of different gases and include a methodological update to
42 incorporate climate-carbon cycle feedbacks associated with the emission of non-CO₂ gases (see Annex
43 II Part II Section 8 for a list of GWP100 metric values). The choice of GWP100 was made inter alia for
44 consistency with decisions under the Rulebook for the Paris Agreement and because it is the dominant
45 metric used in the literature assessed by WG III. Furthermore, for mitigation pathways that *likely* limit
46 global warming to 2°C or lower, using GWP100 to inform cost-effective abatement choices between

1 gases would achieve such long-term temperature goals at close to least global cost within a few percent
2 (*high confidence*).

3 However, GWP100 is not well suited to estimate the cumulative effect on climate from sustained SLCF
4 emissions and the resulting warming at specific points in time. This is because the warming caused by
5 an individual SLCF emission pulse is not permanent, and hence, unlike CO₂, the warming from
6 successive SLCF emission pulses over multiple decades or centuries depends mostly on their ongoing
7 rate of emissions rather than cumulative emissions. Recently developed step/pulse metrics such as the
8 CGTP (Combined Global Temperature Change Potential) and GWP* (referred to as GWP-star and
9 indicated by asterisk) recognise that a sustained increase/decrease in the rate of SLCF emissions has
10 indeed a similar effect on global surface temperature as one-off emission/removal of CO₂. These metrics
11 use this relationship to calculate the CO₂ emissions or removals that would result in roughly the same
12 temperature change as a sustained change in the rate of SLCF emissions (CGTP) over a given time
13 period, or as a varying time series of CH₄ emissions (GWP*). From a mitigation perspective, this makes
14 these metrics well suited in principle to estimate the effect on the remaining carbon budget from more,
15 or less, ambitious SLCF mitigation over multiple decades compared to a given reference scenario (*high*
16 *confidence*). However, potential application in wider climate policy (e.g., to inform equitable and
17 ambitious emission targets or to support sector-specific mitigation policies) is contested and relevant
18 literature still limited.

19 All metrics have limitations and uncertainties, given that they simplify the complexity of the physical
20 climate system and its response to past and future GHG emissions. For this reason, the WG III
21 contribution to the AR6 reports emissions and mitigation options for individual gases where possible;
22 CO₂-equivalent emissions are reported in addition to individual gas emissions where this is judged to
23 be policy-relevant. This approach aims to reduce the ambiguity regarding actual climate outcomes over
24 time arising from the use of any specific GHG emission metric. {Cross-Chapter Box 2 in Chapter 2,
25 Supplementary Material 2.3, Annex II Part II Section 8; WG I Chapter 7.6}

26 † Emission metrics also exist for aerosols, but these are not commonly used in climate policy. This assessment
27 focuses on GHG emission metrics only.

28 ‡ The CMA is the Conference of the Parties serving as the Meeting of the Parties to the Paris Agreement. See
29 18/CMA.1 (Annex, para 37) and 4/CMA.1 (Annex II, para 1) regarding the use of GHG emission metrics in
30 reporting of emissions and removals and accounting for Parties' NDCs.

31 **END BOX TS.2 HERE**

32

33 **Consumption-based CO₂ emissions in developed countries and the Asia and Developing Pacific**
34 **region are higher than in other regions (*high confidence*).** In developed countries, consumption-
35 based CO₂ emissions peaked at 15 GtCO₂ in 2007, declining to about 13 GtCO₂ in 2018. The Asia and
36 Developing Pacific region, with 52% of current global population, has become a major contributor to
37 consumption-based CO₂ emission growth since 2000 (5.5% yr⁻¹ for 2000-2018); in 2015 it exceeded
38 the *developed countries* region, with 16% of global population, as the largest emitter of consumption-
39 based CO₂. {2.3.2, Figure 2.14}

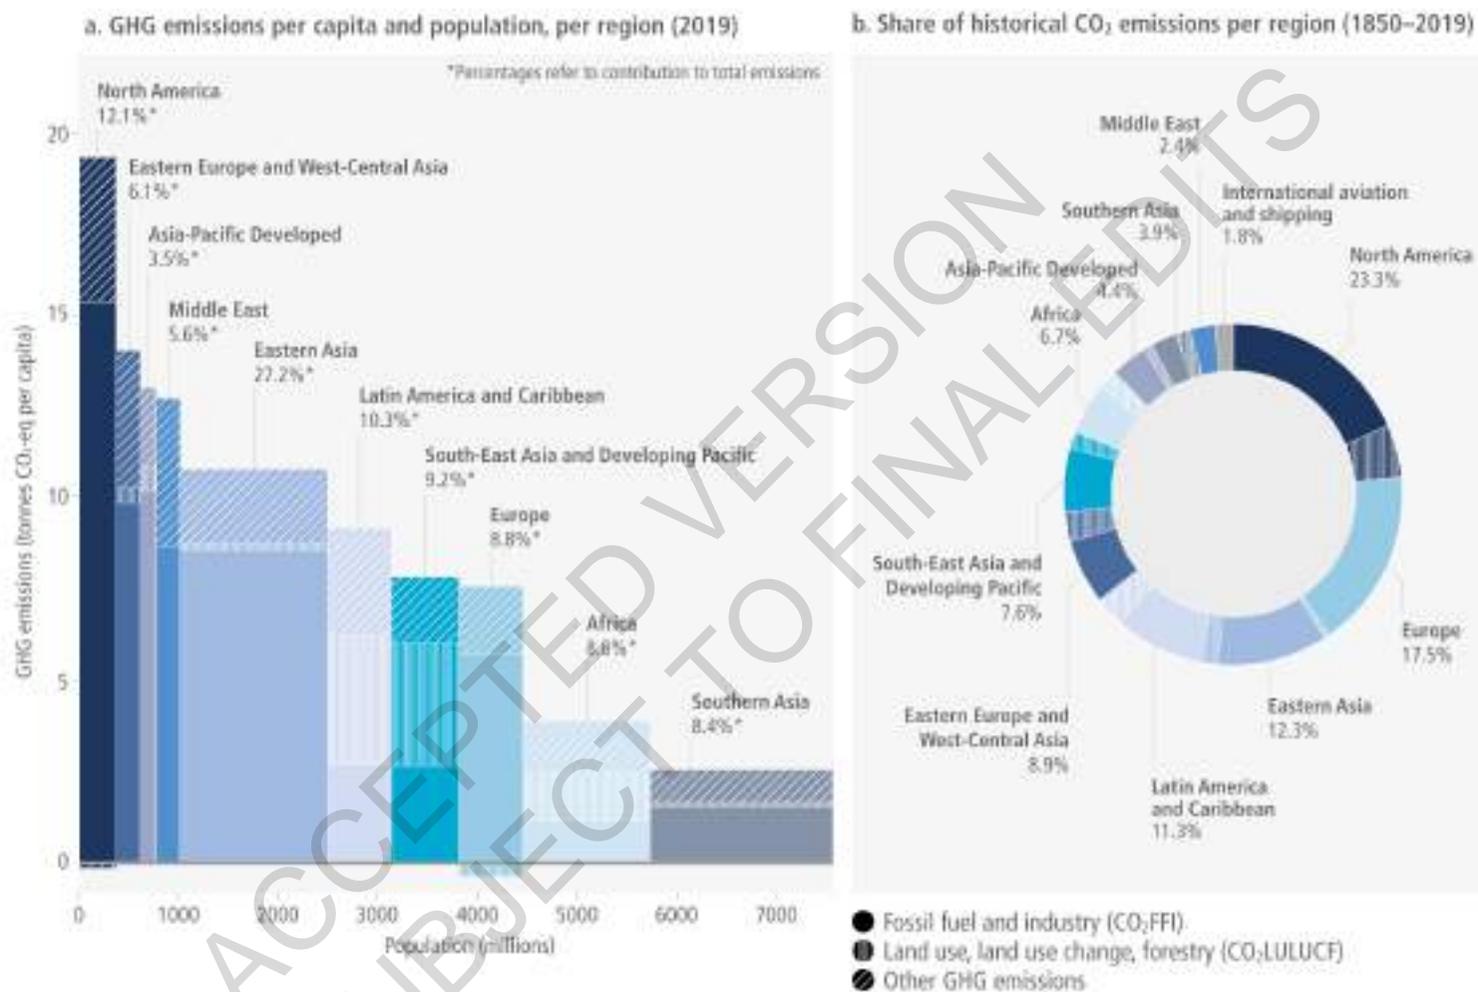

40 **Carbon intensity improvements in the production of traded products has led to a net reduction**
41 **in CO₂ emissions embodied in international trade (*high confidence*).** A decrease in the carbon
42 intensity of traded products has offset increased trade volumes between 2006 and 2016. Emissions
43 embodied in internationally traded products depend on the composition of the global supply chain
44 across sectors and countries and the respective carbon intensity of production processes (emissions per
45 unit of economic output). {2.3, 2.4}

1 **Developed countries tend to be net CO₂ emission importers, whereas developing countries tend**
2 **to be net emission exporters (*high confidence*).** Net CO₂ emission transfers from developing to
3 developed countries via global supply chains have decreased between 2006 and 2016. Between 2004
4 and 2011, CO₂ emission embodied in trade between developing countries have more than doubled (from
5 0.47 to 1.1 Gt) with the centre of trade activities shifting from Europe to Asia. {2.3.4, Figure 2.15}

6 **Territorial emissions from developing country regions continue to grow, mostly driven by**
7 **increased consumption and investment, albeit starting from a low base of per capita emissions**
8 **and with a lower historic contribution to cumulative emissions than developed countries (*high***
9 ***confidence*).** Average 2019 per capita CO₂-FFI emissions in three developing regions Africa (1.2
10 tCO₂), Asia and developing Pacific (4.4 tCO₂), and Latin America and Caribbean (2.7 tCO₂) remained
11 less than half of Developed Countries 2019 CO₂-FFI emissions (9.5 tCO₂). In these three developing
12 regions together, CO₂-FFI emissions grew by 26% between 2010 and 2019 (compared to 260% between
13 1990 and 2010). In contrast, in Developed Countries emissions contracted by 9.9% between 2010-2019
14 and by 9.6% between 1990-2010. Historically, these three developing regions together contributed 28%
15 to cumulative CO₂-FFI emissions between 1850 and 2019, whereas Developed Countries contributed
16 57%, and least developed countries contributed 0.4%. (Figure TS.5) {2.2, Figure 2.9, Figure 2.10}

17 **Globally, households with income in the top 10% contribute about 36-45% of global GHG**
18 **emissions (*robust evidence, medium agreement*).** About two thirds of the top 10% live in developed
19 countries and one third in other economies. The lifestyle consumption emissions of the middle income
20 and poorest citizens in emerging economies are between 5-50 times below their counterparts in high-
21 income countries (*medium confidence*). Increasing inequality within a country can exacerbate dilemmas
22 of redistribution and social cohesion and affect the willingness of the rich and poor to accept policies
23 to protect the environment, and to accept and afford lifestyle changes that favour mitigation (*medium*
24 *confidence*). {2.6.1, 2.6.2, Figure 2.29}

1

2

3

Figure TS.5: Global emissions are distributed unevenly, both in the present day and cumulatively since 1850

1 **Figure TS.5 legend:** Panel a shows the distribution of regional GHG emissions in tonnes CO₂-eq per
 2 capita by region in 2019. GHG emissions are categorised into: CO₂ Fossil fuel and industry (CO₂-FFI), CO₂
 3 Land use, land use change, forestry (CO₂-LULUCF) and other GHG emissions (CH₄, nitrous oxide, F-gas,
 4 expressed in CO₂-eq using GWP100). The height of each rectangle shows per-capita emissions, the width shows
 5 the population of the region, so that the area of the rectangles refers to the total emissions for each
 6 regional. Percentages refer to overall GHG contributions to total global emissions in 2019. Emissions from
 7 international aviation and shipping are not included.
 8 Panel b shows the share of historical net CO₂ emissions per region from 1850 to 2019. This includes CO₂-FFI
 9 and CO₂-LULUCF (GtCO₂). Other GHG emissions are not included. Emissions from international aviation and
 10 shipping are included. {1.3, Figure 1.2a, 2.2, Figure 2.10}

12 **Globally, GHG emissions continued to rise across all sectors and subsectors, and most rapidly in**
 13 **transport and industry (*high confidence*).** In 2019, 34% (20 GtCO₂-eq) of global GHG emissions
 14 came from the energy sector, 24% (14 GtCO₂-eq) from industry, 22% (13 GtCO₂-eq) from agriculture,
 15 forestry and other land use (AFOLU), 15% (8.7 GtCO₂-eq) from transport, and 5.6% (3.3 GtCO₂-eq)
 16 from buildings. Once indirect emissions from energy use are considered, the relative shares of industry
 17 and buildings emissions rise to 34% and 17%, respectively. Average annual GHG emissions growth
 18 during 2010-2019 slowed compared to the previous decade in energy supply (from 2.3% to 1.0%) and
 19 industry (from 3.4% to 1.4%, direct emissions only), but remained roughly constant at about 2% per
 20 year in the transport sector (*high confidence*). Emission growth in AFOLU is more uncertain due to the
 21 high share of CO₂-LULUCF emissions. (Figure TS.8) {2.2.4, Figures 2.13, Figures 2.16-2.21}

22 **There is a discrepancy, equating to 5.5 GtCO₂ yr⁻¹, between alternative methods of accounting for**
 23 **anthropogenic land CO₂ fluxes. Accounting for this discrepancy would assist in assessing**
 24 **collective progress in a global stocktake (*high confidence*).** The principal accounting approaches are
 25 National GHG inventories (NGHGI) and global modelling⁹ approaches. NGHGI, based on IPCC
 26 guidelines, consider a much larger area of forest to be under human management than global models.
 27 NGHGI consider the fluxes due to human-induced environmental change on this area to be
 28 anthropogenic and are thus reported. Global models, in contrast, consider these fluxes to be natural and
 29 are excluded from the total reported anthropogenic land CO₂ flux. The accounting method used will
 30 affect the assessment of collective progress in a global stocktake {Cross-Chapter Box 6 in Chapter 7}
 31 (*medium confidence*). In the absence of these adjustments, allowing a like with like comparison,
 32 collective progress would appear better than it is. {7.2}

33 **This accounting discrepancy also applies to Integrated Assessment Models (IAMs), with the**
 34 **consequence that anthropogenic land CO₂ fluxes reported in IAM pathways cannot be compared**
 35 **directly with those reported in national GHG inventories (*high confidence*).** Methodologies
 36 enabling a more like-for-like comparison between models' and countries' approaches would
 37 support more accurate assessment of the collective progress achieved under the Paris Agreement. {3.4,
 38 7.2.2}

39 **Average annual growth in GHG emissions from energy supply decreased from 2.3% for 2000–**
 40 **2009 to 1.0% for 2010–2019 (*high confidence*).** This slowing of growth is attributable to further
 41 improvements in energy efficiency and reductions in the carbon intensity of energy supply driven by
 42 fuel switching from coal to gas, reduced expansion of coal capacity, particularly in Eastern Asia, and
 43 the increased use of renewables (*medium confidence*). (Figure TS.6) {2.2.4, 2.4.2.1, Figure 2.17}

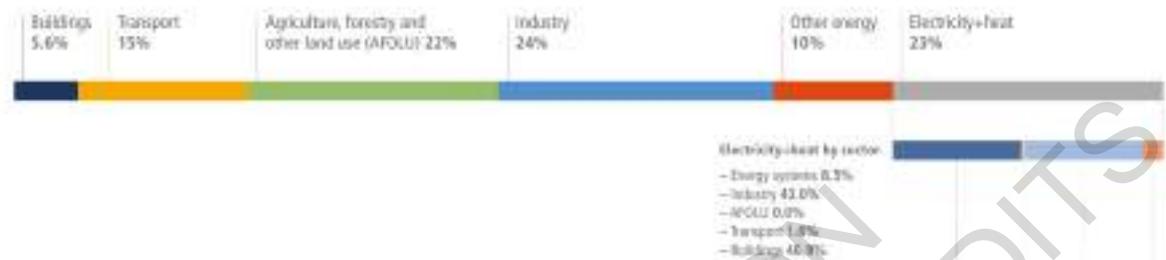

44 **The industry, buildings and transport sectors make up 44% of global GHG emissions, or 66%**
 45 **when the emissions from electricity and heat production are reallocated as *indirect emissions* (*high***
 46 ***confidence*).** This reallocation makes a substantial difference to overall industry and buildings

FOOTNOTE ⁹ Bookkeeping models and dynamic global vegetation models

1 emissions as shown in Figure TS.6. Industry, buildings, and transport emissions are driven, respectively,
 2 by the large rise in demand for basic materials and manufactured products, a global trend of increasing
 3 floor space per capita, building energy service use, travel distances, and vehicle size and weight.
 4 Between 2010-2019, aviation grew particularly fast on average at ~3.3% per annum. Globally, energy
 5 efficiency has improved in all three demand sectors, but carbon intensities have not. (Figure TS.6)
 6 {2.2.4, Figure 2.18, Figure 2.19, Figure 2.20}

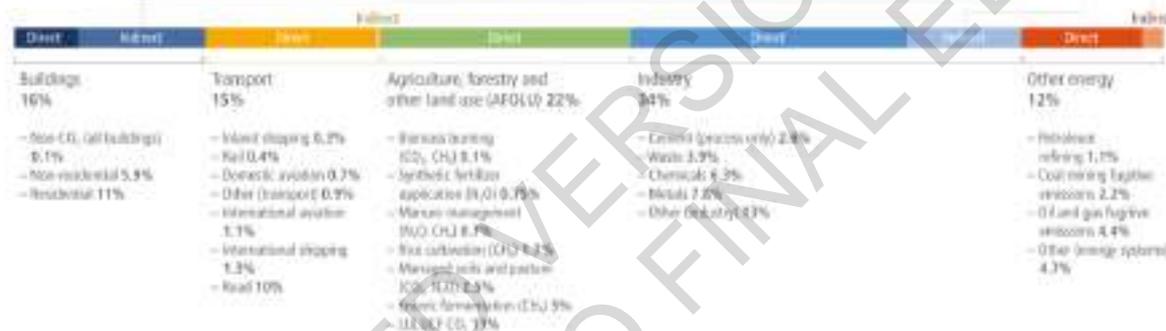

7
 8

Total emissions (59 GtCO₂eq)

9

Direct + indirect emissions by end-use sector (59 GtCO₂eq)

10

11 **Figure TS.6: Total anthropogenic direct and indirect GHG emissions for the year 2019 (in GtCO₂eq) by sector and sub-sector**

13 **Figure TS.6 legend:** Direct emissions estimates assign emissions to the sector in which they arise (scope 1 reporting). Indirect emissions – as used here - refer to the reallocation of emissions from electricity and heat to the sector of final use (scope 2 reporting). Note that cement refers to process emissions only, as a lack of data prevents the full reallocation of indirect emissions to this sector. More comprehensive conceptualisations of indirect emissions including all products and services (scope 3 reporting) are discussed in Chapter 2 section 2.3. Emissions are converted into CO₂-equivalents based on global warming potentials with a 100-year time horizon (GWP100) from the IPCC Sixth Assessment Report. Percentages may not add up to 100 across categories due to rounding at the second significant digit. {Figure 2.12, 2.3}

21 **Providing access to modern energy services universally would increase global GHG emissions by a few percent at most (*high confidence*).** The additional energy demand needed to support *decent living standards*¹⁰ for all is estimated to be well below current average energy consumption (*medium evidence, high agreement*). More equitable income distribution could also reduce carbon emissions, but

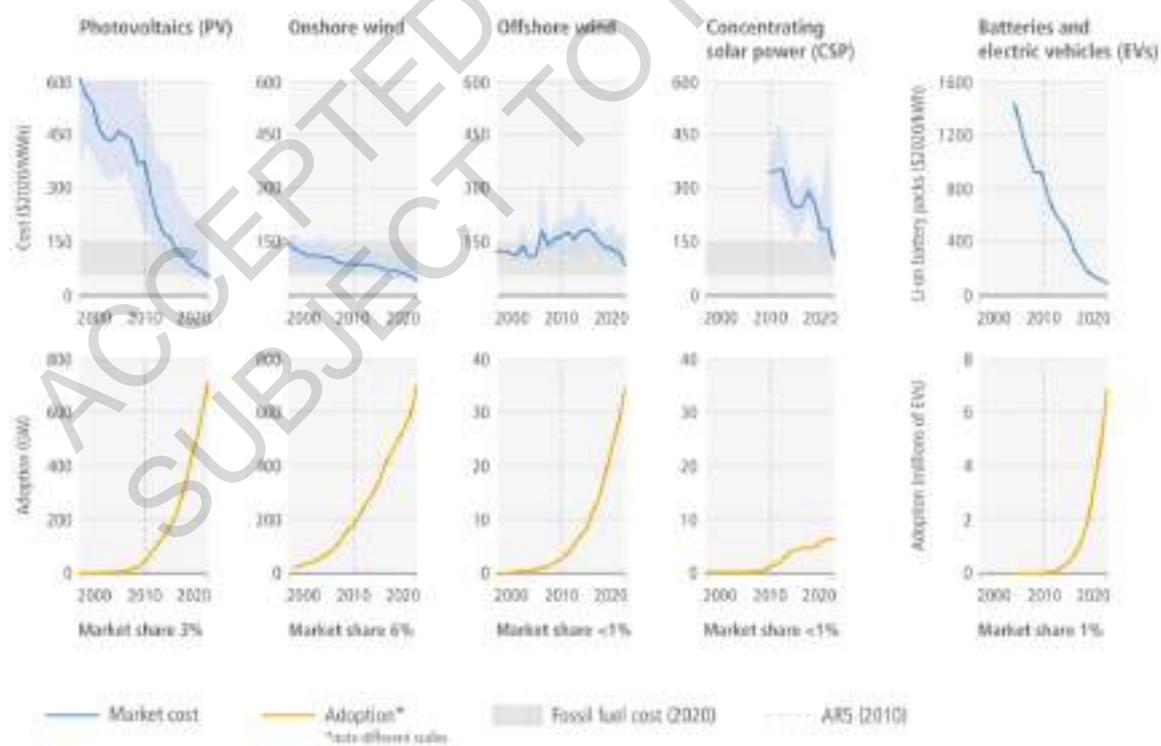

FOOTNOTE ¹⁰ Decent Living Standards (DLS) – a benchmark of material conditions for human well-being – overlaps with many Sustainable Development Goals (SDGs). Minimum requirements of energy use consistent with enabling well-being for all is between 20 and 50 GJ cap-1 yr-1 depending on the context. (Figure TS.22) {5.2.2, 5.2.2, Box 5.3}

1 the nature of this relationship can vary by level of income and development (*limited evidence, medium*
2 *agreement*). {2.4.3}

3 **Evidence of rapid energy transitions exists in some case studies (*medium confidence*).** Emerging
4 evidence since AR5 on past energy transitions identifies a growing number of cases of accelerated
5 technology diffusion at sub-global scales and describes mechanisms by which future energy transitions
6 may occur more quickly than those in the past. Important drivers include technology transfer and
7 cooperation, international policy and financial support, and harnessing synergies among technologies
8 within a sustainable energy system perspective (*medium confidence*). A fast global low-carbon energy
9 transition enabled by finance to facilitate low-carbon technology adoption in developing and
10 particularly in least developed countries can facilitate achieving climate stabilisation targets (*high*
11 *confidence*). {2.5.2, Table 2.5}

12 **Multiple low-carbon technologies have shown rapid progress since AR5 – in cost, performance,**
13 **and adoption – enhancing the feasibility of rapid energy transitions (*high confidence*).** The rapid
14 deployment and unit cost decrease of modular technologies like solar, wind, and batteries have occurred
15 much faster than anticipated by experts and modelled in previous mitigation scenarios, as shown in
16 Figure TS.7 (*high confidence*). The political, economic, social, and technical feasibility of solar energy,
17 wind energy and electricity storage technologies has improved dramatically over the past few years. In
18 contrast, the adoption of nuclear energy and CO₂ capture and storage (CCS) in the electricity sector has
19 been slower than the growth rates anticipated in stabilisation scenarios. Emerging evidence since AR5
20 indicates that small-scale technologies (e.g., solar, batteries) tend to improve faster and be adopted more
21 quickly than large-scale technologies (nuclear, CCS) (*medium confidence*). (Figure TS.7, Box TS.15)
22 {2.5.3, 2.5.4, Figure 2.22, Figure 2.23}

23

24

25 **Figure TS.7: The unit costs of batteries and some forms of renewable energy have fallen significantly,**
26 **and their adoption continues to increase**

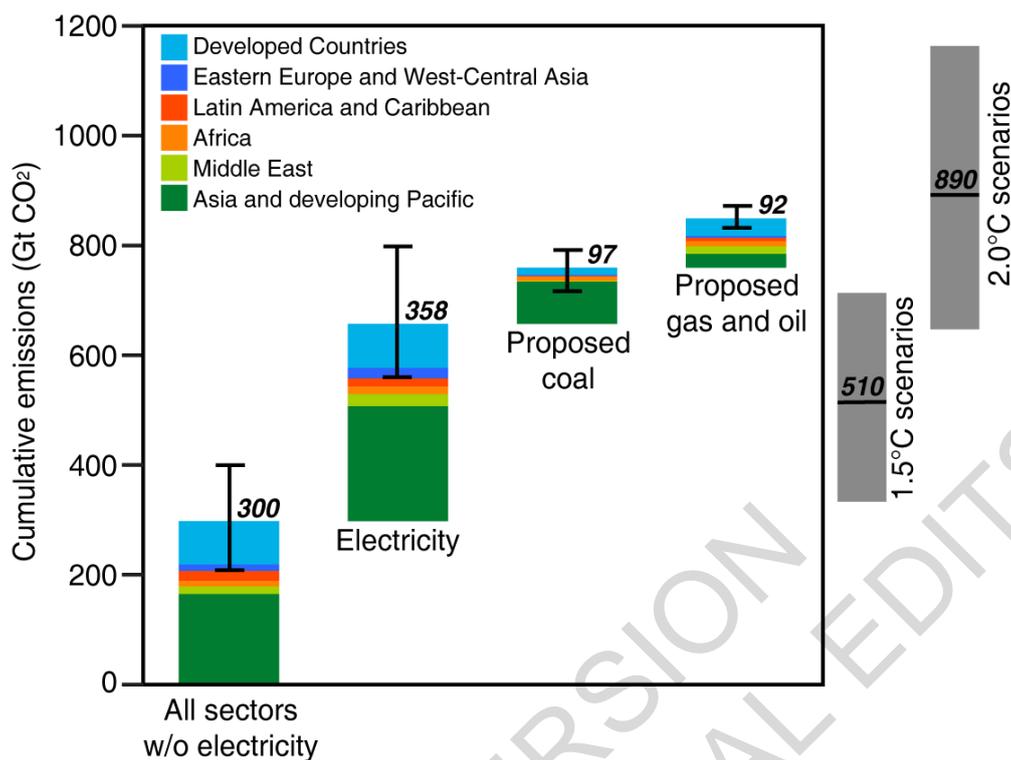

1 **Figure TS.7 legend:** The upper panel shows levelised costs of electricity (LCOE) for rapidly changing
2 mitigation technologies. Solid blue lines indicate average market cost in each year. Light blue shaded areas
3 show the range between the 5th and 95th percentiles in each year. Grey shading indicates the range of fossil fuel
4 (coal and gas) LCOE in 2020 (corresponding to USD55-148 per MWh). LCOE allows consistent comparisons
5 of cost trends across a diverse set of energy technologies to be made; it does not include environmental
6 externalities and does not reflect variation in the value of electricity over time and space (see Chapter 6).

7 The lower panel shows cumulative global adoption for each technology, in GW of installed capacity for
8 renewable energy and in millions of vehicles for electric vehicles. A vertical dashed line is placed in 2010 to
9 indicate change since AR5. The market share percentages shown are the 2020 shares based on provisional data,
10 i.e., percentage of total electricity production (for PV, Onshore wind, Offshore wind, concentrating solar power
11 (CSP)) and of passenger total vehicles (for electric vehicles). The electricity market share is generally lower
12 than the share of production capacity given lower capacity factors for these renewable technologies. {2.5, 6.4}

13
14 **Robust incentives for investment in innovation, especially incentives reinforced by national policy
15 and international agreements, are central to accelerating low-carbon technological change (*robust
16 evidence, medium agreement*).** Policies have driven innovation, including instruments for technology
17 push (e.g., scientific training, research and development (R&D)) and demand pull (e.g., carbon pricing,
18 adoption subsidies), as well as those promoting knowledge flows and especially technology transfer.
19 The magnitude of the scale-up challenge elevates the importance of rapid technology development and
20 adoption. This includes ensuring participation of developing countries in an enhanced global flow of
21 knowledge, skills, experience, equipment, and technology itself requires strong financial, institutional,
22 and capacity building support. {2.5.4, 2.5, 2.8}

23 **Estimates of future CO₂ emissions from existing fossil fuel infrastructures already exceed
24 remaining cumulative net CO₂ emissions in pathways limiting warming to 1.5°C with no or
25 limited overshoot (*high confidence*).** Assuming variations in historic patterns of use and
26 decommissioning, estimated future CO₂ emissions from existing fossil fuel infrastructure alone are 660
27 (460-890) GtCO₂ and from existing and currently planned infrastructure 850 (600-1100) GtCO₂. This
28 compares to overall cumulative net CO₂ emissions until reaching net zero CO₂ of 510 (330-710) GtCO₂
29 in pathways that limit warming to 1.5°C with no or limited overshoot, and 890 (640-1160) GtCO₂ in
30 pathways that *likely* limit warming to 2°C (*high confidence*). While most future CO₂ emissions from
31 existing and currently planned fossil fuel infrastructure are situated in the power sector, most remaining
32 fossil fuel CO₂ emissions in pathways that *likely* limit warming to 2°C and below are from non-electric
33 energy – most importantly from the industry and transportation sectors (*high confidence*).
34 Decommissioning and reduced utilisation of existing fossil fuel installations in the power sector as well
35 as cancellation of new installations are required to align future CO₂ emissions from the power sector
36 with projections in these pathways (*high confidence*). (Figure TS.8) {2.7.2, 2.7.3, Figure 2.26, Table
37 2.6, Table 2.7}

1

2

3 **Figure TS.8: Future CO₂ emissions from existing and currently planned fossil fuel infrastructure in the**
 4 **context of Paris carbon budgets in GtCO₂ based on historic patterns of infrastructure lifetimes and**
 5 **capacity utilisation**

6 **Figure TS.8 legend:** Future CO₂ emissions estimates of existing infrastructure for the electricity sector as well
 7 as all other sectors (industry, transport, buildings, other fossil fuel infrastructures) and of proposed
 8 infrastructures for coal power as well as gas and oil power. Grey bars on the right depict the range (5th – 95th
 9 percentile) in overall cumulative net CO₂ emissions until reaching net zero CO₂ in pathways that limit warming
 10 to 1.5°C with no or limited overshoot (1.5°C scenarios), and in pathways that limit *likely* warming to 2°C (2°C
 11 scenarios). {Figure 2.26}

12

1 **TS. 4 Mitigation and development pathways**

2 While previous WG III assessments have explored mitigation pathways, since AR5 there has been an
3 increasing emphasis in the literature on development pathways, and in particular at the national scale.
4 Chapter 4 assesses near-term (2019-2030) to mid-term (2030- 2050) pathways, complementing Chapter
5 3 which focusses on long-term pathways (up to 2100). While there is considerable literature on country-
6 level mitigation pathways, including but not limited to NDCs, the country distribution of this literature
7 is very unequal (*high confidence*). {4.2.1, Cross-Chapter Box 4 in Chapter 4}

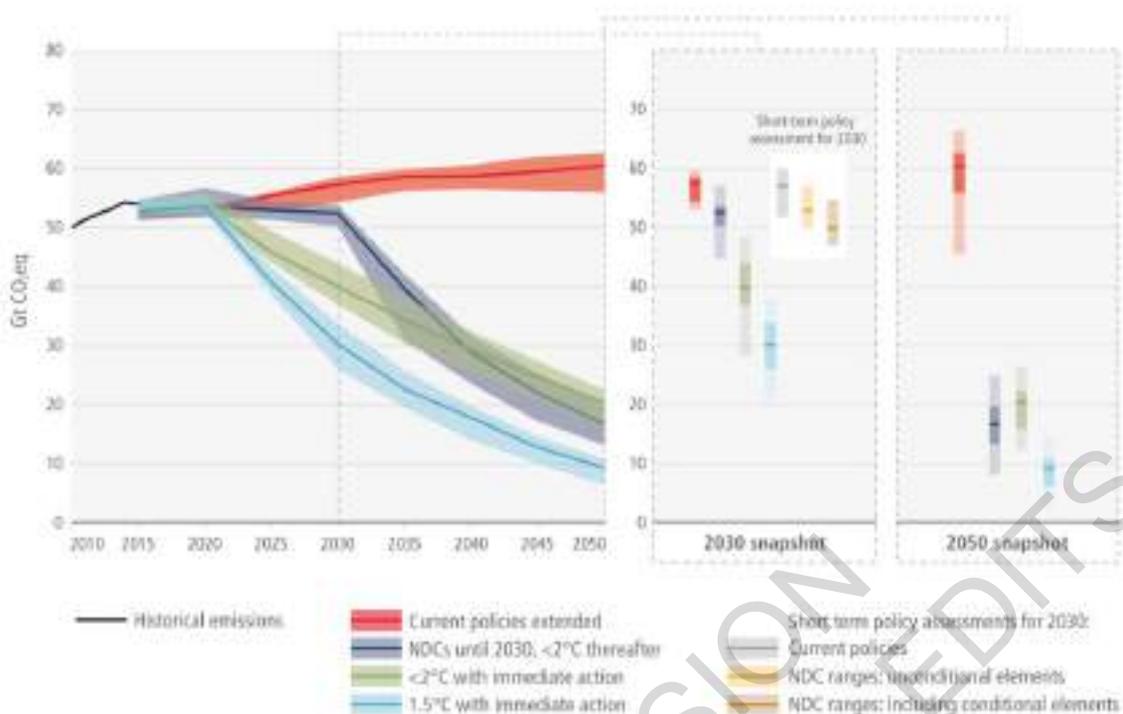

8 **TS. 4.1 Mitigation and development pathways in the near- to mid-term**

9 **An emissions gap persists, exacerbated by an implementation gap, despite mitigation efforts**
10 **including those in nationally determined contributions (NDCs).** In this report the *emissions gap* is
11 understood as the difference between projected global emissions with national determined contributions
12 (NDCs) in 2030, and emissions in 2030 if mitigation pathways consistent with the Paris temperature
13 goals were achieved. The term *implementation gap* refers to the gap between NDC mitigation pledges,
14 and the expected outcome of existing policies.

15 **Pathways consistent with the implementation and extrapolation of countries' current¹¹ policies**
16 **see GHG emissions reaching 57 (52-60) GtCO₂-eq yr⁻¹ by 2030 and to 46-67 GtCO₂-eq yr⁻¹ by**
17 **2050, leading to a median global warming of 2.4°C to 3.5°C by 2100 (*medium confidence*).** NDCs
18 with unconditional and conditional elements¹² lead to 53 (50-57) and 50 (47-55) GtCO₂-eq, respectively
19 (*medium confidence*). {Table 4.1}. This leaves median estimated *emissions gaps* of 14-23 GtCO₂-eq to
20 limit warming to 2°C and 25-34 GtCO₂-eq to limit warming to 1.5°C relative to mitigation pathways.
21 (Figure TS.9) {Cross-Chapter Box 4 Figure 1 in Chapter 4}

FOOTNOTE ¹¹ Current NDCs refers to the most recent nationally determined contributions submitted to the UNFCCC as well as those publicly announced (with sufficient detail on targets, but not yet submitted) up to 11 October 2021, and reflected in literature published up to 11 October 2021. Original INDCs and NDCs refer to those submitted to the UNFCCC in 2015 and 2016.

FOOTNOTE ¹² See {4.2.1} for description of 'unconditional' and 'conditional' elements of NDCs.

1

2 **Figure TS.9 Aggregate GHG emissions of global mitigation pathways (coloured funnels and bars) and**
 3 **projected emission outcomes from current policies and emissions implied by unconditional and**
 4 **conditional elements of NDCs, based on updates available by 11 October 2021 (grey bars).**

5 **Figure TS.9 legend:** Shaded areas show GHG emission medians and 25th–75th percentiles over 2020–2050 for
 6 four types of pathways in the AR6 scenario database: i) Pathways with near-term emissions developments in
 7 line with current policies and extended with comparable ambition levels beyond 2030; ii) Pathways *likely* to
 8 limit warming to 2°C with near term emissions developments reflecting 2030 emissions implied by current
 9 NDCs followed by accelerated emissions reductions; iii) Pathways *likely* to limit warming to 2°C based on
 10 immediate actions from 2020 onwards; iv) Pathways that limit warming to 1.5°C with no or limited overshoot.
 11 Right hand panels show two snapshots of the 2030 and 2050 emission ranges of the pathways in detail (median,
 12 25th–75th and 5th–95th percentiles). The 2030 snapshot includes the projected emissions from the implementation
 13 of the NDCs as assessed in Chapter 4.2 (Table 4.1; median and full range). Historic GHG emissions trends as
 14 used in model studies are shown for 2010–2015. GHG emissions are in CO₂-equivalent using GWP100 values
 15 from AR6. {3.5, Table 4.1, Cross-Chapter Box 4 in Chapter 4}

16 **Projected global emissions from aggregated NDCs place limiting global warming to 1.5°C beyond**
 17 **reach and make it harder after 2030 to limit warming to 2°C (*high confidence*).** Pathways
 18 following NDCs until 2030 show a smaller reduction in fossil fuel use, slower deployment of low carbon
 19 alternatives, and a smaller reduction in CO₂, CH₄ and overall GHG emissions in 2030 compared to
 20 immediate action scenarios. This is followed by a much faster reduction of emissions and fossil fuels
 21 after 2030, and a larger increase in the deployment of low carbon alternatives during the medium term
 22 in order to get close to the levels of the immediate action pathways in 2050. Those pathways also deploy
 23 a larger amount of Carbon Dioxide Removal (CDR) to compensate for higher emissions before 2030.
 24 The faster transition during 2030-2050 entails greater investment in fossil fuel infrastructure and lower
 25 deployment of low carbon alternatives in 2030 which adds to the socio-economic challenges in realising
 26 the higher transition rates. (TS 4.2) {3.5}

1 **Studies evaluating up to 105 updated NDCs¹³ indicate that emissions in NDCs with conditional**
2 **elements have been reduced by 4.5 (2.7-6.3) GtCO₂-eq.** This closes the emission gaps by about one-
3 third to 2°C and about 20% to 1.5°C compared to the original NDCs submitted in 2015/16 (*medium*
4 *confidence*). 4.2.2, Cross-Chapter Box 4 in Chapter 4}. An *implementation gap* also exists between the
5 projected emissions with ‘current policies’ and the projected emissions resulting from the
6 implementation of the unconditional and conditional elements of NDCs; this is estimated to be around
7 4 and 7 GtCO₂-eq in 2030, respectively {4.2.2} (*medium confidence*). Many countries would therefore
8 require additional policies and associated action on climate change to meet their autonomously
9 determined mitigation targets as specified under the first NDCs (*limited evidence*). The disruptions
10 triggered by the COVID-19 pandemic increase uncertainty over the range of projections relative to pre-
11 COVID-19 literature. As indicated by a growing number of studies at the national and global level, how
12 large near- to mid-term emissions implications of the COVID-19 pandemic are, to a large degree
13 depends on how stimulus or recovery packages are designed. {4.2}

14

15

FOOTNOTE ¹³ Submitted by 11 October 2021.

1 **Table TS.2: Comparison of key characteristics of mitigation pathways with immediate action towards limiting warming to 1.5-2°C vs. pathways following current**
 2 **NDCs until 2030.**

Global indicators	Mitigation pathways median (interquartile range)			
	<1.5°C Immediate action, no or limited overshoot	1.5°C by 2100 NDCs until 2030, with high overshoot of 1.5°C	Likely < 2°C	
			Immediate action	NDCs until 2030
	Scenarios category: C1	subset of scenarios category: C2	Scenarios category: C3a	Scenarios category: C3b
Cumulative net negative CO ₂ until 2100 (GtCO ₂)	190 (0,385)	320 (250,440)	10 (0,120)	70 (0,200)

1 **Table TS.2 legend:** Key characteristics are reported for four groups of mitigation pathways: (i) immediate
2 action to limit warming to 1.5°C with no or limited overshoot (C1 in Table TS.3; 97 scenarios), (ii) near term
3 action following the NDCs until 2030 and returning warming to below 1.5°C (50% chance) by 2100 with high
4 overshoot (subset of 42 scenarios following the NDCs until 2030 in C2), (iii) immediate action to *likely* limit
5 warming to 2°C, (C3a in Table TS.3; 204 scenarios) and (iv) near term action following the NDCs until 2030
6 followed by post-2030 action to *likely* limit warming to 2°C (C3b in Table TS.3; 97 scenarios). The groups (i),
7 (iii), and (iv) are depicted in Figure TS.9. Reported are median and interquartile ranges (in brackets) for selected
8 global indicators. Numbers are rounded to the nearest five. Changes from 2019 are relative to modelled 2019
9 values. Emissions reductions are based on harmonised model emissions used for the climate assessment.

10 (Section 3.5) {Table 3.6}

11
12 **There is a need to explore how accelerated mitigation – relative to NDCs and current policies –**
13 **could close both *emission gaps*, and *implementation gaps*.** There is increasing understanding of the
14 technical content of accelerated mitigation pathways, differentiated by national circumstances, with
15 considerable, though uneven, literature at country-level (*medium evidence, high agreement*).
16 Transformative technological and institutional changes for the near-term include demand reductions
17 through efficiency and reduced activity, rapid decarbonisation of the electricity sector and low-carbon
18 electrification of buildings, industry and transport (*robust evidence, medium agreement*). A focus on
19 energy use and supply is essential, but not sufficient on its own – the land sector and food systems
20 deserve attention. The literature does not adequately include demand-side options and systems analysis,
21 and captures the impact from non-CO₂ GHGs with *medium confidence*. {4.2.5}

22 **If obstacles to accelerated mitigation are rooted in underlying structural features of society, then**
23 **transforming such structures can support emission reductions {4.2.6}.** Countries and regions will
24 have different starting points for transition pathways. Some critical differences between countries
25 include climate conditions resulting in different heating and cooling needs, endowments with different
26 energy resources, patterns of spatial development, and political and economic conditions {4.2.5}. The
27 way countries develop determines their capacity to accelerate mitigation and achieve other sustainable
28 development objectives simultaneously (*medium confidence*) {4.3.1, 4.3.2}. Yet meeting ambitious
29 mitigation and development goals cannot be achieved through incremental change (*robust evidence,*
30 *medium agreement*). Though development pathways result from the actions of a wide range of actors,
31 it is possible to shift development pathways through policies and enhancing enabling conditions (*limited*
32 *evidence, medium agreement*).

33 **Shifting development pathways towards sustainability offers ways to broaden the range of levers**
34 **and enablers that a society can use to accelerate mitigation and increases the likelihood of making**
35 **progress simultaneously on climate action and other development goals (Box TS.3) {Cross-**
36 **Chapter Box 5 in Chapter 4, Figure 4.7, 4.3}.** There are practical options to shift development
37 pathways in ways that advance mitigation and other sustainable development objectives, supporting
38 political feasibility, increase resources to meet multiple goals, and reduce emissions (*limited evidence,*
39 *high agreement*). Concrete examples, assessed in chapter 4 of this report, include high employment and
40 low emissions structural change, fiscal reforms for mitigation and social contract, combining housing
41 policies to deliver both housing and transport mitigation, and change economic, social and spatial
42 patterns of development of the agriculture sector provide the basis for sustained reductions in emissions
43 from deforestation. {4.4.1, 4.4, 1.10}

1 **START BOX TS.3 HERE**

2 **Box TS.3: Shifting development pathways to increase sustainability and broaden mitigation** 3 **options**

4 In this report, *development pathways* refer to the patterns of development resulting from multiple
5 decisions and choices made by many actors in the national and global contexts. Each society whether
6 in developing or developed regions follows its own pattern of growth (Figure TS.13). Development
7 pathways can also be described at smaller scales (e.g., for regions or cities) and for sectoral systems.

8 Development pathways are major drivers of GHG emissions {1, 2}. There is compelling evidence to
9 show that continuing along existing development pathways will not achieve rapid and deep emission
10 reductions. In the absence of shifts in development pathways, conventional mitigation policy
11 instruments may not be able to limit global emissions to a degree sufficient to meet ambitious mitigation
12 goals or they may only be able to do so at very high economic and social costs.

13 Policies to shift development pathways, on the other hand, make mitigation policies more effective.
14 Shifting development pathways broadens the scope for synergies between sustainable development
15 objectives and mitigation. Development pathways also determine the enablers and levers available for
16 adaptation {AR6 WG II TS E.1.2} and for achieving other SDGs.

17 There are many instances in which reducing GHG emissions and moving towards the achievement of
18 other development objectives can go hand in hand {Chapter 3, Fig 3.33, Chapters 6-12, 17}. Integrated
19 policies can support the creation of synergies between *action to combat climate change and its impacts*
20 (SDG 13) and other SDGs. For example, when measures promoting walkable urban areas are combined
21 with electrification and clean renewable energy, there are several co-benefits to be attained. These
22 include reduced pressures on agricultural land from reduced urban growth, health co-benefits from
23 cleaner air and benefits from enhanced mobility {8.2, 8.4, 4.4.1}. Energy efficiency in buildings and
24 energy poverty alleviation through improved access to clean fuels also deliver significant health
25 benefits. {9.8.1 and 9.8.2}

26 However, decisions about mitigation actions, and their timing and scale, may entail trade-offs with the
27 achievement of other national development objectives in the near-, mid- and long-term {Chapter 12}.
28 In the near-term, for example, regulations may ban vehicles from city centres to reduce congestion and
29 local air pollution but reduce mobility and choice. Increasing green spaces within cities without caps
30 on housing prices may involve trade-offs with affordable housing and push low-income residents
31 outside the city {8.2.2}. In the mid- and long-term, large-scale deployment of biomass energy raises
32 concerns about food security and biodiversity conservation {3.7.1, 3.7.5, 7.4.4, 9.8.1, 12.5.2, 12.5.3}.
33 Prioritising is one way to manage these trade-offs, addressing some national development objectives
34 earlier than others. Another way is to adopt policy packages aimed at shifting development pathways
35 towards sustainability (SDPS) as they expand the range of tools available to simultaneously achieve
36 multiple development objectives and accelerate mitigation. (Box TS.3 Figure 1)

37 **What does *shifting development pathways towards sustainability* entail?**

38 Shifting development pathways towards sustainability implies making transformative changes that
39 disrupt existing developmental trends. Such choices would not be marginal, but include technological,
40 systemic and socio-behavioural changes {4.4}. Decision points also arise with new infrastructure,
41 sustainable supply chains, institutional capacities for evidence-based and integrated decision-making,
42 financial alignment towards low-carbon socially responsible investments, just transitions and shifts in
43 behaviour and norms to support shifts away from fossil fuel consumption. Adopting multi-level
44 governance modes, tackling corruption where it inhibits shifts to sustainability, and improving social
45 and political trust are also key for aligning and supporting long-term environmentally just policies and
46 processes. {4.4, Cross-Chapter Box 5 in Chapter 4}

1 **How to shift development pathways?**

2 Shifting development paths is complex. Changes that involve ‘dissimilar, unfamiliar and more complex
3 science-based components’ take more time, acceptance and legitimation and involve complex social
4 learning, even when they promise large gains. Despite the complexities of the interactions that result in
5 patterns of development, history also shows that societies can influence the direction of development
6 pathways based on choices made by decision-makers, citizens, the private sector, and social
7 stakeholders. Shifts in development pathways result from both sustained political interventions and
8 bottom-up changes in public opinion. Collective action by individuals as part of social movements or
9 lifestyle changes underpins system change. {5.2.3, 5.4.1, 5.4.5}.

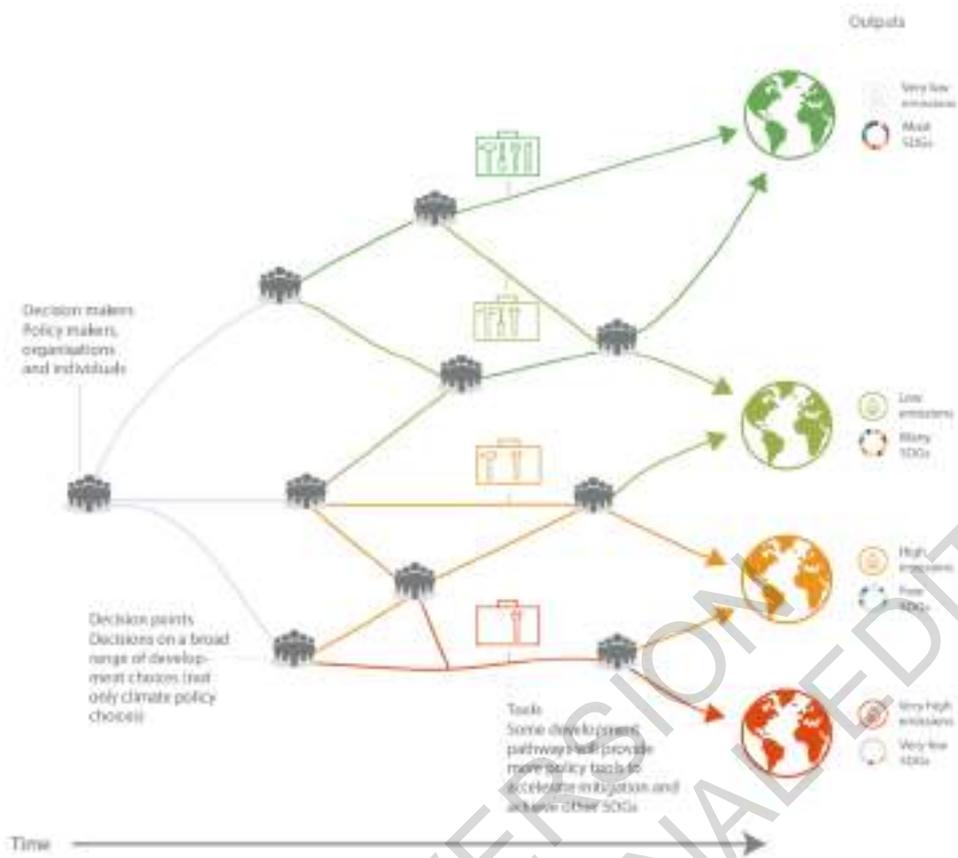

10 Sectoral transitions that aim to shift development pathways often have multiple objectives and deploy
11 a diverse mix of policies and institutional measures. Context specific governance conditions can
12 significantly enable or disable sectoral transitions {Cross-Chapter Box 12 in Chapter 16}.

13 The necessary transformational changes are anticipated to be more acceptable if rooted in the
14 development aspirations of the economy and society within which they take place and may enable a
15 new social contract to address a complex set of inter-linkages across sectors, classes, and the whole
16 economy. Taking advantage of windows of opportunity and disruptions to mindsets and socio-technical
17 systems could advance deeper transformations.

18 **How can shifts in development pathways be implemented by actors in different contexts?**

19 Shifting development pathways to increased sustainability is a shared aspiration. Yet since countries
20 differ in starting points (e.g., social, economic, cultural, political) and historical backgrounds, they have
21 different urgent needs in terms of facilitating the economic, social, and environmental dimensions of
22 sustainable development and, therefore, give different priorities {4.3.2, 17.1}. The appropriate set of
23 policies to shift development pathways thus depends on national circumstances and capacities.

24 Shifting development pathways towards sustainability needs to be supported by multilateral
25 partnerships to strengthen suitable capacity, technological innovation (TS 6.5), and financial flows (TS.
26 6.4). The international community can play a particularly key role by helping ensure the necessary broad
27 participation in climate-mitigation efforts, including by countries at different development levels,
28 through sustained support for policies and partnerships that support shifting development pathways
29 towards sustainability while promoting equity and being mindful of different transition capacities.
30 {Chapter 4.3, 16.5, 16.6}

25

Policies can *shift* development pathways. There are examples of policies implemented in the pursuit of overall societal development objectives, such as job creation, macro-economic stability, economic growth, and public health and welfare. In some countries, such policies are framed as part of a *just transition* (Box TS.3), however, they can have major influence on mitigative capacity, and hence can be seen as tools to broaden mitigation options (*medium confidence*) {4.3.3}. Coordinated policy mixes would need to orchestrate multiple actors – individuals, groups and collectives, corporate actors, institutions and infrastructure actors – to deepen decarbonisation and shift pathways towards sustainability. Shifts in one country may spill over to other countries. Shifting development pathways can jointly support mitigation and adaptation {4.4.2}. Some studies explore the risks of high complexity and potential delay attached to shifting development pathways. (Box TS.4, Figure TS.11) {4.4.3}

An increasing number of mitigation strategies up to 2050 (mid-term) have been developed by various actors. A growing number of such strategies aim at net zero GHG or CO₂ emissions, but it is not yet possible to draw global implications due to the limited size of sample (*medium evidence; low agreement*) {4.2.4}. Non-state actors are also engaging in a wide range of mitigation initiatives. When adding up emission reduction potentials, sub-national and non-state international cooperative initiatives could reduce emissions by up to about 20 GtCO₂-eq in 2030 (*limited evidence, medium agreement*) {4.2.3}. Yet perceived or real conflicts between mitigation and other SDGs can impede such action. If undertaken without precaution, accelerated mitigation is found to have significant implications for development objectives and macroeconomic costs at country level. The

1 literature shows that employment effect of mitigation policies tends to be limited on aggregate but can
2 be significant at sectoral level (*limited evidence, medium agreement*). Detailed design of mitigation
3 policies is critical for distributional impacts and avoiding lock-in (*high confidence*), though further
4 research is needed in that direction. {4.2.6}

5 **The literature identifies a broad set of enabling conditions that can both foster *shifting***
6 ***development pathways and accelerated mitigation (medium evidence, high agreement)***. Policy
7 integration is a necessary component of shifting development pathways, addressing multiple objectives.
8 To this aim, mobilising a range of policies is preferable to single policy instruments (*high confidence*).
9 {4.4.1}. Governance for climate mitigation and shifting development pathways is enhanced when
10 tailored to national and local contexts. Improved institutions and effective governance enable ambitious
11 action on climate and can help bridge implementation gaps (*medium evidence, high agreement*). Given
12 that strengthening institutions may be a long-term endeavour, it needs attention in the near-term {4.4.1}.
13 Accelerated mitigation and shifting development pathways necessitates both re-directing existing
14 financial flows from high- to low-emissions technologies and systems and to provide additional
15 resources to overcome current financial barriers (*high confidence*) {4.4.1}. Opportunities exist in the
16 near-term to close the finance gap {15.2.2}. At the national level, public finance for actions promoting
17 sustainable development helps broaden the scope of mitigation (*medium confidence*). Changes in
18 behaviour and lifestyles are important to move beyond mitigation as incremental change, and when
19 supporting shifts to more sustainable development pathways will broaden the scope of mitigation
20 (*medium confidence*). {4.4.1, Figure 4.8}

21 **Some enabling conditions can be put in place relatively quickly while some others may take time**
22 **to establish underscoring the importance of early action (*high confidence*)**. Depending on context,
23 some enabling conditions such as such as promoting innovation may take time to establish. Other
24 enabling conditions, such as improved access to financing, can be put in place in a relatively short time
25 frame, and can yield rapid results {4.4, Figure 5.14, 13.9, 14.5, 15.6, 16.3, 16.4, 16.5, Cross-Chapter
26 Box 12 in Chapter 16}. Focusing on development pathways and considering how to shift them may also
27 yield rapid results by providing tools to accelerate mitigation and achieve other sustainable development
28 goals. {4.4.1}. Charting just transitions to net zero may provide a vision, which policy measures can
29 help achieve (Box TS.4, Box TS.8).

30 **Equity can be an important enabler, increasing the level of ambition for accelerated mitigation**
31 **(*high confidence*) {4.5}**. Equity deals with the distribution of costs and benefits and how these are
32 shared, as per social contracts, national policy and international agreements. Transition pathways have
33 distributional consequences such as large changes in employment and economic structure (*high*
34 *confidence*). The *just transition* concept has become an international focal point tying together social
35 movements, trade unions, and other key stakeholders to ensure equity is better accounted for in low-
36 carbon transitions (Box TS.4). The effectiveness of cooperative action and the perception of fairness of
37 such arrangements are closely related in that pathways that prioritise equity and allow broad stakeholder
38 participation can enable broader consensus for the transformational change implicit in the need for
39 deeper mitigation (*robust evidence, medium agreement*). (Box TS.4) {4.5, Figure 4.9}

40

41 **START BOX TS.4 HERE**

42

Box TS. 4: Just Transition

43 The Just Transition framework refers to a set of principles, processes and practices aimed at ensuring
44 that no people, workers, places, sectors, countries or regions are left behind in the move from a high-
45 carbon to a low-carbon economy. It includes respect and dignity for vulnerable groups; creation of

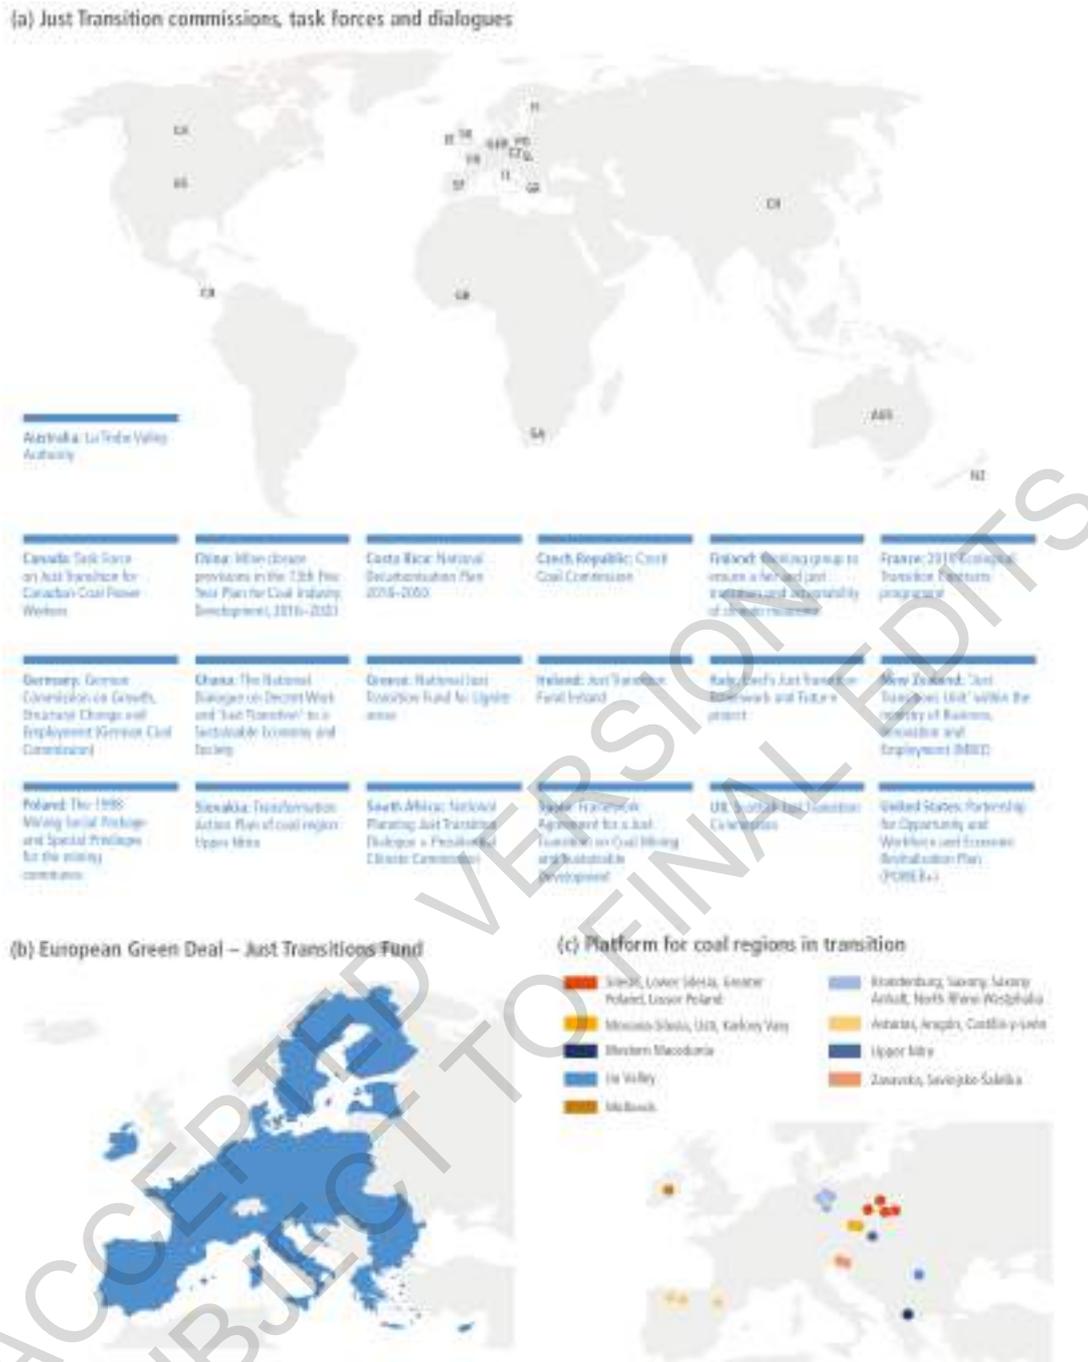

1 decent jobs; social protection; employment rights; fairness in energy access and use and social dialogue
2 and democratic consultation with relevant stakeholders.

3 The concept has evolved, becoming prominent in the United States in 1980, related to environmental
4 regulations that resulted in job losses from highly polluting industries. Traced from a purely labour
5 movement, trade union space, the Just Transition framework emphasises that decent work and
6 environmental protection are not incompatible. During COP 24, with the Just Transition Silesia
7 Declaration, the concept gained in recognition and was signed by 56 Heads of State.

8 Implicit in a Just Transition is the notion of well-being, equity and justice – the realisation that
9 transitions are inherently disruptive and deliberate effort may be required to ensure communities
10 dependent on fossil-fuel based economies and industries do not suffer disproportionately {Chapter 4}.
11 ‘Just transitions’ are integral to the European Union as mentioned in the EU Green Deal, the Scottish
12 Government’s development plans and other national low carbon transition strategies. The US Green
13 New Deal Resolution puts structural inequality, poverty mitigation, and ‘Just Transitions’ at its centre.
14 There is a growing awareness of the need for shifting finance towards Just Transition in the context of
15 the COVID-19, in particular, public finance and governance have a major role in allowing Just
16 Transition broadly {Chapter 15}.

17 In the immediate aftermath of the COVID-19 pandemic, low oil prices created additional financial
18 problems for fossil fuel producer countries faced with loss of revenue and reduced fiscal latitude and
19 space. Public spending and social safety nets associated with the proceeds from producer economies
20 can be affected as assets become stranded and spending on strategic sustainable development goals such
21 as free education and health care services are neglected. Fiscal challenges are intricately linked to ‘Just
22 Transitions’ and the management associated with sustainable energy transition. There is no certainty on
23 how energy systems will recover post-COVID-19. However, ‘Just Transitions’ will have equity
24 implications if stimulus packages are implemented without due regard for the differentiated scales and
25 speeds and national and regional contexts, especially in the context of developing countries.

26 A Just Transition entails targeted and proactive measures from governments, agencies, and other non-
27 state authorities to ensure that any negative social, environmental, or economic impacts of economy-
28 wide transitions are minimised, whilst benefits are maximised for those disproportionately affected.
29 These proactive measures include eradication of poverty, regulating prosperity and creating jobs in
30 “green” sectors. In addition, governments, polluting industries, corporations, and those more able to
31 pay higher associated taxes, can pay for transition costs by providing a welfare safety net and adequate
32 compensation to people, communities, and regions that have been impacted by pollution, or are
33 marginalised, or are negatively impacted by a transition from a high- to low- carbon economy and
34 society. There is, nonetheless, increased recognition that resources that can enable the transition,
35 international development institutions, as well as other transitional drivers such as tools, strategies and
36 finance, are scarce. A sample of global efforts are summarised in Box TS.4 Figure 1.

END BOX TS.4 HERE

1 **TS. 4.2 Long-term mitigation pathways**

2 **The characteristics of a wide range of long-term mitigation pathways, their common elements**
3 **and differences are assessed in Chapter 3. Differences between pathways typically represent**
4 **choices that can steer the system in alternative directions through the selection of different**
5 **combinations of response options (*high confidence*).** More than 2000 quantitative emissions
6 pathways were submitted to the AR6 scenarios database, of which more than 1200 pathways included
7 sufficient information for the associated warming to be assessed (consistent with AR6 WG I methods).
8 (Box TS.5) {3.2, 3.3}

9 **Many pathways in the literature show how to *likely* limit global warming to 2°C with no overshoot**
10 **or to limit warming to 1.5°C with limited overshoot compared to 1850-1900. The likelihood of**
11 **limiting warming to 1.5°C with no or limited overshoot has dropped in AR6 WG III compared**
12 **to AR6 SR1.5 because global GHG emissions have risen since 2017, leading to higher near-term**
13 **emissions (2030) and higher cumulative CO₂ emissions until the time of net zero (*medium***
14 ***confidence*).** Only a small number of published pathways limit global warming to 1.5°C without
15 overshoot over the course of the 21st century. {3.3, Annex III.II.3}

16 **Mitigation pathways limiting warming to 1.5°C with no or limited overshoot reach 50% CO₂**
17 **reductions in the 2030s, relative to 2019, then reduce emissions further to reach net zero CO₂**
18 **emissions in the 2050s. Pathways *likely* limiting warming to 2°C reach 50% reductions in the**
19 **2040s and net zero CO₂ by 2070s (*medium confidence*).** (Figure TS.10, Box TS.6) {3.3}

20 **Cost-effective mitigation pathways assuming immediate action to *likely* limit warming to 2°C are**
21 **associated with net global GHG emissions of 30-49 GtCO₂-eq yr⁻¹ by 2030 and 13-26 GtCO₂-eq**
22 **yr⁻¹ by 2050 (*medium confidence*).** This corresponds to reductions, relative to 2019 levels, of 13-45%
23 by 2030 and 52-76% by 2050. Pathways that limit global warming to below 1.5°C with no or limited
24 overshoot require a further acceleration in the pace of transformation, with net GHG emissions typically
25 around 21-36 GtCO₂-eq yr⁻¹ by 2030 and 1-15 GtCO₂-eq yr⁻¹ by 2050; this corresponds to reductions of
26 34-60% by 2030 and 73-98% by 2050 relative to 2019 levels. {3.3}

27

28 **START BOX TS.5 HERE**

29 **Box TS.5: Illustrative Mitigation Pathways (IMPs), and Shared Socio-economic Pathways**
30 **(SSPs)**

31 ***The Illustrative Mitigation Pathways (IMPs)***

32 The over 2500 model-based pathways submitted to the AR6 scenarios database pathways explore
33 different possible evolutions of future energy and land use (with and without climate policy) and the
34 consequences for greenhouse gas emissions.

35 From the full range of pathways, five archetype scenarios – referred to in this report as *Illustrative*
36 *Mitigation Pathways* (IMPs) – were selected to illustrate key mitigation-strategy themes that flow
37 through several chapters in this report. A further two *pathways illustrative of high emissions* assuming
38 continuation of current policies or moderately increased action were selected to show the consequences
39 of current policies and pledges. Together these pathways provide illustrations of potential future
40 developments that can be shaped by human choices, including: Where are current policies and pledges
41 leading us? What is needed to reach specific temperature goals? What are the consequences of using
42 different strategies to meet these goals? What are the consequences of delay? How can we shift
43 development from current practices to give higher priority to sustainability and the SDGs?

1 Each of the IMPs comprises: a *storyline* and a *quantitative illustration*. The *storyline* describes the key
 2 characteristics of the pathway qualitatively; the *quantitative illustration* is selected from the literature
 3 on long-term scenarios to effectively represent the IMP numerically. The five Illustrative Mitigation
 4 Pathways (IMPs) each emphasise a different scenario element as its defining feature, and are named
 5 accordingly: heavy reliance on renewables (IMP-Ren), strong emphasis on low demand for energy
 6 (IMP-LD), extensive use of Carbon Dioxide Removal (CDR) in the energy and the industry sectors to
 7 achieve net negative emissions (IMP-Neg), mitigation in the context of broader sustainable
 8 development and shifting development pathways (IMP-SP), and the implications of a less rapid and
 9 gradual strengthening of near-term mitigation actions (IMP-GS). In some cases, sectoral chapters may
 10 use different quantifications that follow the same storyline narrative but contain data that better
 11 exemplify the chapter's assessment. Some IMP variants are also used to explore the sensitivity around
 12 alternative temperature goals. {3.2, 3.3}

13 The two additional *pathways illustrative of higher emissions* are current policies (CurPol) and moderate
 14 action (ModAct).

15 This framework is summarised in Box TS.5 Table.1 below, which also shows where the IMPs are
 16 situated with respect to the classification of emissions scenarios into warming levels (C1-C8) introduced
 17 in Chapter 3, and the CMIP6 (Coupled Model Intercomparison Project 6) scenarios used in the AR6
 18 WG I report.

19

20 **Box TS.5 Table.1 Illustrative Mitigation Pathways (IMPs) and pathways illustrative of higher emissions in**
 21 **relation to scenarios' categories, and CMIP6 scenarios**

22

Classification of emissions scenarios into warming levels: C1-C8	Pathways illustrative of higher emissions	Illustrative mitigation pathways (IMPs)	CMIP 6 scenarios
C8 (above 4°C)			SSP5-8.5
C7 (below 4°C)	CurPol		SSP3-7.0
C6 (below 3°C)	ModAct		SSP2-4.5
C5 (below 2.5°C)			SSP4-3.7
C4 (below 2°C)			
C3 (likely below 2°C)		IMP-GS (Sensitivities: Neg; Ren)	SSP2-2.6
C2 (below 1.5°C; large overshoot)		IMP-Neg	
C1 (below 1.5°C; no or limited overshoot)		IMP-LD IMP-Ren IMP-SP	SSP1-1.9

23

24 ***The Shared Socioeconomic Pathways (SSPs)***

25 First published in 2017, the Shared Socioeconomic Pathways (SSPs) are alternative projections of
 26 socio-economic developments that may influence future GHG emissions.

27 The initial set of SSP narratives described worlds with different challenges to mitigation and adaptation:
 28 SSP1 (*sustainability*), SSP2 (*middle of the road*), SSP3 (*regional rivalry*), SSP4 (*inequality*) and SSP5
 29 (*rapid growth*). The SSPs were subsequently quantified in terms of energy, land-use change, and
 30 emission pathways for both i) no-climate-policy reference scenarios and ii) mitigation scenarios that

1 follow similar radiative forcing pathways as the Representative Concentration Pathways (RCPs)
2 assessed in AR5 WG I. {3.2.3}

3 Most of the scenarios in the AR6 database are SSP-based. The majority of the assessed scenarios are
4 consistent with SSP2. Using the SSPs permits a more systematic assessment of future GHG emissions
5 and their uncertainties than was possible in AR5. The main emissions drivers across the SSPs include
6 growth in population reaching 8.5-9.7 billion by 2050, and an increase in global GDP of 2.7-4.1% per
7 year between 2015 and 2050. Final energy demand in the absence of any new climate policies is
8 projected to grow to around 480 to 750 EJ yr⁻¹ in 2050 (compared to around 390 EJ in 2015) (*medium*
9 *confidence*). The highest emissions scenarios in the literature result in global warming of >5°C by 2100,
10 based on assumptions of rapid economic growth and pervasive climate policy failures. (*high confidence*)

5

1 **Table TS.3 legend:** 0 Values in the table refer to the 50th and (5th-95th) percentile values. For emissions-related
2 columns this relates to the distribution of all the pathways in that category. For Temperature Change and
3 Likelihood columns, single upper row values are the 50th percentile value across pathways in that Category for
4 the MAGICC climate model emulator. For the bracketed ranges, the median warming for every pathway in that
5 category is calculated for each of the three climate model emulators (MAGICC, FaIR and CICERO-SCM).
6 Subsequently, the 5th and 95th percentile values across all pathways is calculated. The coolest and warmest
7 outcomes (i.e. the lowest p5 of three emulators, and the highest p95, respectively) are shown in the brackets. Thus
8 these ranges cover the extent of pathway and climate model emulator uncertainty.

9 **1** Category definitions consider at-peak warming and warming at the end-of-century (2100).
10 C1: Below 1.5°C in 2100 with a greater than 50% probability and a peak warming higher than 1.5°C with less
11 than 67% probability.
12 C2: Below 1.5°C in 2100 with a greater than 50% probability but peak warming higher than 1.5°C with a
13 probability of 67% or greater.
14 C3: *Likely* below 2 °C throughout the century with a probability of 67% or greater.
15 C4, C5, C6, C7: Below 2 °C, 2.5 °C, 3 °C and 4 °C throughout the century, respectively, with greater than 50%
16 probability.
17 C8: Peak warming above 4 °C with greater than 50% probability.

18 **2** All warming levels are relative to 1850-1900.
19 **3** The warming profile of the IMP-Neg peaks around 2060 and declines to below 1.5°C (50% likelihood) shortly
20 after 2100. Whilst technically classified as a C3, it strongly exhibits the characteristics of C2 high overshoot
21 pathways, hence it is placed under C2 category.
22 **4** C3 pathways are sub-categorized according to policy ambition and consistent with Figure SPM 6. Two pathways
23 derived from a cost-benefit analysis have been added to C3a, whilst 10 pathways with specifically designed near-
24 term action until 2030 that fall below or above NDCs levels are not included in either of the two subclasses.
25 **5** Percentage GHG reduction ranges shown here are calculated relative to the modelled 2019 emissions based on
26 the harmonized and infilled projections from the models (Annex III, section II.2.5). Negative values (e.g. in C7,
27 C8) represent an increase in emissions.
28 **6** Percentage (%) reductions and emissions milestones are based on model data for CO₂ & GHG emissions, which
29 has been harmonized to 2015 values. See also Footnote 9.
30 **7** The first year range refers to the five year period within which the median peak emissions year or net zero year
31 falls. The second year range refers to the full range (rounded to the nearest five years) within which the 5th and
32 95th percentiles fall.
33 **8** Percentiles reported across all pathways in that category including pathways that do not reach net zero before
34 2100 (fraction of pathways reaching net zero is given in square brackets). If the fraction of pathways that reach
35 net zero before 2100 is lower than the fraction of pathways covered by a percentile (e.g. 0.95 for the 95th
36 percentile), the percentile is not defined and denoted with "...". Fraction of pathways reaching net zero is
37 calculated based on the native model emissions profiles.
38 **9** For cases where models do not report all GHGs, missing GHG species are infilled and calculated as Kyoto
39 basket in CO₂-eq using AR6 GWP100. For each pathway, a minimum of native reporting of CO₂, CH₄, and N₂O
40 emissions was required for the assessment of the climate response and assignment to a climate category. Emissions
41 pathways without climate assessment are not included in the ranges presented here. See Annex III for details.
42 **10** For better comparability with the WG I assessment of the remaining carbon budget, the cumulative GHG
43 emissions of the pathways are harmonized to the 2015 CO₂ emissions levels used in the WG I assessment and are
44 calculated for the future starting in 1 January 2020.
45 **11** Temperature change (Global Surface Air Temperature - GSAT) for category (at peak and in 2100), based on
46 the median warming for each pathway assessed using the probabilistic climate model emulators.
47 **12** Probability of staying below the temperature thresholds for the pathways in each category, taking into
48 consideration the range of uncertainty from the climate model emulators consistent with the WG I AR6
49 assessment. The probabilities refer to the probability at peak temperature. Note that in the case of temperature
50 overshoot (E.g., category C2 and some pathways in C1), the probabilities at the end of the century are higher than
51 the probability at peak temperature.

52 **Pathways following current NDCs until 2030 reach annual emissions of 47-57 GtCO₂-eq yr⁻¹ by**
53 **2030, thereby making it impossible to limit warming to 1.5°C with no or limited overshoot and**

1 **strongly increasing the challenge of likely limiting warming to 2°C (high confidence).** A high
2 overshoot of 1.5°C increases the risks from climate impacts and increases dependence on large scale
3 carbon dioxide removal from the atmosphere. A future consistent with current NDCs implies higher
4 fossil fuel deployment and lower reliance on low carbon alternatives until 2030, compared to mitigation
5 pathways describing immediate action that limits warming to 1.5°C with no or limited overshoot, or
6 *likely* limits warming to 2°C and below. After following the NDCs to 2030, to *likely* limit warming to
7 2°C the pace of global GHG emission reductions would need to abruptly increase from 2030 onward to
8 an average of 1.3-2.1 GtCO₂-eq per year between 2030 and 2050. This is similar to the global CO₂
9 emission reductions in 2020 that occurred due to the COVID-19 pandemic lockdowns, and around 70%
10 faster than in pathways where immediate action is taken to *likely* limit warming to 2°C. Accelerating
11 emission reductions after following an NDC pathway to 2030 would also be particularly challenging
12 because of the continued build-up of fossil fuel infrastructure that would take place between now and
13 2030. (TS 4.1, Table TS.3) {3.5, 4.2}

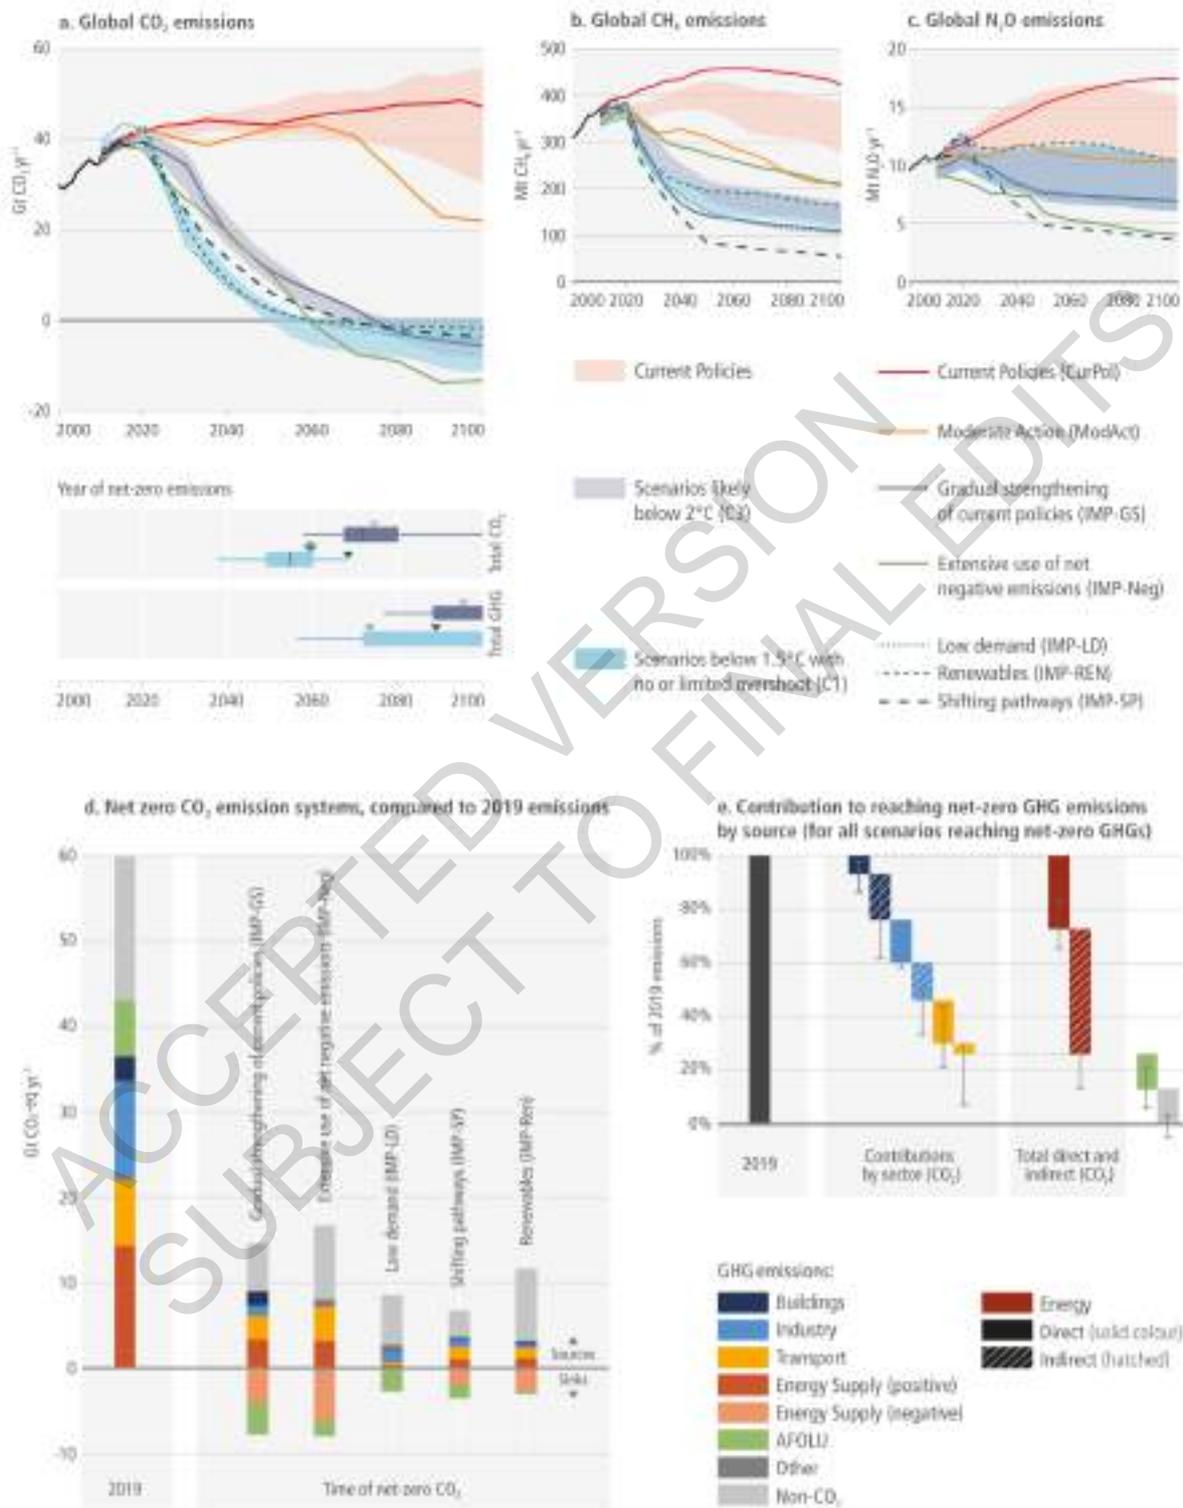

14 **Pathways accelerating action compared to current NDCs – that reduce annual GHG emissions to**
15 **47 (38-51) GtCO₂-eq by 2030 (which is 3-9 GtCO₂-eq below projected emissions from fully**
16 **implementing current NDCs) – make it less challenging to likely limit warming to 2°C after 2030**
17 **(medium confidence).** The accelerated action pathways are characterized by a global, but regionally
18 differentiated, roll-out of regulatory and pricing policies. Compared to current NDCs, they describe less
19 fossil fuel use and more low-carbon fuel use until 2030; they narrow, but do not close the gap to
20 pathways that assume immediate global action using all available least-cost abatement options. All
21 delayed or accelerated action pathways *likely* limiting warming to below 2°C converge to a global
22 mitigation regime at some point after 2030 by putting a significant value on reducing carbon and other
23 GHG emissions in all sectors and regions. {3.5}

24 **In mitigation pathways, peak warming is determined by the cumulative net CO₂ emissions until**
25 **the time of net zero CO₂ together with the warming contribution of other GHGs and climate**
26 **forcers at that time (high confidence).** Cumulative net CO₂ emissions from 2020 to the time of net
27 zero CO₂ are 510 (330-710) GtCO₂ in pathways that limit warming to 1.5°C with no or limited overshoot
28 and 890 (640-1160) GtCO₂ in pathways *likely* limiting warming to 2.0°C. These estimates are consistent
29 with the AR6 WG I assessment of remaining carbon budgets adjusting for methodological differences
30 and non-CO₂ warming. {3.3, Box 3.4}

31 **Rapid reductions in non-CO₂ GHGs, particularly CH₄, would lower the level of peak warming**
32 **(high confidence).** Non-CO₂ emissions – at the time of reaching net zero CO₂ – range between 4-11
33 GtCO₂-eq yr⁻¹ in pathways *likely* limiting warming to 2.0°C or below. CH₄ is reduced by around 20%
34 (1-46%) in 2030 and almost 50% (26-64%) in 2050, relative to 2019. CH₄ emission reductions in
35 pathways limiting warming to 1.5°C with no or limited overshoot are substantially higher by 2030, 33%
36 (19-57%), but only moderately so by 2050, 50% (33-69%). CH₄ emissions reductions are thus attainable
37 at comparatively low costs, but, at the same time, reductions are limited in scope in most 1.5-2°C
38 pathways. Deeper CH₄ emissions reductions by 2050 could further constrain the peak warming. N₂O
39 emissions are also reduced, but similar to CH₄, N₂O emission reductions saturate for more stringent
40 climate goals. The emissions of cooling aerosols in mitigation pathways decrease as fossil fuels use is
41 reduced. The overall impact on non-CO₂-related warming combines all these factors. {3.3}

42 **Net zero GHG emissions imply net negative CO₂ emissions at a level that compensates for residual**
43 **non-CO₂ emissions. Only 30% of the pathways likely limiting warming to 2°C or below reach net**
44 **zero GHG emissions in the 21st century (high confidence).** In those pathways reaching net zero
45 GHGs, net zero GHGs is achieved around 10-20 years later than net zero CO₂ is achieved (*medium*
46 *confidence*). The reported quantity of residual non-CO₂ emissions depends on accounting choices, and
47 in particular the choice of GHG metric (Box TS.2). Reaching and sustaining global net zero GHG

1 emissions – when emissions are measured and reported in terms of GWP100 – results in a gradual
 2 decline in temperature (*high confidence*). (Box TS.6) {3.3}

Figure TS.10: Mitigation pathways that limit warming to 1.5°C, or 2°C, involve deep, rapid and sustained emissions reductions. Net zero CO₂ and net zero GHG emissions are possible through different mitigation portfolios

1 **Figure TS.10 legend:** Panel a shows the development of global CO₂ emissions (upper sub-panel) and timing of
2 when emissions from different sources reach net zero CO₂ and GHG emissions (lower sub-panel). Panels b and
3 c show the development of global CH₄ and N₂O emissions, respectively. Ranges of baseline emissions pathways
4 (red), <scenarios below 1.5°C with no or limited overshoot pathways (light blue, category C1) and <scenarios
5 likely below 2°C pathways (grey, category C3) are compared to the emissions from two pathways illustrative of
6 high emissions (CurPol and ModAct) and five Illustrative Mitigation Pathways (IMPs): IMP-LD (low demand),
7 IMP-Ren (renewables), IMP-SP (shifting pathways), IMP-Neg (extensive use of CDR measures in the energy
8 and the industry sectors to achieve net negative emissions) and IMP-GS (Gradual strengthening of current
9 policies). The assessment of mitigation pathways explores a wide scenario space from the literature within
10 which seven illustrative pathways (IPs) are explored, composed of two sets: (i) one set of five Illustrative
11 Mitigation Pathways (IMPs) and (ii) one set of two reference pathways illustrative for of high emissions.

12 Panel d shows different net zero CO₂ emissions systems for the IMPs and the respective sectoral composition of
13 CO₂ and non-CO₂ emissions sources and sinks. The net zero CO₂ emissions systems are compared to the
14 emissions from the year 2019.

15 Panel e shows the contribution of different sectors and sources to the emissions reductions for reaching net-zero
16 GHG emissions. Bars denote the median emissions reductions for all pathways reaching net zero GHG
17 emissions. The full mitigation contributions of the service sectors (transport, buildings, industry) are split into
18 direct as well as indirect (up-stream) CO₂ emissions reductions. In addition, the contributions from the AFOLU
19 sector and reductions from non-CO₂ emissions sources (green and grey bars) are displayed.

20

21 **Pathways likely limiting warming to 2°C or 1.5°C and below exhibit substantial reductions in**
22 **emissions from all sectors (*high confidence*).** 1.5°C pathways with no or limited overshoot entail CO₂
23 emissions reductions between 2019 and 2050 of around 77% (31-96%) for energy demand, around
24 115% (90 to 167%) for energy supply, and around 148% (94 to 387%) for AFOLU.¹⁴ In pathways
25 likely limiting warming to 2°C, projected CO₂ emissions are reduced between 2019 and 2050 by around
26 49% for energy demand, 97% for energy supply, and 136% for AFOLU. (*medium confidence*) {3.4}

27 **If warming is to be limited, delaying or failing to achieve emissions reductions in one sector or**
28 **region necessitates compensating reductions in other sectors or regions (*high confidence*).**
29 Mitigation pathways show differences in the timing of decarbonisation and when net zero CO₂
30 emissions are achieved across sectors and regions. At the time of *global net zero CO₂ emissions*,
31 emissions in some sectors and regions are positive while others are negative; whether specific sectors
32 and regions are positive or negative depends on the availability and cost of mitigation options in those
33 regions, and the policies implemented. In cost-effective mitigation pathways, the energy supply sector
34 typically reaches net zero CO₂ before the economy as a whole, while the demand sectors reach net zero
35 CO₂ later, if ever (*high confidence*). (Figure TS.10) {3.4}

36 **Pathways likely limiting warming to 2°C or 1.5°C involve substantial reductions in fossil fuel**
37 **consumption and a near elimination of coal use without CCS (*high confidence*).** These pathways
38 show an increase in low carbon energy, with 88% (69-97%) of primary energy coming from low carbon
39 sources by 2100. {3.4}

40 **Stringent emissions reductions at the level required for 2°C or 1.5°C are achieved through the**
41 **increased electrification of buildings, transport, and industry, consequently all pathways entail**
42 **increased electricity generation (*high confidence*).** Nearly all electricity in pathways likely limiting
43 warming to 2°C or 1.5°C is also from low or no carbon technologies, with different shares across

FOOTNOTE ¹⁴ Reductions greater than 100% in energy supply and AFOLU indicate that these sectors would become carbon sinks.

1 pathways of: nuclear, biomass, non-biomass renewables, and fossil fuels in combination with CCS.
2 {3.4}

3 **Measures required to likely limit warming to 2°C or below can result in large scale transformation**
4 **of the land surface (*high confidence*).** These pathways are projected to reach net zero CO₂ emissions
5 in the AFOLU sector between the 2020s and 2070.

6 **Pathways limiting warming to 1.5°C with no or limited overshoot show an increase in forest cover**
7 **of about 322 million ha (-67 to 890 million ha) in 2050 (*high confidence*).** In these pathways the
8 cropland area to supply biomass for bioenergy (including bioenergy with carbon capture and storage
9 (BECCS)) is around 199 (56-482) million ha in 2100. The use of bioenergy can lead to either increased
10 or reduced emissions, depending on the scale of deployment, conversion technology, fuel displaced,
11 and how, and where, the biomass is produced (*high confidence*). {3.4}

12 **Pathways likely to limit warming to 2°C or 1.5°C require some amount of CDR to compensate**
13 **for residual GHG emissions, even after substantial direct emissions reductions are achieved in all**
14 **sectors and regions (*high confidence*).** CDR deployment in pathways serves multiple purposes:
15 accelerating the pace of emissions reductions, offsetting residual emissions, and creating the option for
16 net negative CO₂ emissions in case temperature reductions need to be achieved in the long term (*high*
17 *confidence*). CDR options in pathways are mostly limited to BECCS, afforestation and direct air CO₂
18 capture and storage (DACCS). CDR through some measures in AFOLU can be maintained for decades
19 but not over the very long term because these sinks will ultimately saturate (*high confidence*). {3.4}

20 **Mitigation pathways show reductions in energy demand, relative to reference scenarios that**
21 **assume continuation of current policies, through a diverse set of demand-side interventions (*high***
22 ***confidence*).** Bottom-up and non-IAM studies show significant potential for demand-side mitigation. A
23 stronger emphasis on demand-side mitigation implies less dependence on CDR and, consequently,
24 reduced pressure on land and biodiversity. {3.4, 3.7}

25 **Limiting warming requires shifting energy investments away from fossil-fuels and towards low-**
26 **carbon technologies (*high confidence*).** The bulk of investments are needed in medium- and low-
27 income regions. Investment needs in the electricity sector are on average 2.3 trillion USD₂₀₁₅ yr⁻¹ over
28 2023-2052 for pathways limiting temperature to 1.5°C with no or limited overshoot, and 1.7 trillion
29 USD₂₀₁₅ yr⁻¹ for pathways likely limiting warming to 2°C. {3.6.1}

30 **Pathways likely to avoid overshoot of 2°C warming require more rapid near-term**
31 **transformations and are associated with higher up-front transition costs, but at the same time**
32 **bring long-term gains for the economy as well as earlier benefits in avoided climate change**
33 **impacts (*high confidence*).** This conclusion is independent of the discount rate applied, though the
34 modelled cost-optimal balance of mitigation action over time does depend on the discount rate. Lower
35 discount rates favour earlier mitigation, reducing reliance on CDR and temperature overshoot. {3.6.1,
36 3.8}

37 **Mitigation pathways likely to limit warming to 2°C entail losses in global GDP with respect to**
38 **reference scenarios of between 1.3% and 2.7% in 2050. In pathways limiting warming to 1.5°C**
39 **with no or limited overshoot, losses are between 2.6% and 4.2%. These estimates do not account**
40 **for the economic benefits of avoided climate change impacts (*medium confidence*).** In mitigation
41 pathways likely to limit warming to 2°C, marginal abatement costs of carbon are about 90 (60-120)
42 USD₂₀₁₅/tCO₂ in 2030 and about 210 (140-340) USD₂₀₁₅/tCO₂ in 2050. This compares with about
43 220 (170-290) USD₂₀₁₅/tCO₂ in 2030 and about 630 (430-990) USD₂₀₁₅/tCO₂ in 2050¹⁵ in pathways
44 that limit warming to 1.5°C with no or limited overshoot. Reference scenarios, in the AR6 scenarios

FOOTNOTE ¹⁵ Numbers in parenthesis represent the interquartile range of the scenario samples.

1 database, describe possible emission trajectories in the absence of new stringent climate policies.
2 Reference scenarios have a broad range depending on socioeconomic assumptions and model
3 characteristics. {3.2.1, 3.6.1}

4 **The global benefits of pathways likely to limit warming to 2°C outweigh global mitigation costs**
5 **over the 21st century, if aggregated economic impacts of climate change are at the moderate to**
6 **high end of the assessed range, and a weight consistent with economic theory is given to economic**
7 **impacts over the long-term. This holds true even without accounting for benefits in other**
8 **sustainable development dimensions or non-market damages from climate change (*medium***
9 ***confidence*). The aggregate global economic repercussions of mitigation pathways include: the**
10 **macroeconomic impacts of investments in low-carbon solutions and structural changes away from**
11 **emitting activities; co-benefits and adverse side effects of mitigation; avoided climate change impacts;**
12 **and, reduced adaptation costs. Existing quantifications of the global aggregate economic impacts show**
13 **a strong dependence on socioeconomic development conditions, as these shape exposure and**
14 **vulnerability and adaptation opportunities and responses. Avoided impacts for poorer households and**
15 **poorer countries represent a smaller share in aggregate economic quantifications expressed in GDP or**
16 **monetary terms, whereas their well-being and welfare effects are comparatively larger. When aggregate**
17 **economic benefits from avoided climate change impacts are accounted for, mitigation is a welfare-**
18 **enhancing strategy (*high confidence*). {3.6.2}**

19 **The economic benefits on human health from air quality improvement arising from mitigation**
20 **action can be of the same order of magnitude as mitigation costs, and potentially even larger**
21 **(*medium confidence*). {3.6.3}**

22 **Differences in aggregate employment between mitigation pathways and reference scenarios are**
23 **relatively small, although there may be substantial reallocations across sectors, with job creation**
24 **in some sectors and job losses in others (*medium confidence*). The net employment effect (and**
25 **whether employment increases or decreases) depends on the scenario assumptions, modelling**
26 **framework, and modelled policy design. Mitigation has implications for employment through multiple**
27 **channels, each of which impacts geographies, sectors and skill-categories differently. {3.6.4}**

28 **The economic repercussions of mitigation vary widely across regions and households, depending**
29 **on policy design and the level of international cooperation (*high confidence*). Delayed global**
30 **cooperation increases policy costs across regions, especially in those that are relatively carbon intensive**
31 **at present (*high confidence*). Pathways with uniform carbon values show higher mitigation costs in**
32 **more carbon-intensive regions, in fossil-fuels exporting regions, and in poorer regions (*high***
33 ***confidence*). Aggregate quantifications expressed in GDP or monetary terms undervalue the economic**
34 **effects on households in poorer countries; the actual effects on welfare and well-being are**
35 **comparatively larger (*high confidence*). Mitigation at the speed and scale required to likely limit**
36 **warming to 2°C or below implies deep economic and structural changes, thereby raising multiple types**
37 **of distributional concerns across regions, income classes, and sectors (*high confidence*). (Box TS.7)**
38 **{3.6.1, 3.6.4}**

39

40 **START BOX TS.6 HERE**

41 **Box TS.6: Understanding net zero CO₂ and net zero GHG emissions**

42 Reaching net zero CO₂ emissions* globally along with reductions in other GHG emissions is necessary
43 to halt global warming at any level. At the point of net zero, the amount of CO₂ human activity is putting
44 into the atmosphere equals the amount of CO₂ human activity is removing from the atmosphere.
45 Reaching and sustaining net zero CO₂ emissions globally would stabilise CO₂-induced warming.

1 Moving to net negative CO₂ emissions globally would reduce peak cumulative net CO₂ emissions –
2 which occurs at the time of reaching net zero CO₂ emissions – and lead to a peak and decline in CO₂-
3 induced warming. {Cross-Chapter Box 3 in Chapter 3}

4 Reaching net zero CO₂ emissions sooner can reduce cumulative CO₂ emissions and result in less human-
5 induced global warming. Overall human-induced warming depends not only on CO₂ emissions but also
6 on the contribution from other anthropogenic climate forcers, including aerosols and other GHGs (e.g.
7 CH₄ and F-gases). To halt total human-induced warming, emissions of other GHG, in particular CH₄,
8 need to be strongly reduced.

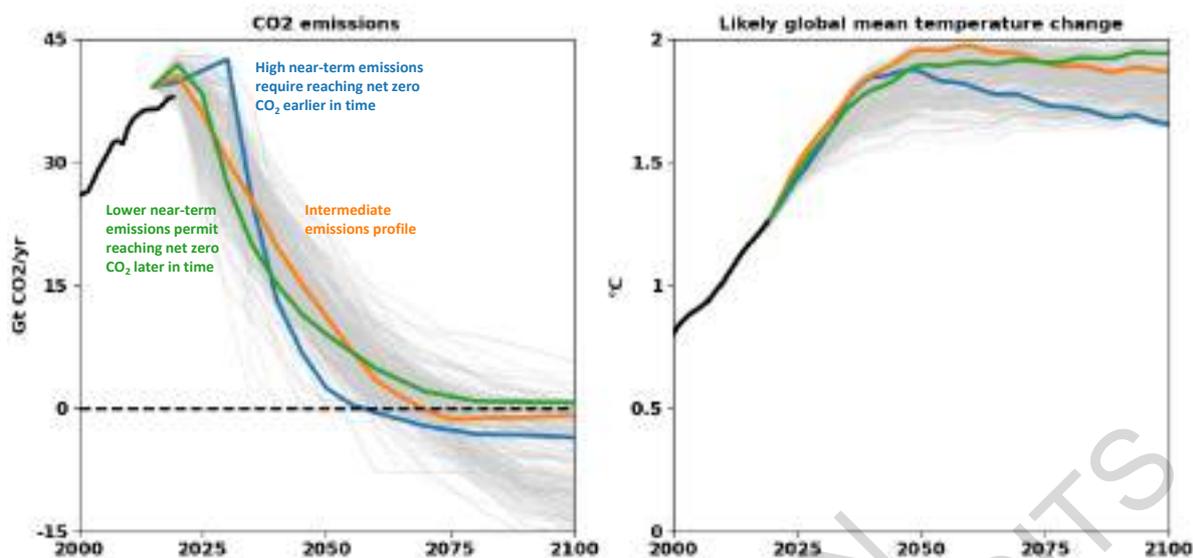

9 In the AR6 scenario database, global emissions pathways limiting warming to 1.5°C with no or limited
10 overshoot reach net zero CO₂ emissions between 2055-2060 (2035-2090) (median and 5-95th percentile
11 ranges; 100% of pathways); pathways *likely* to limit warming to 2°C reach net zero CO₂ emissions
12 between 2070-2075 (2055-2100) (median and 5-95th percentile ranges; 90% of pathways). This is later
13 than assessed in the AR6 SR1.5 primarily due to more pathways in the literature that approach net-zero
14 CO₂ emissions more gradually after a rapid decline of emissions until 2040. (Box TS.6 Figure 1)

15 It does not mean that the world has more time for emissions reductions while still limiting warming to
16 1.5°C than reported in the SR15. It only means that the exact timing of reaching net zero CO₂ after a
17 steep decline of CO₂ emissions until 2040 can show some variation. The SR1.5 median value of 2050
18 is still close to the middle of the current range. If emissions are reduced less rapidly in the period up to
19 2030, an earlier net-zero year is needed.

20 Reaching net zero GHG emissions requires net negative CO₂ emissions to balance residual CH₄, N₂O
21 and F-gas emissions. If achieved globally, net zero GHG emissions would reduce global warming from
22 an earlier peak. Around half global emission pathways limiting warming to 1.5°C, and a third of
23 pathways *likely* to limit warming to 2°C, reach net zero GHG emissions (based on GWP100) in the
24 second half of the century, around 10-40 years later than net zero CO₂ emissions. They show warming
25 being halted at some peak value followed by a gradual decline towards the end of the century. The
26 remainder of the pathways do not reach net zero GHG emissions during the 21st century and show little
27 decline of warming after it stabilised.

28 Global net zero CO₂ or GHG emissions can be achieved even while some sectors and regions continue
29 to be net emitters, provided that others achieve net GHG removal. Sectors and regions have different
30 potentials and costs to achieve net zero or even net GHG removal. The adoption and implementation of
31 net zero emission targets by countries and regions depends on multiple factors, including equity and
32 capacity criteria and international and cross-sectoral mechanisms to balance emissions and removals.
33 The formulation of net zero pathways by countries will benefit from clarity on scope, plans-of-action,
34 and fairness. Achieving net zero emission targets relies on policies, institutions and milestones against
35 which to track progress.

36

1

2 **Box TS.6 Figure 1: CO₂ Emissions (panel a) and temperature change (panel b) of three alternative**
 3 **pathways likely limiting warming to 2°C and reaching net zero CO₂ emissions at different points in time.**

4 **Box TS.6 Figure 1 legend:** Limiting warming to a specific level can be consistent with a range of dates when
 5 net zero CO₂ emissions need to be achieved. This difference in the date of net zero CO₂ emissions reflects the
 6 different emissions profiles that are possible while staying within a specific carbon budget and the associated
 7 warming limit. Shifting the year of net zero to a later point in time (>2050), however, requires more rapid and
 8 deeper near-term emissions reductions (in 2030 and 2040) if warming is to be limited to the same level.

9 *Note: in this assessment the terms *net zero CO₂ emissions* and *carbon neutrality* have different meanings and are
 10 only equivalent at the global scale. At the scale of regions, or sectors, each term applies different system
 11 boundaries. This is also the case for the related terms *net zero GHG* and *GHG neutrality*. {Cross-Chapter Box 3
 12 in Chapter 3}

13 **END BOX TS.6 HERE**

14

15

16

17

18

19

1 START BOX TS.7 HERE**2 Box TS.7 The Long-term Economic Benefits of Mitigation from Avoided Climate Change**
3 Impacts

4 Integrated studies use either a cost-effectiveness analysis (CEA) approach (minimising the total
5 mitigation costs of achieving a given policy goal) or a cost-benefit analysis (CBA) approach
6 (balancing the cost and benefits of climate action). In the majority of studies that have produced the
7 body of work on the cost of mitigation assessed in this report, a CEA approach is adopted, and the
8 feedbacks of climate change impacts on the economic development pathways are not accounted for.
9 This omission of climate impacts leads to overly optimistic economic projections in the reference
10 scenarios, in particular in reference scenarios with no or limited mitigation action where the extent of
11 global warming is the greatest. Mitigation cost estimates computed against no or limited policy
12 reference scenarios therefore omit economic benefits brought by avoided climate change impact along
13 mitigation pathways. {1.7, 3.6.1}

14 The difference in aggregate economic impacts from climate change between two given temperature
15 levels represents the aggregate economic benefits arising from avoided climate change impacts due to
16 mitigation action. Estimates of these benefits vary widely, depending on the methodology used and
17 impacts included, as well as on assumed socioeconomic development conditions, which shape exposure
18 and vulnerability. The aggregate economic benefits of avoiding climate impacts increase with the
19 stringency of the mitigation. Global economic impact studies with regional estimates find large
20 differences across regions, with developing and transitional economies typically more vulnerable.
21 Furthermore, avoided impacts for poorer households and poorer countries represent a smaller share in
22 aggregate quantifications expressed in GDP terms or monetary terms, compared to their influence on
23 well-being and welfare (*high confidence*). {3.6.2, Cross-Working Group Box 1 in Chapter 3}

24 CBA analysis and CBA integrated assessment models remain limited in their ability to represent all
25 damages from climate change, including non-monetary damages, and capture the uncertain and
26 heterogeneous nature of damages and the risk of catastrophic damages, such that other lines of evidence
27 should be considered in decision-making. However, emerging evidence suggests that, even without
28 accounting for co-benefits of mitigation on other sustainable development dimensions, the global
29 benefits of pathways *likely* to limit warming to 2°C outweigh global mitigation costs over the 21st
30 century (*medium confidence*). Depending on the study, the reason for this result lies in assumptions of
31 economic damages from climate change in the higher end of available estimates, in the consideration
32 of risks of tipping-points or damages to natural capital and non-market goods, or in the combination of
33 updated representations of carbon cycle and climate modules, updated damage estimates and updated
34 representations of economic and mitigation dynamics. In the studies that perform a sensitivity analysis,
35 this result is found to be robust to a wide range of assumptions on social preferences (in particular on
36 inequality aversion and pure rate of time preference), and holds except if assumptions of economic
37 damages from climate change are in the lower end of available estimates and the pure rate of time
38 preference is in the higher range of values usually considered (typically above 1.5%). However,
39 although such pathways bring overall net benefits over time (in terms of aggregate discounted present
40 value), they involve distributional consequences between and within generations. {3.6.2}

41 END BOX TS.7 HERE

1 **TS. 5 Mitigation responses in sectors and systems**

2 Chapters 5-12 assess recent advances in knowledge in individual sectors and systems. These chapters
3 – *Energy* (Chapter 6), *Urban and other settlements* (Chapter 8), *Transport* (Chapter 10), *Buildings*
4 Chapter 9), *Industry* (Chapter 11), and *Agriculture, forestry and other land use (AFOLU)* (Chapter 7) –
5 correspond broadly to the IPCC National Greenhouse Gas Inventory reporting categories and build on
6 similar chapters in previous WG III reports. Chapters 5 and 12 tie together the cross-sectoral aspects of
7 this group of chapters including the assessment of costs and potentials, demand side aspects of
8 mitigation, and carbon dioxide removal (CDR).

9 **TS. 5.1 Energy**

10 **A broad-based approach to deploying energy sector mitigation options can reduce emissions over**
11 **the next ten years and set the stage for still deeper reductions beyond 2030 (*high confidence*).**

12 There are substantial, cost-effective opportunities to reduce emissions rapidly, including in electricity
13 generation, but near-term reductions will not be sufficient to *likely* limit warming to 2°C or limit
14 warming to 1.5°C with no or limited overshoot. {6.4, 6.6, 6.7}

15 **Warming cannot be limited to 2°C or 1.5°C without rapid and deep reductions in energy system**
16 **CO₂ and GHG emissions (*high confidence*).** In scenarios *likely* limiting warming to 1.5°C with no or
17 limited overshoot (*likely* below 2°C), net energy system CO₂ emissions (interquartile range) fall by 87%
18 to 97% (60% to 79%) in 2050. In 2030, in scenarios limiting warming to 1.5°C with no or limited
19 overshoot, net CO₂ and GHG emissions fall by 35-51% and 38-52% respectively. In scenarios limiting
20 warming to 1.5°C with no or limited overshoot (*likely* below 2°C), net electricity sector CO₂ emissions
21 reach zero globally between 2045 and 2055 (2050 and 2080) (*high confidence*). {6.7}

22 **Limiting warming to 2°C or 1.5°C will require substantial energy system changes over the next**
23 **30 years. This includes reduced fossil fuel consumption, increased production from low- and zero-**
24 **carbon energy sources, and increased use of electricity and alternative energy carriers (*high***
25 ***confidence*).** Coal consumption without CCS falls by 67% to 82% (interquartile range) in 2030 in
26 scenarios limiting warming to 1.5°C with no or limited overshoot. Oil and gas consumption fall more
27 slowly. Low-carbon sources produce 93% to 97% of global electricity by 2050 in scenarios that *likely*
28 limit warming to 2°C or below. In scenarios limiting warming to 1.5°C with no or limited overshoot
29 (*likely* below 2°C), electricity supplies 48% to 58% (36% to 47%) of final energy in 2050, up from 20%
30 in 2019. {6.7}

31 **Net zero energy systems will share common characteristics, but the approach in every country**
32 **will depend on national circumstances (*high confidence*).** Common characteristics of net-zero energy
33 systems will include: (1) electricity systems that produce no net CO₂ or remove CO₂ from the
34 atmosphere; (2) widespread electrification of end uses, including light-duty transport, space heating,
35 and cooking; (3) substantially lower use of fossil fuels than today; (4) use of alternative energy carriers
36 such as hydrogen, bioenergy, and ammonia to substitute for fossil fuels in sectors less amenable to
37 electrification; (5) more efficient use of energy than today; (6) greater energy system integration across
38 regions and across components of the energy system; and (7) use of CO₂ removal including DACCS
39 and BECCS to offset residual emissions. {6.6}

40 **Energy demands and energy sector emissions have continued to rise (*high confidence*).** From 2015
41 to 2019, global final energy consumption grew by 6.6%, CO₂ emissions from the global energy system
42 grew by 4.6%, and total GHG emissions from energy supply rose by 2.7%. Fugitive CH₄ emissions
43 from oil, gas, and coal, accounted for 5.8% of GHG emissions in 2019. Coal electricity capacity grew
44 by 7.6% between 2015 and 2019, as new builds in some countries offset declines in others. Total
45 consumption of oil and oil products increased by 5%, and natural gas consumption grew by 15%.

1 Declining energy intensity in almost all regions has been balanced by increased energy consumption.
2 {6.3}

3 **The unit costs for several key energy system mitigation options have dropped rapidly over the**
4 **last five years, notably solar PV, wind power, and batteries (*high confidence*).** From 2015 to 2020,
5 the costs of electricity from PV and wind dropped 56% and 45%, respectively, and battery prices
6 dropped by 64%. Electricity from PV and wind is now cheaper than electricity from fossil sources in
7 many regions, electric vehicles are increasingly competitive with internal combustion engines, and
8 large-scale battery storage on electricity grids is increasingly viable. (Figure TS.7) {6.3, 6.4}

9 **Global wind and solar PV capacity and generation have increased rapidly driven by policy,**
10 **societal pressure to limit fossil generation, low interest rates, and cost reductions (*high***
11 ***confidence*).** Solar PV grew by 170% (to 680 TWh); wind grew by 70% (to 1420 TWh) from 2015 to
12 2019. Solar PV and wind together accounted for 21% of total low-carbon electricity generation and 8%
13 of total electricity generation in 2019. Nuclear generation grew 9% between 2015 and 2019 and
14 accounted for 10% of total generation in 2019 (2790 TWh); hydroelectric power grew by 10% and
15 accounted for 16% (4290 TWh) of total generation. In total, low- and zero-carbon electricity generation
16 technologies produced 37% of global electricity in 2019. {6.3, 6.4}

17 **If investments in coal and other fossil infrastructure continue, energy systems will be locked-in to**
18 **higher emissions, making it harder to limit warming to 2°C or 1.5°C (*high confidence*).** Many
19 aspects of the energy system – physical infrastructure; institutions, laws, and regulations; and behaviour
20 – are resistant to change or take many years to change. New investments in coal-fired electricity without
21 CCS are inconsistent with limiting warming to 2°C or 1.5°C. {6.3, 6.7}

22 **Limiting warming to 2°C or 1.5°C will strand fossil-related assets, including fossil infrastructure**
23 **and unburned fossil fuel resources (*high confidence*).** The economic impacts of stranded assets could
24 amount to trillions of dollars. Coal assets are most vulnerable over the coming decade; oil and gas assets
25 are more vulnerable toward mid-century. CCS can allow fossil fuels to be used longer, reducing
26 potential stranded assets. (Box TS.8) {6.7}

27

28 **START BOX TS.8 HERE**

29

Box TS. 8: Stranded Assets

30 Limiting warming to 2°C or 1.5°C is expected to result in the “stranding” of carbon-intensive
31 assets. Stranded assets can be broadly defined as assets which “suffer from unanticipated or premature
32 write-offs, downward revaluations or conversion to liabilities”. Climate policies, other policies and
33 regulations, innovation in competing technologies, and shifts in fuel prices could all lead to stranded
34 assets. The loss of wealth from stranded assets would create risks for financial market
35 stability, reduce fiscal revenue for hydrocarbon dependent economies, in turn affecting macro-
36 economic stability and the prospects for a just transition. (Box TS.4) {6.7, 15.6, Chapter 17}

37 Two types of assets are at risk of being stranded: i) in-ground fossil resources and ii) human-made
38 capital assets (e.g., power plants, cars). About 30% of oil, 50% of gas, and 80% of coal reserves will
39 remain unburnable if warming is limited to 2°C. {6.7, Box 6.11}

40 Practically all long-lived technologies and investments that cannot be adapted to low-carbon and zero-
41 emission modes could face stranding under climate policy – depending on their current age and
42 expected lifetimes. Scenario evidence suggests that without carbon capture, the worldwide fleet of coal-
43 and gas power plants would need to retire about 23 and 17 years earlier than expected lifetimes,
44 respectively in order to limit global warming to 1.5°C and 2°C {2.7}. Blast furnaces and cement
45 factories without CCS {11.4}, new fleets of airplanes and internal combustion engine vehicles {10.4,

1 10.5}, and new urban infrastructures adapted to sprawl and motorisation may also be stranded
2 {Chapter 8; Box 10.1}.

3 Many countries, businesses, and individuals stand to lose wealth from stranded assets. Countries,
4 businesses, and individuals may therefore desire to keep assets in operation even if financial, social, or
5 environmental concerns call for retirement. This creates political economic risks, including actions by
6 asset owners to hinder climate policy reform {6.7; Box 6.11}. It will be easier to retire these assets
7 if the risks are communicated, if sustainability reporting is mandated and enforced, and if
8 corporations are protected with arrangements that shield them from short-term shareholder value
9 maximisation.

10 Without early retirements, or reductions in utilisation, the current fossil infrastructure will emit more
11 GHGs than is compatible with limiting warming to 1.5°C {2.7}. Including the pipeline of planned
12 investments would push these future emissions into the uncertainty range of 2°C carbon budgets {2.7}.
13 Continuing to build new coal-fired power plants and other fossil infrastructure will increase future
14 transition costs and may jeopardize efforts to *likely* limit warming to 2°C or 1.5°C with no or limited
15 overshoot. One study has estimated that USD11.8 trillion in current assets will need to be stranded by
16 2050 for 2°C world; further delaying action for another 10 years would result in an additional USD7.7
17 trillion in stranded assets by 2050. {15.5.2}

18 Experience from past stranding indicates that compensation for the devaluation costs of private sector
19 stakeholders by the public sector is common. Limiting new investments in fossil technologies hence
20 also reduces public finance risks in the long term. {15.6.3}

21 **END BOX TS.8 HERE**

22

23 **A low-carbon energy transition will shift investment patterns and create new economic**
24 **opportunities (*high confidence*)**. Total energy investment needs will rise, relative to today, over the
25 next decades, if it is to be likely that warming is limited to 2°C, or if warming is limited to 1.5°C with
26 no or limited overshoot. These increases will be far less pronounced, however, than the reallocations of
27 investment flows that are anticipated across sub-sectors, namely from fossil fuels (extraction,
28 conversion, and electricity generation) without CCS and toward renewables, nuclear power, CCS,
29 electricity networks and storage, and end-use energy efficiency. A significant and growing share of
30 investments between now and 2050 will be made in emerging economies, particularly in Asia. {6.7}

31 **Climate change will affect many future local and national low-carbon energy systems. The**
32 **impacts, however, are uncertain, particularly at the regional scale (*high confidence*)**. Climate
33 change will alter hydropower production, bioenergy and agricultural yields, thermal power plant
34 efficiencies, and demands for heating and cooling, and it will directly impact power system
35 infrastructure. Climate change will not affect wind and solar resources to the extent that it would
36 compromise their ability to reduce emissions. {6.5}

37 **Electricity systems powered predominantly by renewables will be increasingly viable over the**
38 **coming decades, but it will be challenging to supply the entire energy system with renewable**
39 **energy (*high confidence*)**. Large shares of variable solar PV and wind power can be incorporated in
40 electricity grids through batteries, hydrogen, and other forms of storage; transmission; flexible non-
41 renewable generation; advanced controls; and greater demand-side responses. Because some
42 applications (e.g., aviation) are not currently amenable to electrification, it is anticipated that 100%
43 renewable energy systems will need to include alternative fuels such as hydrogen or biofuels. Economic,
44 regulatory, social, and operational challenges increase with higher shares of renewable electricity and
45 energy. The ability to overcome these challenges in practice is not fully understood. (Box TS.9) {6.6}

1 START BOX TS.9 HERE

2

3

Box TS.9: The Transformation in Energy Carriers: Electrification and Hydrogen

4

5

6

7

8

To use energy, it must be “carried” from where it was produced – at a power plant, for example, or a refinery, or a coal mine – to where it is used. As countries reduce CO₂ emissions, they will need to switch from gasoline and other petroleum-based fuels, natural gas, coal, and electricity produced from these fossil fuels to energy carriers with little or no carbon footprint. An important question is which new energy carriers will emerge to support low-carbon transitions.

9

Low-carbon energy systems are expected to rely heavily on end-use electrification, where electricity produced with low GHG emissions is used for building and industrial heating, transport and other applications that rely heavily on fossil fuels at present. But not all end-uses are expected to be commercially electrifiable in the short to medium term {11.3.5}, and many will require low GHG liquid and gaseous fuels, i.e., hydrogen, ammonia, and biogenic and synthetic low GHG hydrocarbons made from low GHG hydrogen, oxygen and carbon sources (the latter from CCU¹⁶, biomass, or direct air capture {11.3.6}). The future role of hydrogen and hydrogen derivatives will depend on how quickly and how far production technology improves, i.e. from electrolysis (“green”), biogasification, and fossil fuel reforming with CCS (“blue”) sources. As a general rule, and across all sectors, it is more efficient to use electricity directly and avoid the progressively larger conversion losses from producing hydrogen, ammonia, or constructed low GHG hydrocarbons. What hydrogen does do, however, is add time and space option value to electricity produced using variable clean sources, for use as hydrogen, as stored future electricity via a fuel cell or turbine, or as an industrial feedstock. Furthermore, electrification and hydrogen involve a symbiotic range of general-purpose technologies, such as electric motors, power electronics, heat pumps, batteries, electrolysis, fuel cells etc., that have different applications across sectors but cumulative economies of innovation and production scale benefits. Finally, neither electrification nor hydrogen produce local air pollutants at point of end-use.

26

27

28

29

30

For almost 140 years we have primarily produced electricity by burning coal, oil, and gas to drive steam turbines connected to electricity generators. When switching to low-carbon energy sources – renewable sources, nuclear power, and fossil or bioenergy with CCS – electricity is expected to become a more pervasive energy carrier. Electricity is a versatile energy carrier, with much higher end-use efficiencies than fuels, and it can be used directly to avoid conversion losses.

42

An increasing reliance on electricity from variable renewable sources, notably wind and solar power, disrupts old concepts and makes many existing guidelines obsolete for power system planning, e.g., that specific generation types are needed for baseload, intermediate load, and peak load to follow and meet demand. In future power systems with high shares of variable electricity from renewable sources, system planning and markets will focus more on demand flexibility, grid infrastructure and interconnections, storage on various timelines (on the minute, hourly, overnight and seasonal scale), and increased coupling between the energy sector and the building, transport and industrial sectors. This shifts the focus to energy systems that can handle variable supply rather than always follow demand. Hydrogen may prove valuable to improve the resilience of electricity systems with high penetration of variable renewable electricity. Flexible hydrogen electrolysis, hydrogen power plants and long-duration hydrogen storage may all improve resilience. Electricity-to-hydrogen-to-electricity round-trip efficiencies are projected to reach up to 50% by 2030. {6.4.3}

FOOTNOTE¹⁶ Carbon dioxide capture and utilisation (CCU) refers to a process in which CO₂ is captured and the carbon is then used in a product. The climate effect of CCU depends on the product lifetime, the product it displaces, and the CO₂ source (fossil, biomass or atmosphere). CCU is sometimes referred to as Carbon Dioxide Capture and Use, or Carbon Capture and Utilisation.

1 Electrification is expected to be the dominant strategy in buildings as electricity is increasingly used for
2 heating and for cooking. Electricity will help to integrate renewable energy into buildings and will also
3 lead to more flexible demand for heating, cooling, and electricity. District heating and cooling offers
4 potential for demand flexibility through energy storage and supply flexibility through cogeneration.
5 Heat pumps are increasingly used in buildings and industry for heating and cooling {9.3.3, Box 9.3}.
6 The ease of switching to electricity means that hydrogen is not expected to be a dominant pathway for
7 buildings {Box 9.6}. Using electricity directly for heating, cooling and other building energy demand
8 is more efficient than using hydrogen as a fuel, for example, in boilers or fuel cells. In addition,
9 electricity distribution is already well developed in many regions compared to essentially non-existent
10 hydrogen infrastructure, except for a few chemicals industry pipelines. At the same time, hydrogen
11 could potentially be used for on-site storage should technology advance sufficiently.

12 Electrification is already occurring in several modes of personal and light freight transport, and vehicle-
13 to-grid solutions for flexibility have been extensively explored in the literature and small-scale pilots.
14 The role of hydrogen in transport depends on how far technology develops. Batteries are currently a
15 more attractive option than hydrogen and fuel-cells for light-duty vehicles. Hydrogen and hydrogen-
16 derived synthetic fuels, such as ammonia and methanol, may have a more important role in heavy
17 vehicles, shipping, and aviation {10.3}. Current transport of fossil fuels may be replaced by future
18 transport of hydrogen and hydrogen carriers such as ammonia and methanol, or energy intensive basic
19 materials processed with hydrogen (e.g. reduced iron) in regions with bountiful renewable resources.
20 {Box 11.1}

21 Both light and heavy industry are potentially large and flexible users of electricity for both final energy
22 use (e.g., directly and using heat pumps in light industry) and for feedstocks (e.g., hydrogen for steel
23 making and chemicals). For example, industrial process heat demand, ranging from below 100°C to
24 above 1000 °C, can be met through a wide range of electrically powered technologies instead of using
25 fuels. Future demand for hydrogen (e.g., for nitrogen fertiliser or as reduction agent in steel production)
26 also offers electricity demand flexibility for electrolysis through hydrogen storage and flexible
27 production cycles {11.3.5}. The main use of hydrogen and hydrogen carriers in industry is expected to
28 be as feedstock (e.g., for ammonia and organic chemicals) rather than for energy as industrial
29 electrification increases.

30 **END BOX TS.9 HERE**

31

32 **Multiple energy supply options are available to reduce emissions over the next decade (*high***
33 ***confidence*)**. Nuclear power and hydropower are already established technologies. Solar PV and wind
34 are now cheaper than fossil-generated electricity in many locations. Bioenergy accounts for about a
35 tenth of global primary energy. Carbon capture is widely used in the oil and gas industry, with early
36 applications in electricity production and biofuels. It will not be possible to widely deploy all of these
37 and other options without efforts to address the geophysical, environmental-ecological, economic,
38 technological, socio-cultural, and institutional factors that can facilitate or hinder their implementation.
39 (*high confidence*). (Figure TS.11, Figure TS.31) {6.4}

40 **Enhanced integration across energy system sectors and across scales will lower costs and facilitate**
41 **low-carbon energy system transitions (*high confidence*)**. Greater integration between the electricity
42 sector and end use sectors can facilitate integration of variable renewable energy options. Energy
43 systems can be integrated across district, regional, national, and international scales (*high confidence*).
44 {6.4, 6.6}

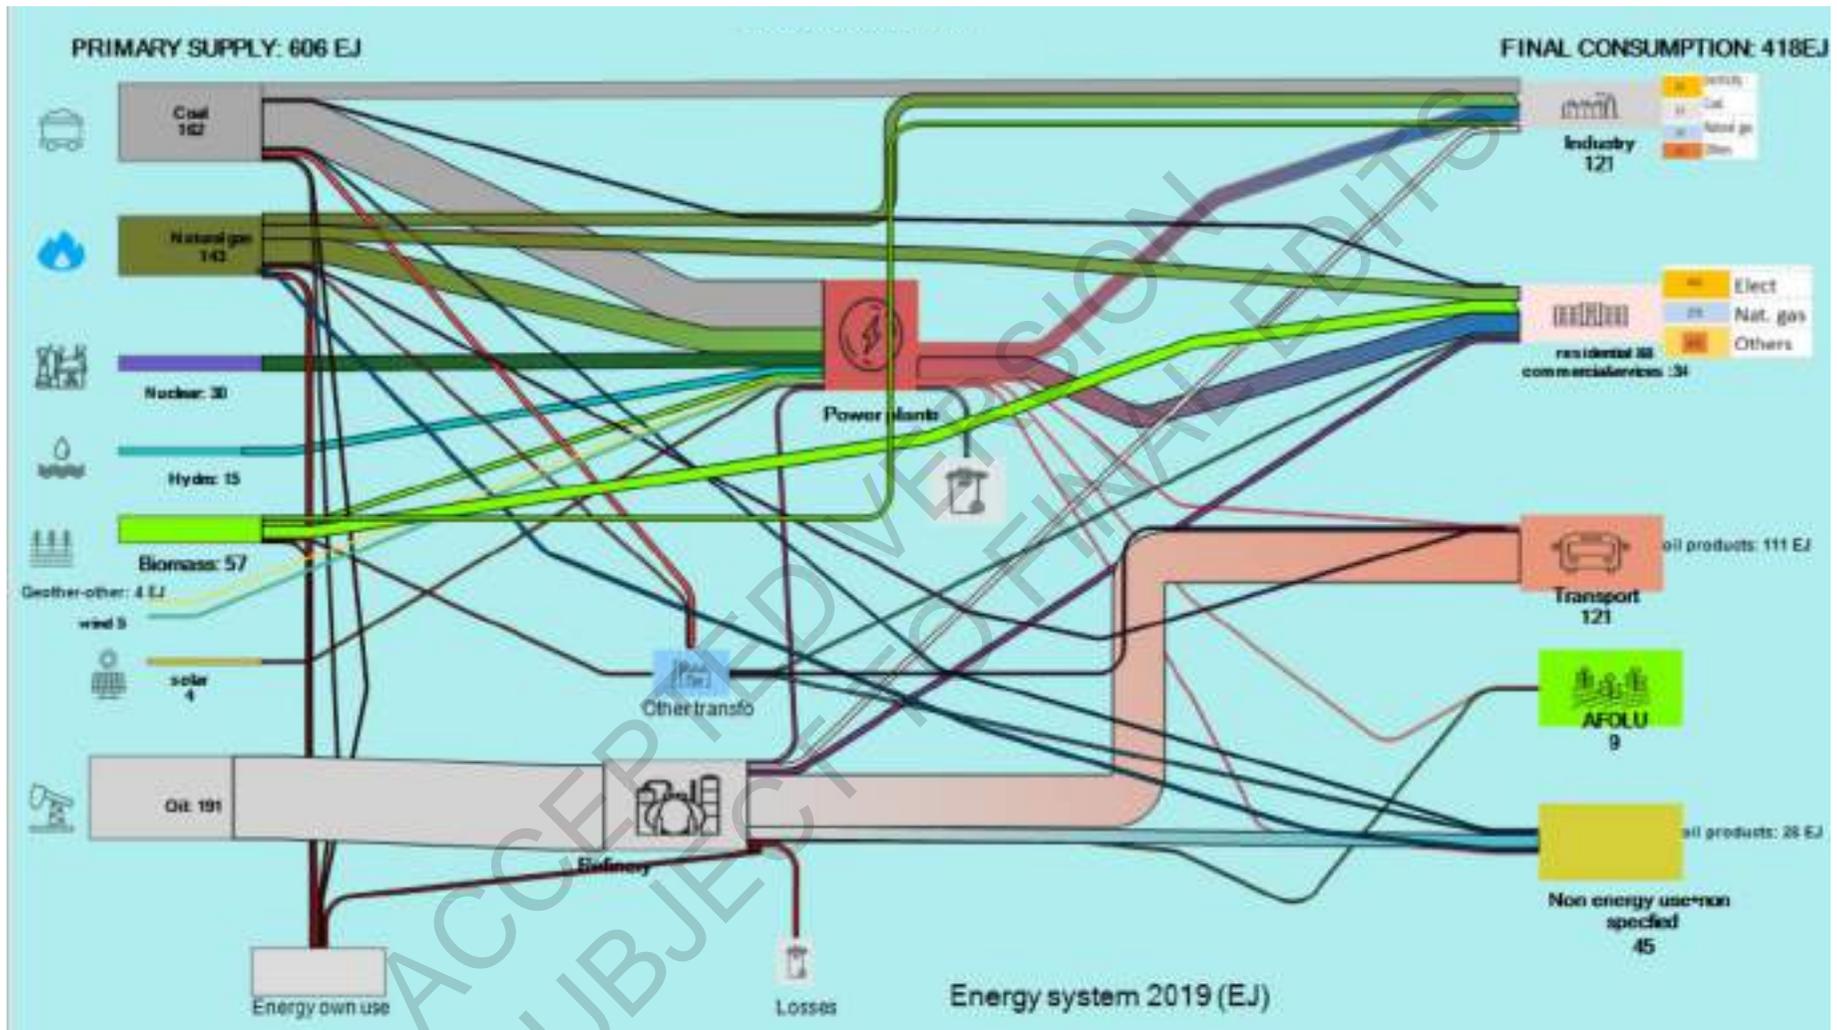

45 **The viable speed and scope of a low-carbon energy system transition will depend on how well it**
46 **can support SDGs and other societal objectives (*high confidence*)**. Energy systems are linked to a

1 range of societal objectives, including energy access, air and water pollution, health, energy security,
2 water security, food security, economic prosperity, international competitiveness, and employment.
3 These linkages and their importance vary among regions. Energy sector mitigation and efforts to
4 achieve SDGs generally support one another, though there are important region-specific exceptions.
5 (*high confidence*). (Figure TS.29) {6.1, 6.7}

6 **The economic outcomes of low-carbon transitions in some sectors and regions may be on par with,**
7 **or superior to those of an emissions-intensive future (*high confidence*).** Cost reductions in key
8 technologies, particularly in electricity and light-duty transport, have increased the economic
9 attractiveness of near-term low-carbon transitions. Long-term mitigation costs are not well understood
10 and depend on policy design and implementation, and the future costs and availability of technologies.
11 Advances in low-carbon energy resources and carriers such as next-generation biofuels, hydrogen
12 produced from electrolysis, synthetic fuels, and carbon-neutral ammonia would substantially improve
13 the economics of net zero energy systems (*medium confidence*). {6.4, 6.7}

Panel b: flows within an illustrative future net zero CO₂ emissions global energy system

Panel c: flows within an illustrative future net zero CO₂ emissions global energy system

Figure TS.11 Global energy flows within the 2019 global energy system (panel a) and within two illustrative futures, net zero CO₂ emissions global energy systems (panels b and c)

Figure TS.11 legend: Flows below 1 EJ are not represented, rounded figures. The illustrative net zero scenarios correspond to the year in which net energy system CO₂ emissions reach zero {Figure 6.1}

1 **TS. 5.2 Urban and other settlements**

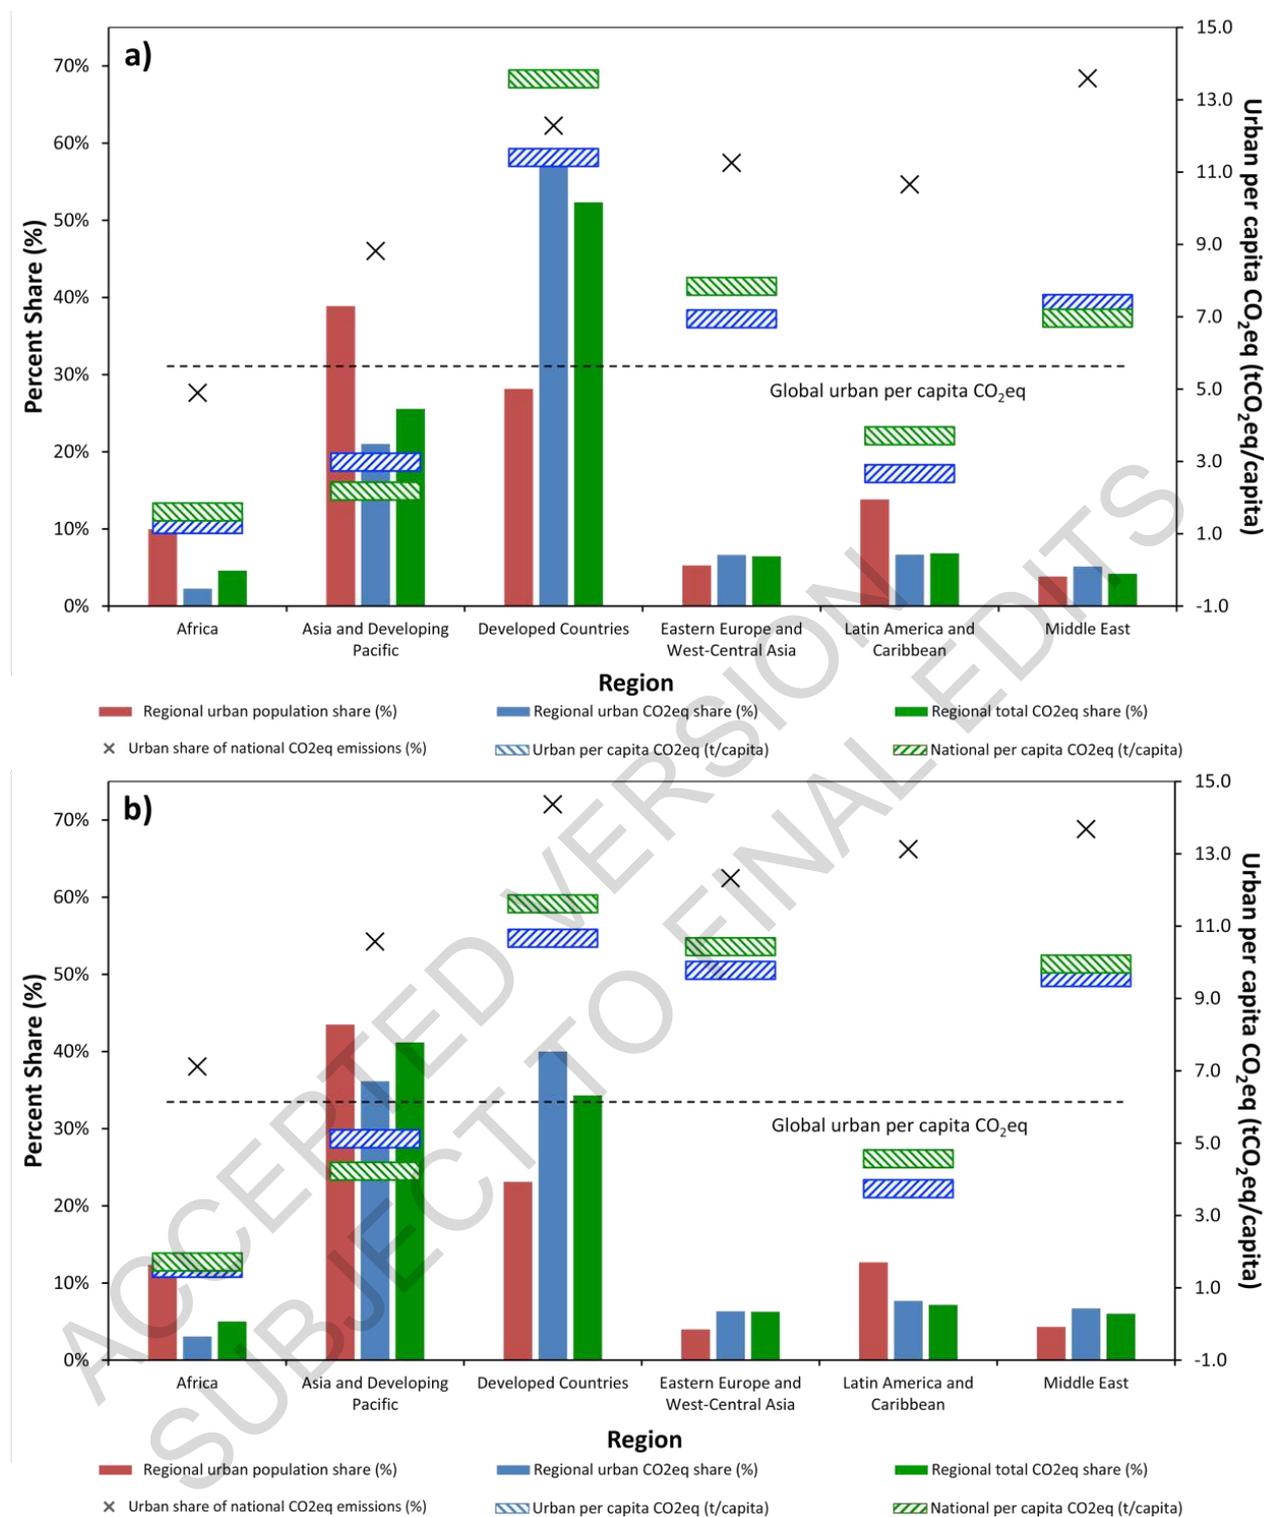

2 **Although urbanisation is a global trend often associated with increased incomes and higher**
3 **consumption, the growing concentration of people and activities is an opportunity to increase**
4 **resource efficiency and decarbonise at scale (*very high confidence*).** The same urbanisation level can
5 have large variations in per capita urban carbon emissions. For most regions, per capita urban emissions
6 are lower than per capita national emissions (*very high confidence*). {8.1.4, 8.3.3, 8.4, Box 8.1}

7 **Most future urban population growth will occur in developing countries, where per capita**
8 **emissions are currently low but are expected to increase with the construction and use of new**
9 **infrastructure and the built environment, and changes in incomes and lifestyles (*very high***
10 ***confidence*).** The drivers of urban GHG emissions are complex and include an interplay of population
11 size, income, state of urbanisation, and how cities are laid out. How new cities and towns are designed,
12 constructed, managed, and powered will lock-in behaviour, lifestyles, and future urban GHG emissions.
13 Urban strategies can improve well-being while minimising impact on GHG emissions. However,
14 urbanisation can result in increased global GHG emissions through emissions outside the city's
15 boundaries (*very high confidence*). {8.1.4, 8.3, Box 8.1, 8.4, 8.6}

16 **The urban share of combined global (CO₂ and CH₄ emissions is substantial and continues to**
17 **increase (*high confidence*).** Urban areas generated between 67–72% (~28 GtCO₂-eq) of combined
18 global CO₂ and CH₄ emissions in 2020 through the production and consumption of goods and services.
19 These emissions are projected to rise to 34–65 GtCO₂-eq by 2050 with moderate to no mitigation efforts,
20 driven by a growing population, infrastructure, and service demands in urban areas. About 100 of the
21 highest emitting urban areas account for approximately 18% of the global carbon footprint (*high*
22 *confidence*). {8.1.6, 8.3.3}

23 **The urban share of regional GHG emissions increased between 2000 and 2015, with much inter-**
24 **regional variation in the magnitude of the increase (*high confidence*).** Globally, the urban share of
25 national emissions increased six percentage points, from 56% in 2000 to 62% in 2015. For 2000 to
26 2015, the urban emissions share increased from 28% to 38% in Africa, from 46% to 54% in Asia and
27 Developing Pacific, from 62% to 72% in Developed Countries, from 57% to 62% in Eastern Europe
28 and West-Central Asia, from 55% to 66% in Latin America and Caribbean, and from 68% to 69% in
29 the Middle East (*high confidence*). {8.1.6, 8.3.3}

30 **Per capita urban GHG emissions increased between 2000 and 2015, with cities in developed**
31 **countries accounting for nearly seven times more per capita than the lowest emitting region**
32 **(*medium confidence*).** From 2000 to 2015, global urban GHG emissions per capita increased from 5.5
33 to 6.2 tCO₂-eq per person (an increase of 11.8%). Emissions in Africa increased from 1.3 to 1.5 tCO₂-
34 eq per person (22.6%); in Asia and Developing Pacific from 3.0 to 5.1 tCO₂-eq per person (71.7%); in
35 Eastern Europe and West-Central Asia from 6.9 to 9.8 tCO₂-eq per person (40.9%); in Latin America
36 and the Caribbean from 2.7 to 3.7 tCO₂-eq per person (40.4%); and in the Middle East from 7.4 to 9.6
37 tCO₂-eq per person (30.1%). Albeit starting from the highest level, developed countries showed a
38 modest decline of 11.4 to 10.7 tCO₂-eq per person (-6.5%). (Figure TS.12) {8.3.3}

Figure TS.12 Changes in six metrics associated with urban and national-scale combined CO₂ and CH₄ emissions represented in the WG III AR6 6-region aggregation, with (a) 2000 and (b) 2015

Figure TS.12 legend: The total values exclude aviation, shipping, and biogenic sources. The dashed grey line represents the global average urban per capita CO₂-eq emissions. The regional urban population share, regional CO₂-eq share in total emissions, and national per capita CO₂-eq emissions by region are given for comparison. {Figure 8.9}

1 **The global share of future urban GHG emissions is expected to increase through 2050 with**
2 **moderate to no mitigation efforts due to growth trends in population, urban land expansion and**
3 **infrastructure and service demands, but the extent of the increase depends on the scenario and**
4 **the scale and timing of urban mitigation action (*medium confidence*).** With aggressive and
5 immediate mitigation policies to limit global warming to 1.5°C by the end of the century, including
6 high levels of electrification, energy and material efficiency, renewable energy preferences, and socio-
7 behavioural responses, urban GHG emissions could approach net zero and reach a maximum of 3
8 GtCO₂-eq in 2050. Under a scenario with aggressive but not immediate urban mitigation policies to
9 limit global warming to 2°C, urban emissions could reach 17 GtCO₂-eq in 2050. With no urban
10 mitigation efforts, urban emissions could more than double from 2020 levels and reach 65 GtCO₂-eq in
11 2050, while being limited to 34 GtCO₂-eq in 2050 with only moderate mitigation efforts. (Figure TS.13)
12 {8.3.4}

3 **Figure TS.13 Panel a: Carbon dioxide equivalent emissions from global urban areas from 1990 to 2100. Urban areas are aggregated to five regional domains;**
 4 **Panel b: Comparison of urban emissions under different urbanisation scenarios ($GtCO_2\text{-eq yr}^{-1}$) for different regions {Figure 8.13, Figure 8.14}**

1 **Urban land areas could triple between 2015 and 2050, with significant implications for future**
2 **carbon lock-in (*medium confidence*)**. There is a large range in the forecasts of urban land expansion
3 across scenarios and models, which highlights an opportunity to shape future urban development
4 towards low- or net zero GHG emissions. By 2050, urban areas could increase up to 211% over the
5 2015 global urban extent, with the median projected increase ranging from 43% to 106%. While the
6 largest absolute amount of new urban land is forecasted to occur in Asia and Developing Pacific, and
7 in Developed Countries, the highest rate of urban land growth is projected to occur in Africa, Eastern
8 Europe and West-Central Asia, and in the Middle East. Given past trends, the expansion of urban areas
9 is expected to take place on agricultural lands and forests, with implications for the loss of carbon
10 stocks. The infrastructure that will be constructed concomitant with urban land expansion will lock-in
11 patterns of energy consumption that will persist for decades. {8.3.1, 8.3.4, 8.4.1, 8.6}

12 **The construction of new, and upgrading of existing, urban infrastructure through 2030 will add**
13 **to emissions (*medium evidence, high agreement*)**. The construction of new and upgrading of existing
14 urban infrastructure using conventional practices and technologies can result in significant increase in
15 CO₂ emissions, ranging from 8.5 GtCO₂ to 14 GtCO₂ annually up to 2030 and more than double annual
16 resource requirements for raw materials to about 90 billion tonnes per year by 2050, up from 40 billion
17 tonnes in 2010. {8.4.1, 8.6}

18 **Given the dual challenges of rising urban GHG emissions and future projections of more frequent**
19 **extreme climate events, there is an urgent need to integrate urban mitigation and adaptation**
20 **strategies for cities to address climate change (*very high confidence*)**. Mitigation strategies can
21 enhance resilience against climate change impacts while contributing to social equity, public health,
22 and human well-being. Urban mitigation actions that facilitate economic decoupling can have positive
23 impacts on employment and local economic competitiveness. {8.2, Cross-Working Group Box 2 in
24 Chapter 8, 8.4}

25 **Cities can achieve net zero or near net zero GHG emissions only through deep decarbonisation**
26 **and systemic transformation (*very high confidence*)**. Effective emission reductions in cities entail
27 implementing three broad strategies concurrently: (1) reducing urban energy consumption across all
28 sectors, including through compact and efficient urban forms and supporting infrastructure; (2)
29 electrification and switching to low carbon energy sources; and (3) enhancing carbon uptake and stocks
30 (*medium evidence, high agreement*). Given the regional and global reach of urban supply chains, a city
31 cannot achieve net zero GHG emissions by only focusing on reducing emissions within its
32 administrative boundaries. {8.1.6, 8.3.4, 8.4, 8.6}

33 **Packages of mitigation policies that implement multiple urban-scale interventions can have**
34 **cascading effects across sectors, reduce GHG emissions outside a city's administrative**
35 **boundaries, and reduce emissions more than the net sum of individual interventions, particularly**
36 **if multiple scales of governance are included (*high confidence*)**. Cities have the ability to implement
37 policy packages across sectors using an urban systems approach, especially those that affect key
38 infrastructure based on spatial planning, electrification of the urban energy system, and urban green and
39 blue infrastructure. The institutional capacity of cities to develop, coordinate, and integrate sectoral
40 mitigation strategies within their jurisdiction varies by context, particularly those related to governance,
41 the regulatory system, and budgetary control. {8.4, 8.5, 8.6}

42 **Integrated spatial planning to achieve compact and resource-efficient urban growth through co-**
43 **location of higher residential and job densities, mixed land use, and transit-oriented development**
44 **could reduce urban energy use between 23-26% by 2050 compared to the business-as-usual**
45 **scenario (*high confidence*)**. Compact cities with shortened distances between housing and jobs, and
46 interventions that support a modal shift away from private motor vehicles towards walking, cycling,
47 and low-emissions shared, or public, transportation, passive energy comfort in buildings, and urban

1 green infrastructure can deliver significant public health benefits and lower GHG emissions. {8.2, 8.3.4,
2 8.4, 8.6}

3 **Urban green and blue infrastructure can mitigate climate change through carbon sinks, avoided**
4 **emissions, and reduced energy use while offering multiple co-benefits (*high confidence*).** Urban
5 green and blue infrastructure, including urban forests and street trees, permeable surfaces, and green
6 roofs offer potentials to mitigate climate change directly through storing carbon, and indirectly by
7 inducing a cooling effect that reduces energy demand and reducing energy use for water treatment.
8 Globally, urban trees store approximately 7.4 billion tonnes of carbon, and sequester approximately 217
9 million tonnes of carbon annually, although carbon storage is highly dependent on biome. Among the
10 multiple co-benefits of green and blue infrastructure are reducing the urban heat island (UHI) effect and
11 heat stress, reducing stormwater runoff, improving air quality, and improving the mental and physical
12 health of urban dwellers. Many of these options also provide benefits to climate adaptation. {8.2, 8.4.4}

13 **The potentials and sequencing of mitigation strategies to reduce GHG emissions will vary**
14 **depending on a city's land use and spatial form and its state of urbanisation, whether it is an**
15 **established city with existing infrastructure, a rapidly growing city with new infrastructure, or**
16 **an emerging city with infrastructure build-up (*medium confidence*).** The long lifespan of urban
17 infrastructures locks in behaviour and emissions. Urban infrastructures and urban form can enable
18 socio-cultural and lifestyle changes that can significantly reduce carbon footprints. Rapidly growing
19 cities can avoid higher future emissions through urban planning to co-locate jobs and housing to achieve
20 compact urban form, and by leapfrogging to low-carbon technologies. Established cities will achieve
21 the largest GHG emissions savings by replacing, repurposing, or retrofitting the building stock, strategic
22 infilling and densifying, as well as through modal shift and the electrification of the urban energy
23 system. New and emerging cities have unparalleled potential to significantly reduce GHG emissions
24 while achieving high quality of life by creating compact, co-located, and walkable urban areas with
25 mixed land use and transit-oriented design, that also preserve existing green and blue assets. {8.2, 8.4,
26 8.6}

27 **With over 880 million people living in informal settlements, there are opportunities to harness**
28 **and enable informal practices and institutions in cities related to housing, waste, energy, water,**
29 **and sanitation to reduce resource use and mitigate climate change (*low evidence, medium***
30 ***agreement*).** The upgrading of informal settlements and inadequate housing to improve resilience and
31 well-being offers a chance to create a low-carbon transition. However, there is limited quantifiable data
32 on these practices and their cumulative impacts on GHG emissions. {8.1.4, 8.2.2, Cross-Working Group
33 Box 2 in Chapter 8, 8.3.2, 8.4, 8.6, 8.7}

34 **Achieving transformational changes in cities for climate change mitigation and adaptation will**
35 **require engaging multiple scales of governance, including governments and non-state actors, and**
36 **in connection with substantial financing beyond sectoral approaches (*very high confidence*).** Large
37 and complex infrastructure projects for urban mitigation are often beyond the capacity of local
38 municipality budgets, jurisdictions, and institutions. Partnerships between cities and international
39 institutions, national and region governments, transnational networks, and local stakeholders play a
40 pivotal role in mobilizing global climate finance resources for a range of infrastructure projects with
41 low-carbon emissions and related spatial planning programs across key sectors. {8.4, 8.5}

42

1 **TS. 5.3 Transport**

2 **Meeting climate mitigation goals would require transformative changes in the transport sector.**
3 In 2019, direct GHG emissions from the transport sector were 8.7 GtCO₂-eq (up from 5.0 GtCO₂-eq in
4 1990) and accounted for 23% of global energy-related CO₂ emissions. 70% of direct transport emissions
5 came from road vehicles, while 1%, 11%, and 12% came from rail, shipping, and aviation, respectively.
6 Emissions from shipping and aviation continue to grow rapidly. Transport-related emissions in
7 developing regions of the world have increased more rapidly than in Europe or North America, a trend
8 that is expected to continue in coming decades. (*high confidence*) {10.1, 10.5, 10.6}

9 **Since AR5 there has been a growing awareness of the need for demand management solutions**
10 **combined with new technologies, such as the rapidly growing use of electromobility for land**
11 **transport and the emerging options in advanced biofuels and hydrogen-based fuels for shipping**
12 **and aviation and in other specific land-based contexts (*high confidence*).** There is a growing need
13 for systemic infrastructure changes that enable behavioural modifications and reductions in demand for
14 transport services that can in turn reduce energy demand. The response to the COVID-19 pandemic has
15 also shown that behavioural interventions can reduce transport-related GHG emissions. For example,
16 COVID-19-based lockdowns have confirmed the transformative value of telecommuting replacing
17 significant numbers of work and personal journeys as well as promoting local active transport. There
18 are growing opportunities to implement strategies that drive behavioural change and support the
19 adoption of new transport technology options. {Chapter 5, 10.2, 10.3, 10.4, 10.8}

20 **Changes in urban form, behaviour programs, the circular economy, the shared economy, and**
21 **digitalisation trends can support systemic changes that lead to reductions in demand for transport**
22 **services or expands the use of more efficient transport modes (*high confidence*).** Cities can reduce
23 their transport-related fuel consumption by around 25% through combinations of more compact land
24 use and the provision of less car-dependent transport infrastructure. Appropriate infrastructure,
25 including protected pedestrian and bike pathways, can also support much greater localised active
26 travel.¹⁷ Transport demand management incentives are expected to be necessary to support these
27 systemic changes. There is mixed evidence of the effect of circular economy initiatives, shared economy
28 initiatives, and digitalisation on demand for transport services (Box TS.14). For example, while
29 dematerialisation can reduce the amount of material that needs to be transported to manufacturing
30 facilities, an increase in online shopping with priority delivery can increase demand for freight transport.
31 Similarly, while teleworking could reduce travel demand, increased ridesharing could increase vehicle-
32 km travelled. {Chapter 1, Chapter 5, 10.2, 10.8}

33 **Battery-electric vehicles (BEVs) have lower life cycle greenhouse gas emissions than internal**
34 **combustion engine vehicles (ICEVs) when BEVs are charged with low carbon electricity (*high***
35 ***confidence*).** Electromobility is being rapidly implemented in micro-mobility (e-autorickshaws, e-
36 scooters, e-bikes), in transit systems, especially buses, and to a lesser degree, in personal vehicles. BEVs
37 could also have the added benefit of supporting grid operations. The commercial availability of mature
38 lithium-ion batteries (LIBs) has underpinned this growth in electromobility. As global battery
39 production increases, unit costs are declining. Further efforts to reduce the GHG footprint of battery
40 production, however, are essential for maximising the mitigation potential of BEVs. The continued
41 growth of electromobility for land transport would entail investments in electric charging and related
42 grid infrastructure. Electromobility powered by low-carbon electricity has the potential to rapidly
43 reduce transport GHG and can be applied with multiple co-benefits, especially in the developing
44 countries. {10.3, 10.4, 10.8}

FOOTNOTE ¹⁷ 'Active travel' is travel that requires physical effort, for example journeys made by walking or cycling.

1 **Land-based, long-range, heavy-duty trucks can be decarbonised through battery-electric haulage**
2 **(including the use of electric road systems), complemented by hydrogen- and biofuel-based fuels**
3 **in some contexts. These same technologies and expanded use of available electric rail systems can**
4 **support rail decarbonisation (*medium confidence*).** Initial deployments of battery-electric, hydrogen-
5 and bio-based haulage are underway, and commercial operations of some of these technologies are
6 considered feasible by 2030 (*medium confidence*). These technologies nevertheless face challenges
7 regarding driving range, capital and operating costs, and infrastructure availability. In particular, fuel
8 cell durability, high energy consumption, and costs continue to challenge the commercialisation of
9 hydrogen-based fuel cell vehicles. Increased capacity for low-carbon hydrogen production would also
10 be essential for hydrogen-based fuels to serve as an emissions reduction strategy (*high confidence*).
11 (Box TS.15) {10.3, 10.4, 10.8}

12 **Decarbonisation options for shipping and aviation still require R&D, though advanced biofuels,**
13 **ammonia, and synthetic fuels are emerging as viable options (*medium confidence*).** Increased
14 efficiency has been insufficient to limit the emissions from shipping and aviation, and natural gas-based
15 fuels are expected to be inadequate to meet stringent decarbonisation goals for these segments (*high*
16 *confidence*). High energy density, low carbon fuels are required, but they have not yet reached
17 commercial scale. Advanced biofuels could provide low carbon jet fuel (*medium confidence*). The
18 production of synthetic fuels using low-carbon hydrogen with CO₂ captured through DACCS/BECCS
19 could provide jet and marine fuels but these options still require demonstration at scale (*low confidence*).
20 Ammonia produced with low-carbon hydrogen could also serve as a marine fuel (*medium confidence*).
21 Deployment of these fuels requires reductions in production costs. (Figure TS.14) {10.2, 10.3, 10.4,
22 10.5, 10.6, 10.8}

23 **Scenarios from bottom-up and top-down models indicate that, without intervention, CO₂**
24 **emissions from transport could grow in the range of 16% and 50% by 2050 (*medium confidence*).**
25 The scenarios literature projects continued growth in demand for freight and passenger services,
26 particularly in developing countries in Africa and Asia (*high confidence*). This growth is projected to
27 take place across all transport modes. Increases in demand notwithstanding, scenarios that limit
28 warming to 1.5°C degree with no or limited overshoot suggest that a 59% reduction (42-68%
29 interquartile range) in transport-related CO₂ emissions by 2050, compared to modelled 2020 levels is
30 required. While many global scenarios place greater reliance on emissions reduction in sectors other
31 than transport, a quarter of the 1.5°C scenarios describe transport-related CO₂ emissions reductions in
32 excess of 68% (relative to modelled 2020 levels) (*medium confidence*). Illustrative Mitigation Pathways
33 IMP-ren and IMP-LD (TS 4.2) describe emission reductions of 80% and 90% in the transport sector,
34 respectively, by 2050. Transport-related emission reductions, however, may not happen uniformly
35 across regions. For example, transport emissions from the Developed Countries, and Eastern Europe
36 and West-Central Asia countries decrease from 2020 levels by 2050 across all scenarios limiting global
37 warming to 1.5°C by 2100, but could increase in Africa, Asia and developing Pacific (APC), Latin
38 America and Caribbean, and the Middle East in some of these scenarios. {10.7}

39 **The scenarios literature indicates that fuel and technology shifts are crucial in reducing carbon**
40 **emissions to meet temperature goals (*high confidence*).** In general terms, electrification tends to play
41 the key role in land-based transport, but biofuels and hydrogen (and derivatives) could play a role in
42 decarbonisation of freight in some contexts. Biofuels and hydrogen (and derivatives) are expected to be
43 more prominent in shipping and aviation. The shifts towards these alternative fuels must occur
44 alongside shifts towards clean technologies in other sectors. {10.7}

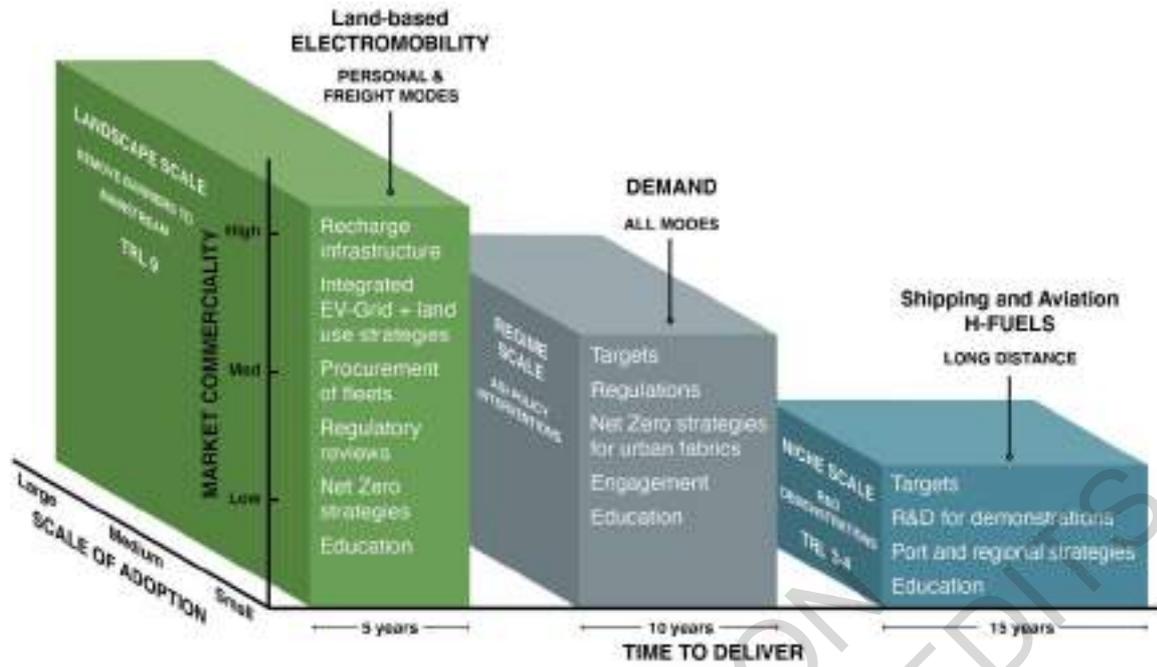

45 **There is a growing awareness of the need to plan for the significant expansion of low-carbon**
46 **energy infrastructure, including low-carbon power generation and hydrogen production, to**
47 **support emissions reductions in the transport sector (*high confidence*).** Integrated energy planning

1 and operations that take into account energy demand and system constraints across all sectors (transport,
2 buildings, and industry) offer the opportunity to leverage sectoral synergies and avoid inefficient
3 allocation of energy resources. Integrated planning of transport and power infrastructure would be
4 particularly useful in developing countries where ‘greenfield’ development doesn’t suffer from
5 constraints imposed by legacy systems. {10.3, 10.4, 10.8}

6 **The deployment of low-carbon aviation and shipping fuels that support decarbonisation of the**
7 **transport sector could require changes to national and international governance structures**
8 **(medium confidence).** The UNFCCC does not specifically cover emissions from international shipping
9 and aviation. Reporting emissions from international transport is at the discretion of each country. While
10 the International Civil Aviation Organisation (ICAO) and International Maritime Organisation (IMO)
11 have established emissions reductions targets, only strategies to improve fuel efficiency and demand
12 reductions have been pursued, and there has been minimal commitment to new technologies. {10.5,
13 10.6, 10.7}

14 **There are growing concerns about resource availability, labour rights, non-climate**
15 **environmental impacts, and costs of critical minerals needed for lithium-ion batteries (medium**
16 **confidence).** Emerging national strategies on critical minerals and the requirements from major vehicle
17 manufacturers are leading to new, more geographically diverse mines. The standardisation of battery
18 modules and packaging within and across vehicle platforms, as well as increased focus on design for
19 recyclability are important. Given the high degree of potential recyclability of lithium-ion batteries, a
20 nearly closed-loop system in the future could mitigate concerns about critical mineral issues (*medium*
21 *confidence*). {10.3, 10.8}

22 **Legislated climate strategies are emerging at all levels of government, and together with pledges**
23 **for personal choices, could spur the deployment of demand and supply-side transport mitigation**
24 **strategies (medium confidence).** At the local level, legislation can support local transport plans that
25 include commitments or pledges from local institutions to encourage behaviour change by adopting an
26 organisational culture that motivates sustainable behaviour with inputs from the creative arts. Such
27 institution-led mechanisms could include bike-to-work campaigns, free transport passes, parking
28 charges, or eliminating car benefits. Community-based solutions like *solar sharing*, *community*
29 *charging*, and *mobility as a service* can generate new opportunities to facilitate low-carbon transport
30 futures. At the regional and national levels, legislation can include vehicle and fuel efficiency standards,
31 R&D support, and large-scale investments in low-carbon transport infrastructure. (Figure TS.14) {10.8,
32 Chapter 15}

Figure TS.14: Mitigation Options and Enabling Conditions for Transport. ‘Niche’ scale includes strategies that still require innovation. (Figure 10.22)

ASI: Avoid Shift, Improve; TRL: Technology readiness level

1 **TS. 5.4 Buildings**

2 **Global GHG emissions from buildings were 12 GtCO₂-eq in 2019, equivalent to 21% of global**
3 **GHG emissions. Of this, 57% (6.8 GtCO₂-eq) were indirect emissions from offsite generation of**
4 **electricity and heat, 24% (2.9 GtCO₂-eq) direct emissions produced onsite and 18% (2.2 GtCO₂-**
5 **eq) were embodied emissions from the production of cement and steel used in buildings (*high***
6 ***confidence*).** Most building sector emissions are CO₂. Final energy demand from buildings reached 128
7 EJ globally in 2019 (around 31% of global final energy demand), and electricity demand from buildings
8 was slightly above 43 EJ globally (around 18% of global electricity demand). Residential buildings
9 consumed 70% (90 EJ) of the global final energy demand from buildings. Over the period 1990-2019,
10 global CO₂ emissions from buildings increased by 50%, global final energy demand from buildings
11 grew by 38% and global final electricity demand increased by 161%. {9.3}

12 **In most regions, historical improvements in efficiency have been approximately matched by**
13 **growth in floor area per capita (*high confidence*).** At the global level, building specific drivers of
14 GHG emissions include: (i) population growth, especially in developing countries; (ii) increasing floor
15 area per capita, driven by the increasing size of dwellings while the size of households kept decreasing,
16 especially in developed countries; (iii) the inefficiency of newly constructed buildings, especially in
17 developing countries, and the low renovation rates and low ambition level in developed countries when
18 existing buildings are renovated; iv) the increase in use, number and size of appliances and equipment,
19 especially Information and Communication Technologies (ICT) and cooling, driven by income; and,
20 (v) the continued reliance on carbon intensive electricity and heat. These factors taken together are
21 projected to continue driving increased GHG emissions in the building sector in the future. {9.3, 9.6,
22 9.9}

23 **Building sector GHG emissions were assessed using the Sufficiency, Efficiency, Renewable (SER)**
24 **framework. Sufficiency measures tackle the causes of GHG emissions by limiting the demand for**
25 **energy and materials over the lifecycle of buildings and appliances (*high confidence*).** In Chapter
26 9 of this report, *sufficiency* differs from *efficiency*. *Sufficiency* is about long-term actions driven by non-
27 technological solutions, which consume less energy in absolute terms. *Efficiency*, in contrast is about
28 continuous short-term marginal technological improvements. Use of the SER framework reduces the
29 cost of constructing and using buildings without reducing occupant's well-being and comfort. {9.1, 9.4,
30 9.5, 9.9}

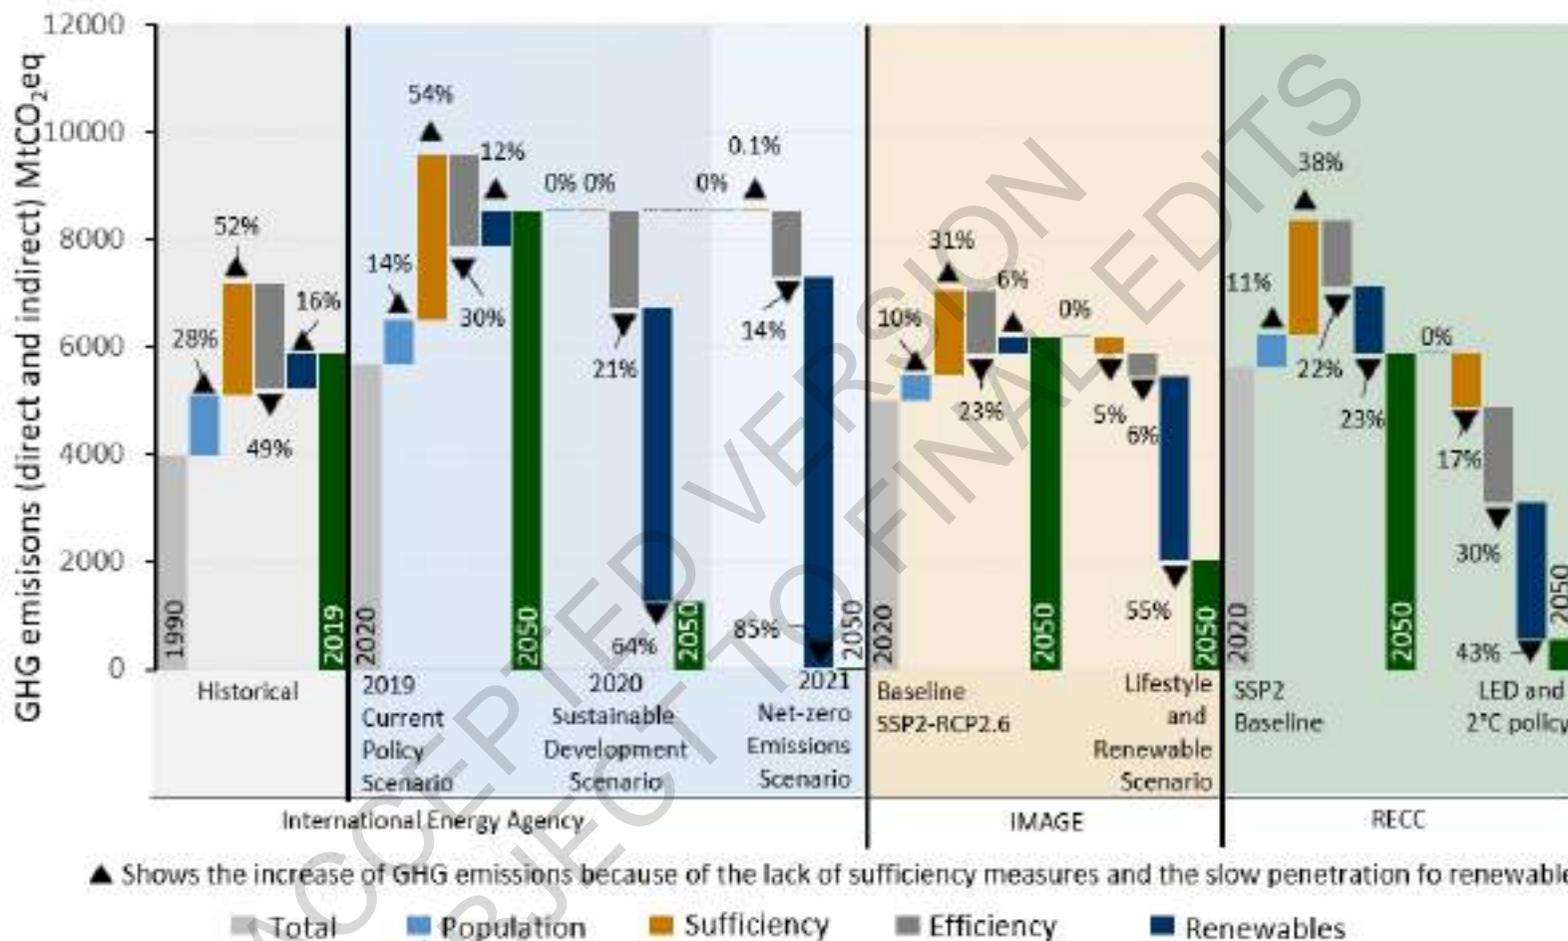

31 **Sufficiency interventions do not consume energy during the use phase of buildings and do not**
32 **require maintenance nor replacement over the lifetime of buildings.** Density, compactness,
33 bioclimatic design to optimise the use of nature-based solutions, multi-functionality of space through
34 shared space and to allow for adjusting the size of buildings to the evolving needs of households,
35 circular use of materials and repurposing unused existing buildings to avoid using virgin materials,
36 optimisation of the use of buildings through lifestyle changes, use of the thermal mass of buildings to
37 reduce thermal needs, moving from ownership to usership of appliances are among the sufficiency
38 interventions implemented in leading municipalities (*high confidence*). At a global level, up to 17% of
39 the mitigation potential in the buildings sector could be captured by 2050 through sufficiency
40 interventions (*medium confidence*). (Figure TS. 15) {9.2, 9.3, 9.4, 9.5, 9.9}.

41 **The potential associated with sufficiency measures, as well as the replacement of appliances,**
42 **equipment and lights by efficient ones, is below zero cost (*high confidence*).** The construction of
43 high-performance buildings is expected to become a business-as-usual technology by 2050 with costs
44 below USD20 tCO₂⁻¹ in developed countries and below USD100 tCO₂⁻¹ in developing countries
45 (*medium confidence*). For existing buildings, there have been many examples of deep retrofits where
46 additional costs per CO₂ abated are not significantly higher than those of shallow retrofits. However,
47 for the whole building stock they tend to be in cost intervals of USD-200 tCO₂⁻¹ and >USD200 tCO₂⁻¹

1 (*medium confidence*). Literature emphasizes the critical role of the 2020-2030 decade in accelerating
2 the learning of know-how and skills to reduce the costs and remove feasibility constraints for achieving
3 high efficiency buildings at scale and set the sector in the pathway to realize its full potential (*high*
4 *confidence*). {9.3, 9.6, 9.9}.

Panel b: regional

Figure TS.15: Decompositions of changes in historical residential energy emissions 1990-2019, changes in emissions projected by baseline scenarios for 2020-2050, and differences between scenarios in 2050 using scenarios from three models: IEA, IMAGE, and RECC.

1
2
3
4

1 **Figure TS.15 legend:** RECC-LED data include only space heating and cooling and water heating in residential
2 buildings (a) Global resolution, and (b) for nine world regions. Emissions are decomposed using the equation
3
$$\text{CO}_2 \text{ Pop} \times \frac{\text{m}^2}{\text{Pop}} \times \frac{\text{EJ}}{\text{m}^2} \times \frac{\text{MtCO}_2}{\text{EJ}} = \text{Pop} \times \text{Sufficiency} \times \text{Efficiency} \times \text{Renewable}$$
, which shows changes in
4 driver variables of population, sufficiency (floor area per capita), efficiency (final energy per floor area), and
5 renewables (GHG emissions per final energy). ‘Renewables’ is a summary term describing changes in GHG
6 intensity of energy supply. Emission projections to 2050, and differences between scenarios in 2050,
7 demonstrate mitigation potentials from the dimensions of the SER framework realised in each model scenario.
8 In most regions, historical improvements in efficiency have been approximately matched by growth in floor area
9 per capita. Implementing sufficiency measures that limit growth in floor area per capita, particularly in
10 developed regions, reduces the dependence of climate mitigation on technological solutions. {Figure 9.5, Box
11 9.2}

12 **The development, since AR5, of integrated approaches to the construction and retrofit of**
13 **buildings has led to increasing the number of zero energy or zero carbon buildings in almost all**
14 **climate zones.** The complementarity and interdependency of measures leads to cost reductions, while
15 optimising the mitigation potential achieved and avoiding the lock-in-effect (*medium confidence*). {9.6,
16 9.9}

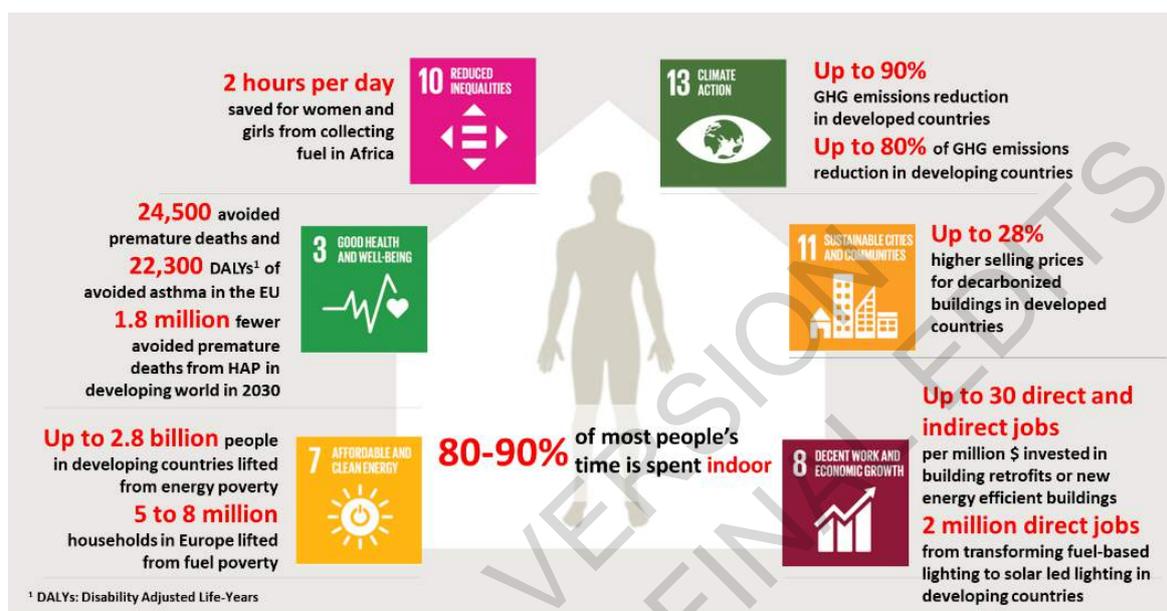

17 **The decarbonisation of buildings is constrained by multiple barriers and obstacles as well as**
18 **limited finance flows (*high confidence*).** **The lack of institutional capacity, especially in developing**
19 **countries, and appropriate governance structures slow down the decarbonisation of the global**
20 **building stock (*medium confidence*).** The building sector is highly heterogenous with many different
21 building types, sizes, and operational uses. The sub-segment representing rented property faces
22 principal/agent problems where the tenant benefits from the decarbonisation’s investment made by the
23 landlord. The organisational context and the governance structure could trigger or hinder the
24 decarbonisation of buildings. Global investment in the decarbonisation of buildings was estimated at
25 USD164 billion in 2020. However, this is not enough by far to close the investment gap (*high*
26 *confidence*). {9.9}

27 **Policy packages could grasp the full mitigation potential of the global building stock. Building**
28 **energy codes represent the main regulatory instrument to reduce emissions from both new and**
29 **existing buildings (*high confidence*).** The most advanced building energy codes include requirements
30 on each of the three pillars of the SER framework in the *use* and *construction* phase of buildings.
31 Building energy codes have proven to be effective if compulsory and combined with other regulatory
32 instruments such as minimum energy performance standard for appliances and equipment, if the
33 performance level is set at the level of the best available technologies in the market (*high confidence*).
34 Market-based instruments such as carbon taxes with recycling of the revenues and personal or building
35 carbon allowances could also contribute to fostering the decarbonisation of the building sector (*medium*
36 *confidence*). {9.9}

37 **Adapting buildings to future climate while ensuring well-being for all requires action. Expected**
38 **heatwaves will inevitably increase cooling needs to limit the health impacts of climate change**
39 **(*medium confidence*).** Global warming will impact cooling and heating needs but also the performance,
40 durability and safety of buildings, especially historical and coastal ones, through changes in
41 temperature, humidity, atmospheric concentrations of CO₂ and chloride, and sea level rise. Adaptation
42 measures to cope with climate change may increase the demand for energy and materials leading to an
43 increase in GHG emissions if not mitigated. Sufficiency measures which anticipate climate change, and
44 include natural ventilation, white walls, and nature-based solutions (e.g. green roofs) will decrease the
45 demand for cooling. Shared cooled spaces with highly efficient cooling solutions are among the
46 mitigation strategies which can limit the effect of the expected heatwaves on people’s health. {9.7, 9.8}

1 **Well-designed and effectively implemented mitigation actions in the buildings sector have**
 2 **significant potential to help achieve the SDGs (*high confidence*).** As shown in Figure TS.16, the
 3 impacts of mitigation actions in the building sector go far beyond the goal of climate action (SDG13)
 4 and contribute to meeting fifteen other SDGs. Mitigation actions in the building sector bring health
 5 gains through improved indoor air quality and thermal comfort, and have positive significant macro-
 6 and micro-economic effects, such as increased productivity of labour, job creation, reduced poverty,
 7 especially energy poverty, and improved energy security (*high confidence*). (Figure TS.29) {9.8}

8

Key point: Achieving SDG targets requires implementation of ambitious climate mitigation policies which include sufficiency measures to align building design, size and use with SDGs, efficiency measures to ensure high penetration of best available technologies and supplying the remaining energy needs with renewable energy sources

9

10 **Figure TS.16. Contribution of building sector mitigation policies to meeting sustainable development**
 11 **goals. {Figure 9.18}**

12 **The COVID-19 pandemic emphasised the importance of buildings for human well-being and**
 13 **highlighted the inequalities in access for all to suitable, healthy buildings, which provide natural**
 14 **daylight and clean air to their occupants (*medium confidence*).** The new WHO health
 15 recommendations emphasised indoor air quality, preventive maintenance of centralised mechanical
 16 heating, ventilation, and cooling systems. There are opportunities for repurposing existing non-
 17 residential buildings, no longer in use due to the expected spread of teleworking triggered by the health
 18 crisis and enabled by digitalisation. (TS BOX.14) {9.1}

19

1 **TS. 5.5 Industry**

2 The industry chapter focuses on new developments since AR5 and emphasises the role of the energy-
3 intensive and emissions-intensive basic materials industries in strategies for reaching net zero
4 emissions. The Paris Agreement, the SDGs and the COVID-19 pandemic provide a new context for the
5 evolution of industry and mitigation of industry greenhouse gas (GHG) emissions (*high confidence*).
6 {11.1.1}

7 **Net zero CO₂ industrial sector emissions are possible but challenging (*high confidence*).** Energy
8 efficiency will continue to be important. Reduced materials demand, material efficiency, and circular
9 economy solutions can reduce the need for primary production. Primary production options include
10 switching to new processes that use low to zero GHG energy carriers and feedstocks (e.g., electricity,
11 hydrogen, biofuels, and carbon dioxide capture and utilisation (CCU) to provide carbon feedstocks).
12 Carbon capture and storage (CCS) will be required to mitigate remaining CO₂ emissions {11.3}. These
13 options require substantial scaling up of electricity, hydrogen, recycling, CO₂, and other infrastructure,
14 as well as phase-out or conversion of existing industrial plants. While improvements in the GHG
15 intensities of major basic materials have nearly stagnated over the last 30 years, analysis of historical
16 technology shifts and newly available technologies indicate these intensities can be significantly
17 reduced by mid-century. {11.2, 11.3, 11.4}

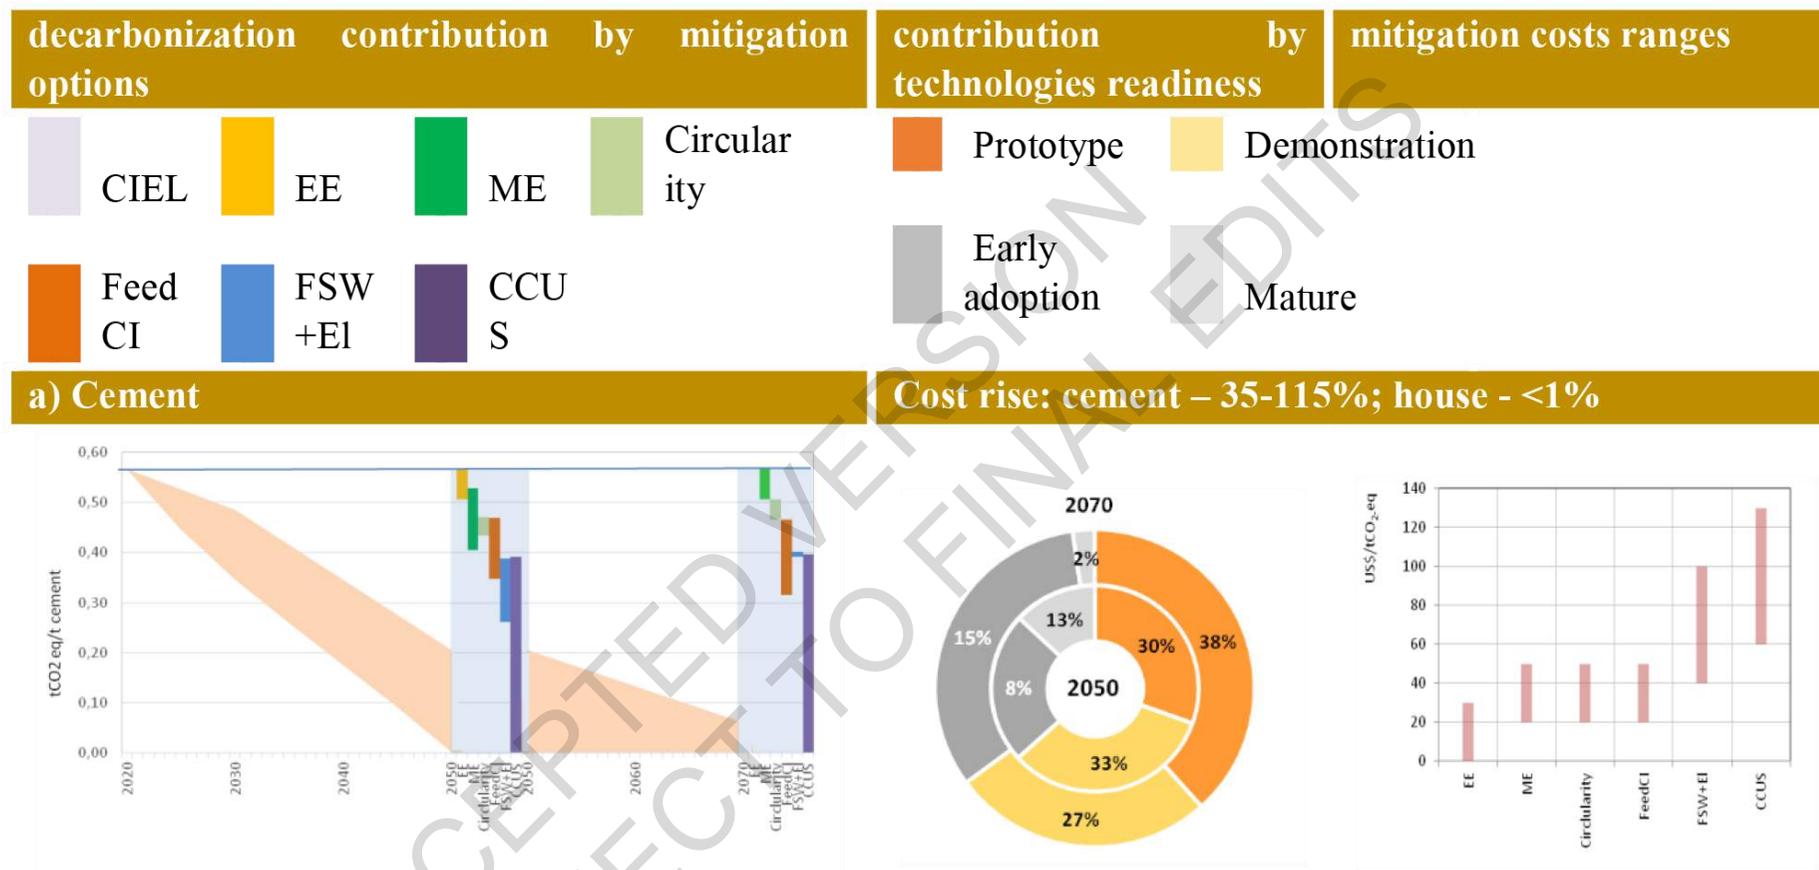

18 **Industry sector emissions have been growing faster since 2000 than emissions in any other sector,**
19 **driven by increased basic materials extraction and production (*high confidence*).** GHG emissions
20 attributed to the industrial sector originate from fuel combustion, process emissions, product use and
21 waste, which jointly accounted for 14.1 GtCO₂-eq or 24% of all direct anthropogenic emissions in 2019,
22 second behind the energy supply sector. Industry is a leading GHG emitter - 20 GtCO₂-eq or 34% of
23 global emissions in 2019 - if indirect emissions from power and heat generation are included. The share
24 of emissions originating from direct fuel combustion is decreasing and was 7 GtCO₂-eq, 50% of direct
25 industrial emissions in 2019. {11.2.2}

26 **Global material intensity – the in-use stock of manufactured capital in tonnes per unit of GDP–**
27 **is increasing (*high confidence*).** In-use stock of manufactured capital per capita has been growing
28 faster than GDP per capita since 2000. Total global in-use stock of manufactured capital grew by 3.4%
29 yr⁻¹ in 2000–2019. At the same time, per capita material stocks in several developed countries have
30 stopped growing, showing a decoupling from GDP per capita. {11.2.1, 11.3.1}

31 **The demand for plastic has been growing most strongly since 1970 (*high confidence*).** The current
32 >99% reliance on fossil feedstock, very low recycling, and high emissions from petrochemical
33 processes is a challenge for reaching net zero emissions. At the same time, plastics are important for
34 reducing emissions elsewhere, for example, light-weighting vehicles. There are as yet no shared visions
35 for fossil-free plastics, but several possibilities. {11.4.1.3}

36 **Scenario analyses show that significant reductions in global GHG emissions and even close to net**
37 **zero emissions from GHG intensive industry (e.g., steel, plastics, ammonia, and cement) can be**
38 **achieved by 2050 by deploying multiple available and emerging options (*medium confidence*).**
39 Significant reductions in industry emissions require a reorientation from the historic focus on important
40 but incremental improvements (e.g., energy efficiency) to transformational changes in energy and
41 feedstock sourcing, materials efficiency, and more circular material flows. {11.3, 11.4}

b) Steel

Cost rise: steel – 10-50%; house or car - <1%

c) Primary chemicals

Cost rise: primary chemicals – 15-115%; plastic bottle - <1%

1

Figure TS.17 Page-ii: Potentials and costs for zero-carbon mitigation options for industry and basic materials

d) Industry (waste excluded)

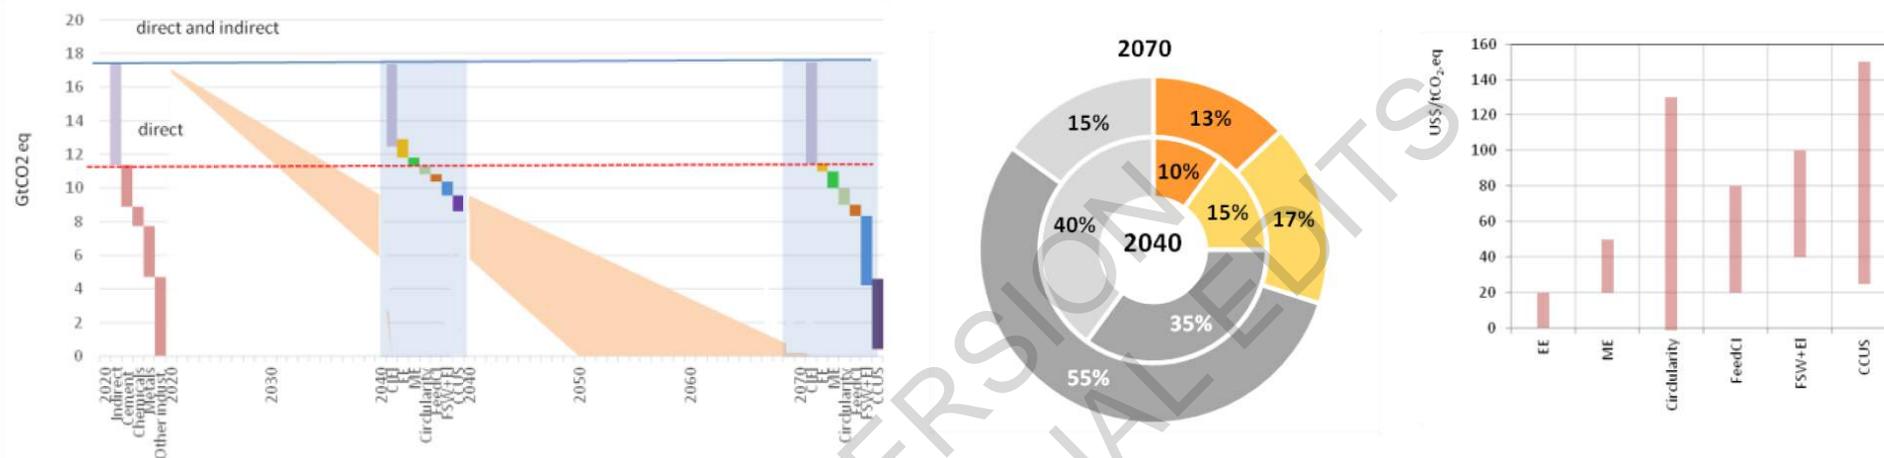

Figure TS.17 page-iii : Potentials and costs for zero-carbon mitigation options for industry and basic materials

Figure TS.17 legend: Key shown on Figure TS.17 page-i also applies to TS.17 pages ii & iii. CIEI –carbon intensity of electricity for indirect emissions; EE – energy efficiency; ME – material efficiency; Circularity - material flows (clinker substituted by coal fly ash, blast furnace slag or other by-products and waste, steel scrap, plastic recycling, etc.); FeedCI – feedstock carbon intensity (hydrogen, biomass, novel cement, natural clinker substitutes); FSW+EI – fuel switch and processes electrification with low carbon electricity. Ranges for mitigation options are shown based on bottom-up studies for grouped technologies packages, not for single technologies. In circles contribution to mitigation from technologies based on their readiness are shown for 2050 (2040) and 2070. Direct emissions include fuel combustion and process emissions. Indirect emissions include emissions attributed to consumed electricity and purchased heat. For basic chemicals only methanol, ammonia and high-value chemicals are considered. Total for industry does not include emissions from waste. Negative mitigation costs for some options like Circularity are not reflected. {Figure 11.13}

1 **Key mitigation options such as materials efficiency, circular material flows and emerging primary**
2 **processes, are not well represented in climate change scenario modelling and integrated**
3 **assessment models, albeit with some progress in recent years (*high confidence*).** The character of
4 these interventions (e.g., appearing in many forms across complex value chains, making cost estimates
5 difficult) combined with the limited data on new fossil free primary processes help explain why they
6 are less represented in models than, for example, CCS. As a result, overall mitigation costs and the need
7 for CCS may be overestimated. {11.4.2.1}

8 **Electrification is emerging as a key mitigation option for industry (*high confidence*).** Using
9 electricity directly, or indirectly via hydrogen from electrolysis for high temperature and chemical
10 feedstock requirements, offers many options to reduce emissions. It also can provide substantial grid
11 balancing services, for example through electrolysis and storage of hydrogen for chemical process use
12 or demand response. (Box TS.9) {11.3.5}

13 **Carbon is a key building block in organic chemicals, fuels and materials and will remain**
14 **important (*high confidence*).** In order to reach net zero CO₂ emissions for the carbon needed in society
15 (e.g., plastics, wood, aviation fuels, solvents, etc.), it is important to close the use loops for carbon and
16 carbon dioxide through increased circularity with mechanical and chemical recycling, more efficient
17 use of biomass feedstock with addition of low GHG hydrogen to increase product yields (e.g., for
18 biomethane and methanol), and potentially direct air capture of CO₂ as a new carbon source. {11.3,
19 11.4.1}

20 **Production costs for very low to zero emissions basic materials may be high but the cost for final**
21 **consumers and the general economy will be low (*medium confidence*).** Costs and emissions
22 reductions potential in industry, and especially heavy industry, are highly contingent on innovation,
23 commercialisation, and market uptake policies. Technologies exist to take all industry sectors to very
24 low or zero emissions, but require 5–15 years of intensive innovation, commercialisation, and policy to
25 ensure uptake. Mitigation costs are in the rough range of USD50–150 tCO₂-eq⁻¹, with wide variation
26 within and outside this band. This affects competitiveness and requires supporting policy. Although
27 production cost increases can be significant, they translate to very small increases in the costs for final
28 products, typically less than a few percent depending on product, assumptions, and system boundaries.
29 (Figure TS.17) {11.4.1.5}

30 **Several technological options exist for very low to zero emissions steel, but their uptake will**
31 **require integrated material efficiency, recycling, and production decarbonisation policies (*high***
32 ***confidence*).** Material efficiency can potentially reduce steel demand by up to 40% based on design for
33 less steel use, long life, reuse, constructability, and low contamination recycling. Secondary production
34 through high quality recycling must be maximised. Production decarbonisation will also be required,
35 starting with the retrofitting of existing facilities for partial fuel switching (e.g., to biomass or hydrogen),
36 CCU and CCS, followed by very low and zero emissions production based on high-capture CCS or
37 direct hydrogen, or electrolytic iron ore reduction followed by an electric arc furnace. {11.3.2, 11.4.1.1}

38 **Several current and emerging options can significantly reduce cement and concrete emissions.**
39 **Producer, user, and regulator education, as well as innovation and commercialisation policy are**
40 **needed (*medium confidence*).** Cement and concrete are currently overused because they are
41 inexpensive, durable, and ubiquitous, and consumption decisions typically do not give weight to their
42 production emissions. Basic material efficiency efforts to use only well-made concrete thoughtfully and
43 only where needed (e.g., using right-sized, prefabricated components) could reduce emissions by 24–
44 50% through lower demand for clinker. Cementitious material substitution with various materials (e.g.,
45 ground limestone and calcined clays) can reduce process calcination emissions by up to 50% and
46 occasionally much more. Until a very low GHG emissions alternative binder to Portland cement is
47 commercialised – which is not anticipated in the near to medium term – CCS will be essential for

1 eliminating the limestone calcination process emissions for making clinker, which currently represent
2 60% of GHG emissions in best available technology plants. {11.3.2, 11.3.6, 11.4.1.2}

3 **While several technological options exist for decarbonizing the main industrial feedstock**
4 **chemicals and their derivatives, the costs vary widely (*high confidence*).** Fossil fuel-based
5 feedstocks are inexpensive and still without carbon pricing, and their biomass- and electricity-based
6 replacements are expected to be more expensive. The chemical industry consumes large amounts of
7 hydrogen, ammonia, methanol, carbon monoxide, ethylene, propylene, benzene, toluene, and mixed
8 xylenes & aromatics from fossil feedstock, and from these basic chemicals produces tens of thousands
9 of derivative end-use chemicals. Hydrogen, biogenic or air-capture carbon, and collected plastic waste
10 for the primary feedstocks can greatly reduce total emissions. Biogenic carbon feedstock is expected to
11 be limited due to competing land-uses. {11.4.1}

12 **Light industry and manufacturing can be largely decarbonized through switching to low GHG**
13 **fuels (e.g., biofuels and hydrogen) and electricity (e.g., for electrothermal heating and heat**
14 **pumps) (*high confidence*).** Most of these technologies are already mature, for example for low
15 temperature heat, but a major challenge is the current low cost of fossil CH₄ and coal relative to low and
16 zero GHG electricity, hydrogen, and biofuels. {11.4.1}

17 **The pulp and paper industry has significant biogenic carbon emissions but relatively small fossil**
18 **carbon emissions. Pulp mills have access to biomass residues and by-products and in paper mills**
19 **the use of process heat at low to medium temperatures allows for electrification (*high confidence*).**
20 Competition for feedstock will increase if wood substitutes for building materials and petrochemicals
21 feedstock. The pulp and paper industry can also be a source of biogenic carbon dioxide, carbon for
22 organic chemicals feedstock, and for CDR using CCS. {11.4.1}

23 **The geographical distribution of renewable resources has implications for industry (*medium***
24 ***confidence*).** The potential for zero emission electricity and low-cost hydrogen from electrolysis
25 powered by solar and wind, or hydrogen from other very low emission sources, may reshape where
26 currently energy and emissions intensive basic materials production is located, how value chains are
27 organized, trade patterns, and what gets transported in international shipping. Regions with bountiful
28 solar and wind resources, or low fugitive CH₄ co-located with CCS geology, may become exporters of
29 hydrogen or hydrogen carriers such as methanol and ammonia, or home to the production of iron and
30 steel, organic platform chemicals, and other energy intensive basic materials. {11.2, 11.4, Box 11.1}

31 **The level of policy maturity and experience varies widely across the mitigation options (*high***
32 ***confidence*).** Energy efficiency is a well-established policy field with decades of experience from
33 voluntary and negotiated agreements, regulations, energy auditing and demand side-management
34 (DSM) programs. In contrast, materials demand management and efficiency are not well understood
35 and addressed from a policy perspective. Barriers to recycling that policy could address are often
36 specific to the different material loops (e.g., copper contamination for steel and lack of technologies or
37 poor economics for plastics) or waste management systems. For electrification and fuel switching the
38 focus has so far been mainly on innovation and developing technical supply-side solutions rather than
39 creating market demand. {11.5.2, 11.6}

40 **Industry has so far largely been sheltered from the impacts of climate policy and carbon pricing**
41 **due to concerns about carbon leakage¹⁸ and reducing competitiveness (*high confidence*).** New
42 approaches to industrial development policy are emerging for a transition to net zero GHG emissions.
43 The transition requires a clear direction towards net zero, technology development, market demand for
44 low-carbon materials and products, governance capacity and learning, socially inclusive phase-out
45 plans, as well as international coordination of climate and trade policies (see also TS 6.5). It requires

FOOTNOTE ¹⁸ See section TS 5.9

- 1 comprehensive and sequential industrial policy strategies leading to immediate action as well as
- 2 preparedness for future decarbonisation, governance at different levels (from international to local) and
- 3 integration with other policy domains. {11.6}

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1 **TS. 5.6 Agriculture, forestry and other land uses, and food systems**

2 **TS. 5.6.1 AFOLU**

3 **The Agriculture, Forestry and Other Land Uses (AFOLU)¹⁹ sector encompasses managed**
4 **ecosystems and offers significant mitigation opportunities while providing food, wood and other**
5 **renewable resources as well as biodiversity conservation, provided the sector adapts to climate**
6 **change.** Land-based mitigation measures can reduce GHG emissions within the AFOLU sector, deliver
7 CDR and provide biomass thereby enabling emission reductions in other sectors.²⁰ The rapid
8 deployment of AFOLU measures features in all pathways that limit global warming to 1.5°C. Where
9 carefully and appropriately implemented, AFOLU mitigation measures are positioned to deliver
10 substantial co-benefits and help address many of the wider challenges associated with land
11 management. If AFOLU measures are deployed badly then, when taken together with the increasing
12 need to produce sufficient food, feed, fuel and wood, they may exacerbate trade-offs with the
13 conservation of habitats, adaptation, biodiversity and other services. At the same time the capacity of
14 the land to support these functions may be threatened by climate change. (*high confidence*) {WG I
15 Figure SPM7; WG II, 7.1, 7.6}

16 **The AFOLU sector, on average, accounted for 13-21% of global total anthropogenic GHG**
17 **emissions in the period 2010-2019. At the same time managed and natural terrestrial ecosystems**
18 **were a carbon sink, absorbing around one third of anthropogenic CO₂ emissions (*medium***
19 ***confidence*).** Estimated anthropogenic net CO₂ emissions from AFOLU (based on bookkeeping models)
20 result in a net source of $+5.9 \pm 4.1$ GtCO₂ yr⁻¹ between 2010 and 2019 with an unclear trend. Based on
21 FAOSTAT or national GHG inventories, the net CO₂ emissions from AFOLU were 0.0 to +0.8 GtCO₂
22 yr⁻¹ over the same period. There is a discrepancy in the reported CO₂ AFOLU emissions magnitude
23 because alternative methodological approaches that incorporate different assumptions are used {7.2.2}.
24 If the responses of all managed and natural land to both anthropogenic environmental change and
25 natural climate variability, estimated to be a gross sink of -12.5 ± 3.2 GtCO₂ yr⁻¹ for the period 2010–
26 2019, are added to land-use emissions, then land overall constituted a net sink of -6.6 ± 5.2 GtCO₂ yr⁻¹
27 in terms of CO₂ emissions (*medium confidence*). (Table TS.4) {7.2, Table 7.1}

28 **Land use change drives net AFOLU CO₂ emission fluxes. The rate of deforestation, which**
29 **accounts for 45% of total AFOLU emissions, has generally declined, while global tree cover and**
30 **global forest growing stock levels are *likely* increasing (*medium confidence*).** There are substantial
31 regional differences, with losses of carbon generally observed in tropical regions and gains in temperate
32 and boreal regions. Agricultural CH₄ and N₂O emissions are estimated to average 157 ± 47.1 MtCH₄
33 yr⁻¹ and 6.6 ± 4.0 MtN₂O yr⁻¹ or 4.2 ± 1.3 and 1.8 ± 1.1 GtCO₂-eq yr⁻¹ (using IPCC AR6 GWP100
34 values for CH₄ and N₂O) respectively between 2010 and 2019 {7.2.1, 7.2.3}. AFOLU CH₄ emissions
35 continue to increase, the main source of which is enteric fermentation from ruminant animals. Similarly,
36 AFOLU N₂O emissions are increasing, dominated by agriculture, notably from manure application,

FOOTNOTE ¹⁹ AFOLU is a sector in the 2019 Refinement to the 2006 IPCC Guidelines for National Greenhouse Gas Inventories. AFOLU anthropogenic greenhouse gas emissions and removals by sinks reported by governments under the UNFCCC are defined as all those occurring on ‘managed land’. Managed land is land where human interventions and practices have been applied to perform production, ecological or social functions.

FOOTNOTE ²⁰ For example: in the 2019 Refinement to the 2006 IPCC Guidelines for National Greenhouse Gas Inventories, CO₂ emissions from biomass used for energy are reported in the AFOLU sector, calculated as an implicit component of carbon stock changes. In the energy sector, CO₂ emissions from biomass combustion for energy are recorded as an information item that is not included in the sectoral total emissions for the that sector.

1 nitrogen deposition, and nitrogen fertiliser use (*high confidence*). In addition to being a net carbon sink
 2 and source of GHG emissions, land plays an important role in climate through albedo effects,
 3 evapotranspiration, and aerosol loading through emissions of volatile organic compounds (VOCs). The
 4 combined role of CH₄, N₂O and aerosols in total climate forcing, however, is unclear and varies strongly
 5 with bioclimatic region and management practice. {2.4.2.5, 7.2, 7.3}

6 **Table TS.4 Net anthropogenic emissions (annual averages for 2010–2019^a) from Agriculture, Forestry
 7 and Other Land Use (AFOLU)**
 8

9 **For context, the net flux due to the natural response of land to climate and environmental change is also**
 10 **shown for CO₂ in column E. Positive values represent emissions, negative values represent removals.**
 11 **Due to different approaches to estimate anthropogenic fluxes, AFOLU CO₂ estimates in the table**
 12 **below are not directly comparable to LULUCF in National Greenhouse Gas Inventories (NGHGs).**
 13

Anthropogenic						Natural Response	Natural + Anthropogenic
Gas	Units	AFOLU Net anthropogenic emissions	Non-AFOLU anthropogenic GHG emissions	Total net anthropogenic emissions (AFOLU + non-AFOLU) by gas	AFOLU as a % of total net anthropogenic emissions by gas	Natural land sinks including natural response of land to anthropogenic environmental change and climate variability	Net-land atmosphere CO ₂ flux (i.e. anthropogenic AFOLU + natural fluxes across entire land surface)
		A	B	C = A+B	D = (A/C) *100	E	F=A+E
CO ₂	GtCO ₂ -eq yr ⁻¹	5.9 ± 4.1 (bookkeeping models only) 0 to 0.8 (NGHGI/FAOSTAT data)	36.2 ± 2.9	42.0 ± 29.0	14%	-12.5 ± 3.2	-6.6 ± 4.6
	MtCH ₄ yr ⁻¹	157.0 ± 47.1	207.5 ± 62.2	364.4 ± 109.3			
CH ₄	GtCO ₂ -eq yr ⁻¹	4.2 ± 1.3	5.9 ± 1.8	10.2 ± 3.0	41%		
	MtN ₂ O yr ⁻¹	6.6 ± 4.0	2.8 ± 1.7	9.4 ± 5.6			
N ₂ O	GtCO ₂ -eq yr ⁻¹	1.8 ± 1.1	0.8 ± 0.5	2.6 ± 1.5	69%		
Total	GtCO ₂ -eq yr ⁻¹	11.9 ± 4.4 (CO ₂ component considers bookkeeping models only)	44 ± 3.4	55.9 ± 6.1	21%		

14 ^a Estimates are given for 2019 as this is the latest date when data are available for all gases, consistent with Chapter 2, this
 15 report. Positive fluxes are emission from land to the atmosphere. Negative fluxes are removals.
 16 {Table 7.1}

17
 18 **The AFOLU sector offers significant near-term mitigation potential at relatively low cost and can**
 19 **provide 20-30% of the 2050 emissions reduction described in scenarios that likely limit warming**
 20 **to 2°C or lower (*high evidence, medium agreement*).** The AFOLU sector can provide 20–30%
 21 (interquartile range) of the global mitigation needed for a 1.5 °C or 2°C pathway towards 2050, though
 22 there are highly variable mitigation strategies for how AFOLU potential can be deployed for achieving
 23 climate targets {Illustrative Mitigation Pathways in 7.5}. The estimated economic (< USD100 tCO₂-eq⁻¹)
 24 AFOLU sector mitigation potential is 8 to 14 GtCO₂-eq yr⁻¹ between 2020-2050, with the bottom end
 25 of this range representing the mean from IAMs and the upper end representing the mean estimate from
 26 global sectoral studies. The economic potential is about half of the technical potential from AFOLU,
 27 and about 30-50% could be achieved under USD20 tCO₂-eq⁻¹ {7.4}. The implementation of robust
 28 measurement, reporting and verification processes is paramount to improving the transparency of

1 changes in land carbon stocks and this can help prevent misleading assumptions or claims on mitigation.
2 {7.1, 7.4, 7.5}

3 **Between 2020 and 2050, mitigation measures in forests and other natural ecosystems provide the**
4 **largest share of the AFOLU mitigation potential (up to USD100 tCO₂-eq⁻¹), followed by**
5 **agriculture and demand-side measures (*high confidence*).** In the global sectoral studies, the
6 protection, improved management, and restoration of forests, peatlands, coastal wetlands, savannas and
7 grasslands have the potential to reduce emissions and/or sequester 7.3 mean (3.9–13.1 range) GtCO₂-
8 eq yr⁻¹. Agriculture provides the second largest share of the mitigation potential, with 4.1 (1.7–6.7)
9 GtCO₂-eq yr⁻¹ (up to USD100 tCO₂-eq⁻¹) from cropland and grassland soil carbon management,
10 agroforestry, use of biochar, improved rice cultivation, and livestock and nutrient management.
11 Demand-side measures including shifting to sustainable healthy diets, reducing food waste, building
12 with wood, biochemicals, and bio-textiles, have a mitigation potential of 2.2 (1.1–3.6) GtCO₂-eq yr⁻¹.
13 Most mitigation options are available and ready to deploy. Emissions reductions can be achieved
14 relatively quickly, whereas CDR needs upfront investment. Sustainable intensification in agriculture,
15 shifting diets, and reducing food waste could enhance efficiencies and reduce agricultural land needs,
16 and are therefore critical for enabling supply-side measures such as reforestation, restoration, as well as
17 decreasing CH₄ and N₂O emissions from agricultural production. In addition, emerging technologies
18 (e.g., vaccines or CH₄ inhibitors) have the potential to substantially increase the CH₄ mitigation
19 potential beyond current estimates. AFOLU mitigation is not only relevant in countries with large land
20 areas. Many smaller countries and regions, particularly with wetlands, have disproportionately high
21 levels of AFOLU mitigation potential density. {7.4, 7.5}

22 **The economic and political feasibility of implementing AFOLU mitigation measures is hampered**
23 **by persistent barriers. Assisting countries to overcome barriers will help to achieve significant**
24 **short-term mitigation (*medium confidence*).** Finance forms a critical barrier to achieving these gains
25 as currently mitigation efforts rely principally on government sources and funding mechanisms which
26 do not provide sufficient resources to enable the economic potential to be realised. Differences in
27 cultural values, governance, accountability and institutional capacity are also important barriers.
28 Climate change itself could reduce the mitigation potential from the AFOLU sector, although an
29 increase in the capacity of natural sinks could occur despite changes in climate (*medium confidence*)
30 {WG I Figure SPM7 and Sections 7.4 and 7.6}. The continued loss of biodiversity makes ecosystems
31 less resilient to climate change extremes and this may further jeopardise the achievement of the AFOLU
32 mitigation potentials indicated in this chapter (*high confidence*). (Box TS.15) {7.6}

33 **The provision of biomass for bioenergy (with/without BECCS) and other biobased products**
34 **represents an important share of the total mitigation potential associated with the AFOLU sector,**
35 **though these mitigation effects accrue to other sectors (*high confidence*).** Recent estimates of the
36 technical bioenergy potential, when constrained by food security and environmental considerations, are
37 within the ranges 5–50 and 50–250 EJ yr⁻¹ by 2050 for residues and dedicated biomass production
38 systems, respectively.²¹ (TS 5.7) {7.4, 12.3}

FOOTNOTE ²¹ These potentials do not include avoided emissions resulting from bioenergy use associated with BECCS, which depends on energy substitution patterns, conversion efficiencies, and supply chain emissions for both the BECCS and substituted energy systems. Estimates of substitution effects of bioenergy indicate that this additional mitigation would be of the same magnitude as provided through CDR using BECCS. Biobased products with long service life, e.g., construction timber, can also provide mitigation through substitution of steel, concrete, and other products, and through carbon storage in the biobased product pool. See section TS 5.7 for the CDR potential of BECCS. {7.4, 12.3}

1 **Bioenergy is the most land-intensive energy option, but total land occupation of other renewable**
2 **energy options can also become significant in high deployment scenarios. While not as closely**
3 **connected to the AFOLU sector as bioenergy, other renewable energy options can influence**
4 **AFOLU activities in both synergistic and detrimental ways (*high confidence*).** The character of land
5 occupation, and associated impacts, vary considerably among mitigation options and also for the same
6 option depending on geographic location, scale, system design and deployment strategy. Land
7 occupation can be large uniform areas, e.g., reservoir hydropower dams and tree plantations, and more
8 distributed occupation that is integrated with other land uses, e.g., wind turbines and agroforestry in
9 agriculture landscapes. Deployment can be partly decoupled from additional land use, e.g., use of
10 organic waste and residues and integration of solar PV into buildings and other infrastructure (*high*
11 *confidence*). Wind and solar power can coexist with agriculture in beneficial ways (*medium confidence*).
12 Indirect land occupation includes new agriculture areas following displacement of food production with
13 bioenergy plantations and expansion of mining activities providing minerals required for manufacture
14 of EV batteries, PV, and wind power. {7.4, 12.5}

15 **The deployment of land-based mitigation measures can provide co-benefits, but there are also**
16 **risks and trade-offs from inappropriate land management (*high confidence*).** Such risks can best
17 **be managed if AFOLU mitigation is pursued in response to the needs and perspectives of multiple**
18 **stakeholders to achieve outcomes that maximise synergies while limiting trade-offs (*medium***
19 ***confidence*).** The results of implementing AFOLU measures are often variable and highly context
20 specific. Depending on local conditions (e.g., ecosystem, climate, food system, land ownership) and
21 management strategies (e.g., scale, method), mitigation measures can positively or negatively affect
22 biodiversity, ecosystem functioning, air quality, water availability and quality, soil productivity, rights
23 infringements, food security, and human well-being. The agriculture and forestry sectors can devise
24 management approaches that enable biomass production and use for energy in conjunction with the
25 production of food and timber, thereby reducing the conversion pressure on natural ecosystems (*medium*
26 *confidence*). Mitigation measures addressing GHGs may also affect other climate forcers such as albedo
27 and evapotranspiration. Integrated responses that contribute to mitigation, adaptation, and other land
28 challenges will have greater likelihood of being successful (*high confidence*); measures which provide
29 additional benefits to biodiversity and human well-being are sometimes described as ‘Nature-based
30 Solutions’. {7.1, 7.4, 7.6, 12.4, 12.5}

31 **AFOLU mitigation measures have been well understood for decades but deployment remains**
32 **slow, and emissions trends indicate unsatisfactory progress despite beneficial contributions to**
33 **global emissions reduction from forest-related options (*high confidence*).** Globally, the AFOLU
34 sector has so far contributed modestly to net mitigation, as past policies have delivered about 0.65
35 GtCO₂ yr⁻¹ of mitigation during 2010–2019 or 1.4% of global gross emissions. The majority (>80%) of
36 emission reduction resulted from forestry measures. Although the mitigation potential of AFOLU
37 measures is large from a biophysical and ecological perspective, its feasibility is hampered by lack of
38 institutional support, uncertainty over long-term additionality and trade-offs, weak governance,
39 fragmented land ownership, and uncertain permanence effects. Despite these impediments to change,
40 AFOLU mitigation options are demonstrably effective and with appropriate support can enable rapid
41 emission reductions in most countries. {7.4, 7.6}

42 **Concerted, rapid and sustained effort by all stakeholders, from policy makers and investors to**
43 **land-owners and managers is a pre-requisite for achieving high levels of mitigation in the AFOLU**
44 **sector (*high confidence*).** To date USD0.7 billion yr⁻¹ is estimated to have been spent on AFOLU
45 mitigation. This is well short of the more than USD400 billion yr⁻¹ that is estimated to be necessary to
46 deliver the up to 30% of global mitigation effort envisaged in deep mitigation scenarios (*medium*
47 *confidence*). This estimate of the global funding requirement is smaller than current subsidies provided

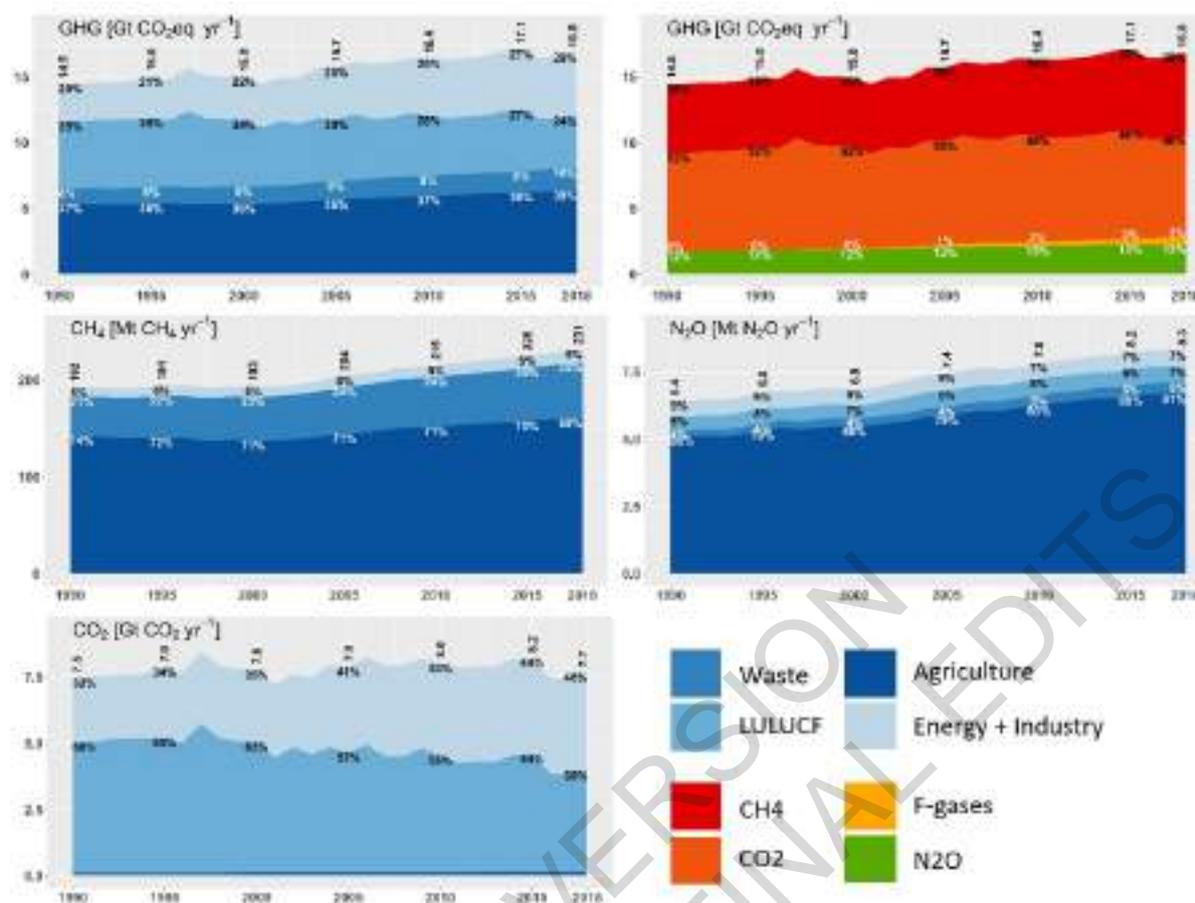

1 to agriculture and forestry. A gradual redirection of existing agriculture and forestry subsidies would
2 greatly advance mitigation. Effective policy interventions and national (investment) plans as part of
3 NDCs, specific to local circumstances and needs, are urgently needed to accelerate the deployment of
4 AFOLU mitigation options. These interventions are effective when they include funding schemes and
5 long-term consistent support for implementation with governments taking the initiative together with
6 private funders and non-state actors. {7.6}

7 **Realising the mitigation potential of the AFOLU sector depends strongly on policies that directly**
8 **address emissions and drive the deployment of land-based mitigation options, consistent with**
9 **carbon prices in deep mitigation scenarios (*high confidence*).** Examples of successful policies and
10 measures include establishing and respecting tenure rights and community forestry, improved
11 agricultural management and sustainable intensification, biodiversity conservation, payments for
12 ecosystem services, improved forest management and wood chain usage, bioenergy, voluntary supply
13 chain management efforts, consumer behaviour campaigns, private funding and joint regulatory efforts
14 to avoid e.g., leakage. The efficacy of different policies, however, will depend on numerous region-
15 specific factors. In addition to funding, these factors include governance, institutions, long-term
16 consistent execution of measures, and the specific policy setting. While the governance of land-based
17 mitigation can draw on lessons from previous experience with regulating biofuels and forest carbon
18 integrating these insights requires governance that goes beyond project-level approaches emphasising
19 integrated land use planning and management within the frame of the sustainable development goals.
20 {7.4, Box 7.2, 7.6}

21 **Addressing the many knowledge gaps in the development and testing of AFOLU mitigation**
22 **options can rapidly advance the likelihood of achieving sustained mitigation (*high confidence*).**
23 Research priorities include improved quantification of anthropogenic and natural GHG fluxes and
24 emissions modelling, better understanding of the impacts of climate change on the mitigation potential,
25 permanence and additionality of estimated mitigation actions, and improved (real time and cheap)
26 measurement, reporting and verification. There is a need to include a greater suite of mitigation
27 measures in IAMs, informed by more realistic assessments that take into account local circumstances
28 and socio-economic factors and cross-sector synergies and trade-offs. Finally, there is a critical need
29 for more targeted research to develop appropriate country-level, locally specific, policy and land
30 management response options. These options could support more specific NDCs with AFOLU
31 measures that enable mitigation while also contributing to biodiversity conservation, ecosystem
32 functioning, livelihoods for millions of farmers and foresters, and many other SDGs. {7.7, Figure 17.1}

33 *TS. 5.6.2 Food systems*

34 **Realising the full mitigation potential from the food system requires change at all stages from**
35 **producer to consumer and waste management, which can be facilitated through integrated policy**
36 **packages (*high confidence*).** 23-42% of global GHG emissions are associated with food systems, while
37 there is still wide-spread food insecurity and malnutrition. Absolute GHG emissions from food systems
38 increased from 14 to 17 GtCO₂-eq yr⁻¹ in the period 1990-2018. Both supply and demand side measures
39 are important to reduce the GHG intensity of food systems. Integrated food policy packages based on a
40 combination of market-based, administrative, informative, and behavioural policies can reduce cost
41 compared to uncoordinated interventions, address multiple sustainability goals, and increase acceptance
42 across stakeholders and civil society (*limited evidence, medium agreement*). Food systems governance
43 may be pioneered through local food policy initiatives complemented by national and international
44 initiatives, but governance on the national level tends to be fragmented, and thus have limited capacity
45 to address structural issues like inequities in access. (Figure TS.18, Table TS.5, Table TS.6) {7.2, 7.4,
46 12.4}

1
2 **Figure TS.18: Food system GHG emissions from the agriculture, Land Use, Land-Use Change & Forestry**
3 **(LULUCF), Waste, and energy & industry sectors. {Figure 12.5}**

4
5 **Diets high in plant protein and low in meat and dairy are associated with lower GHG emissions**
6 **(high confidence).** Ruminant meat shows the highest GHG intensity. Beef from dairy systems has lower
7 emissions intensity than beef from beef herds (8-23 and 17-94 kgCO₂-eq (100g protein)⁻¹, respectively)
8 when some emissions are allocated to dairy products. The wide variation in emissions reflects
9 differences in production systems, which range from intensive feedlots with stock raised largely on
10 grains through to rangeland and transhumance production systems. Where appropriate, a shift to diets
11 with a higher share of plant protein, moderate intake of animal-source foods and reduced intake of
12 saturated fats could lead to substantial decreases in GHG emissions. Benefits would also include
13 reduced land occupation and nutrient losses to the surrounding environment, while at the same time
14 providing health benefits and reducing mortality from diet-related non-communicable diseases. (Figure
15 TS.19) {7.4.5, 12.4}

16 **Emerging food technologies such as cellular fermentation, cultured meat, plant-based**
17 **alternatives to animal-based food products, and controlled environment agriculture, can bring**
18 **substantial reduction in direct GHG emissions from food production (limited evidence, high**
19 **agreement).** These technologies have lower land, water, and nutrient footprints, and address concerns
20 over animal welfare. Realising the full mitigation potential depends on access to low-carbon energy as
21 some emerging technologies are relatively more energy intensive. This also holds for deployment of
22 cold chain and packaging technologies, which can help reduce food loss and waste, but increase energy
23 and materials use in the food system. (Table TS.5) {11.4.1.3, 12.4}

1
2

Table TS.5 Food system mitigation opportunities

Food system mitigation options (I: incremental; T: transformative)		Direct and indirect effect on GHG mitigation (+/0/-) ^a	Co-benefits / Adverse effects ^b
Food from agricultural, aquaculture and fisheries	(I) Dietary shift, in particular increased share of plant-based protein sources	D+ ↓ GHG footprint	A+ Animal welfare L+ Land sparing H+ Good nutritional properties, potentially ↓ risk from zoonotic diseases, pesticides and antibiotics
	(I/T) Digital agriculture	D+ ↑ logistics	L+ Land sparing R+ ↑ resource use efficiencies
	(T) Gene technology	D+ ↑ productivity or efficiency	H+ ↑ nutritional quality E0 ↓ use of agrochemicals; ↑ probability of off-target impacts
	(I) Sustainable intensific. land use optimisation	D+ ↓ GHG footprint E0 Mixed effects	L+ Land sparing R- Might ↑ pollution/biodiversity loss
	(I) Agroecology	D+ ↓ GHG/area, positive micro-climatic effects E+ ↓ energy, possibly ↓ transport FL+ Circular approaches	E+ Focus on co-benefits/ecosystem services R+ Circular, ↑ nutrient and water use efficiencies
Controlled environment agriculture	(T) Soilless agriculture	D+ ↑ productivity, weather independent FL+ Harvest on demand E- Currently ↑ energy demand, but ↓ transport, building spaces can be used for renewable energy	R+ Controlled loops ↑ nutrient and water use efficiency L+ Land sparing H+ Crop breeding can be optimised for taste and/or nutritional quality
Emerging Food Production technologies	(T) Insects	D0 Good feed conversion efficiency FW+ Can be fed on food waste	H0 Good nutritional qualities but attention to allergies and food safety issues required
	(I/T) Algae and bivalves	D+ ↓ GHG footprints	A+ Animal welfare L+ Land sparing H+ Good nutritional qualities; risk of heavy metal and pathogen contamination R+ Biofiltration of nutrient-polluted waters
	(I/T) Plant-based alternatives to animal-based food products	D+ No emissions from animals, ↓ inputs for feed	A+ Animal welfare L+ Land sparing H+ Potentially ↓ risk from zoonotic diseases, pesticides and antibiotics; but ↑ processing demand

Food system mitigation options (I: incremental; T: transformative)		Direct and indirect effect on GHG mitigation (+/0/-) ^a	Co-benefits / Adverse effects ^b
	(T) Cellular agriculture (including cultured meat, microbial protein)	D+ No emissions from animals, high protein conversion efficiency E- ↑ energy need FLW+ ↓ food loss & waste	A+ Animal welfare R+ ↓ emissions of reactive nitrogen or other pollutants H0 Potentially ↓ risk from zoonotic diseases, pesticides and antibiotics; ↑ research on safety aspects needed
Food processing and packaging	(I) Valorisation of by-products, FLW logistics and management	M+ Substitution of bio-based materials FL+ ↓ of food losses	
	(I) Food conservation	FW+ ↓ of food waste E0 ↑ energy demand but also energy savings possible (e.g., refrigeration, transport)	
	(I) Smart packaging and other technologies	FW+ ↓ of food waste M0 ↑ material demand and ↑ material-efficiency E0 ↑ energy demand; energy savings possible	H+ Possibly ↑ freshness/reduced food safety risks
	(I) Energy efficiency	E+ ↓ energy	
Storage and distribution	(I) Improved logistics	D+ ↓ transport emissions FL+ ↓ losses in transport FW- Easier access to food could ↑ food waste	
	(I) Specific measures to reduce food waste in retail and food catering	FW+ ↓ of food waste E+ ↓ downstream energy demand M+ ↓ downstream material demand	
	(I) Alternative fuels/transport modes	D+ ↓ emissions from transport	
	(I) Energy efficiency	E+ ↓ energy in refrigeration, lightening, climatisation	
	(I) Replacing refrigerants	D+ ↓ emissions from the cold chain

Table TS.6 Assessment of food system policies targeting (post-farm gate) food chain actors and consumers

	Level	Transformative potential	Environ. effective.	Feasibility	Distributional effects	Cost	Co-benefits ^a and adverse side-effect	Implications for coordination, coherence and consistency in policy package ^b
Integrated food policy packages	NL	■	■	■	can be controlled	Cost efficient	+ balanced, addresses multiple sustainability goals	Reduces cost of uncoordinated interventions; increases acceptance across stakeholders and civil society (<i>high confidence</i>).
Taxes on food products	GN	■	■	■	regressive	low ^{#1}	- unintended substitution effects	High enforcing effect on other food policies; higher acceptance if compensation or hypothecated taxes (<i>medium evidence, high agreement</i>).
GHG taxes on food	GN	■	■	■	regressive	low ^{#2}	-unintended substitution effects +high spillover effect	Supportive, enabling effect on other food policies, agricultural/fishery policies; requires changes in power distribution and trade agreements (<i>medium confidence</i>).
Trade policies	G	■	■	■	impacts global distribution	complex effects	+ counters leakage effects +/- effects on market structure and jobs	Requires changes in existing trade agreements (<i>medium evidence, high agreement</i>).
Investment into research & innovation	GN	■	■	■	none	medium	+ high spillover effect + converging with digital society	Can fill targeted gaps for coordinated policy packages (e.g. monitoring methods) (<i>high confidence</i>).
Food and marketing regulations	N	■	■	■		low		Can be supportive; might be supportive to realise innovation; voluntary standards might be less effective (<i>medium confidence</i>).
Organisational level procurement policies	NL	■	■	■		low	+ can address multiple sustainability goals	Enabling effect on other food policies; reaches large share of population (<i>medium evidence, high agreement</i>).
Sustainable food-based dietary guidelines	GNL	■	■	■	none	low	+ can address multiple sustainability goals	Little attention so far on environmental aspects; can serve as benchmark for other policies (labels, food formulation standards, etc.) (<i>medium confidence</i>).
Food labels/information	GNL	■	■	■	education level relevant	low	+ empowers citizens + increases awareness + multiple objectives	Effective mainly as part of a policy package; incorporation of other objectives (e.g., animal welfare, fair trade...); higher effect if mandatory (<i>medium confidence</i>).
Nudges	NL	■	■	■	none	low	+ possibly counteracting information deficits in population subgroups	High enabling effect on other food policies (<i>medium evidence, high agreement</i>).

4

5 **Color code: Effect of measures:** negative ■, none/unclear ■, slightly positive ■, positive ■; **Level:** G: global/multinational, N: national, L: local; #1 Minimum level
6 to be effective 20% price increase; #2 Minimum level to be effective 50-80 USD tCO₂-eq⁻¹.

7

a. In addition, all interventions are assumed to address health and climate change mitigation.

8

b. Requires coordination between policy areas, participation of stakeholders, transparent methods and indicators to manage trade-offs and prioritisation between possibly

9

conflicting objectives; and suitable indicators for monitoring and evaluation against objectives. {Table 12.9}

1 **TS. 5.7 Carbon dioxide removal (CDR)**

2 **CDR is a key element in scenarios that likely limit warming to 2°C or 1.5°C by 2100 (high**
3 **confidence).** Implementation strategies need to reflect that CDR methods differ in terms of removal
4 process, timescale of carbon storage, technological maturity, mitigation potential, cost, co-benefits,
5 adverse side-effects, and governance requirements. (Box TS.10)

6 **All the illustrative mitigation pathways (IMPs) assessed in this report use land-based biological**
7 **CDR (primarily afforestation/reforestation (A/R)) and/or bioenergy with carbon capture and**
8 **storage (BECCS). Some also include direct air CO₂ capture and storage (DACCS) (high**
9 **confidence).** Across the scenarios likely limiting warming to 2°C or below, cumulative volumes²² of
10 BECCS reach 328 (168–763) GtCO₂, net CO₂ removal on managed land (including A/R) reaches 252
11 (20–418) GtCO₂, and DACCS reaches 29 (0–339) GtCO₂, for the 2020–2100 period. Annual volumes
12 in 2050 are 2.75 (0.52–9.45) GtCO₂ yr⁻¹ for BECCS, 2.98 (0.23–6.38) GtCO₂ yr⁻¹ for the net CO₂
13 removal on managed land (including A/R), and 0.02 (0 -1.74) GtCO₂ yr⁻¹ for DACCS. (Box TS.10)
14 {12.3, Cross-Chapter Box 8 in Chapter 12}

15 **Despite limited current deployment, estimated mitigation potentials for DACCS, enhanced**
16 **weathering (EW) and ocean-based CDR methods (including ocean alkalinity enhancement and**
17 **ocean fertilisation) are moderate to large (medium confidence).** The potential for DACCS (5–40
18 GtCO₂ yr⁻¹) is limited mainly by requirements for low-carbon energy and by cost (100–300 (full range:
19 84–386) USD tCO₂⁻¹). DACCS is currently at a medium technology readiness level. EW has the
20 potential to remove 2–4 (full range: <1 to ~100) GtCO₂ yr⁻¹, at costs ranging from 50 to 200 (full range:
21 24–578) USD tCO₂⁻¹. Ocean-based methods have a combined potential to remove 1–100 GtCO₂ yr⁻¹ at
22 costs of USD40–500 tCO₂⁻¹, but their feasibility is uncertain due to possible side-effects on the marine
23 environment. EW and ocean-based methods are currently at a low technology readiness level. {12.3}

24 **CDR governance and policymaking can draw on widespread experience with emissions reduction**
25 **measures (high confidence).** Additionally, to accelerate research, development, and demonstration,
26 and to incentivise CDR deployment, a political commitment to formal integration into existing climate
27 policy frameworks is required, including reliable measurement, reporting and verification MRV of
28 carbon flows. {12.3.3, 12.4, 12.5}

29

30 **START BOX TS.10 HERE**

31 **Box TS.10: Carbon Dioxide Removal**

32 Carbon Dioxide Removal (CDR) is necessary to achieve net zero CO₂ and GHG emissions both globally
33 and nationally, counterbalancing ‘hard-to-abate’ residual emissions. CDR is also an essential element
34 of scenarios that limit warming to 1.5°C or likely below 2°C by 2100, regardless of whether global
35 emissions reach near zero, net zero or net negative levels. While national mitigation portfolios aiming
36 at net zero emissions or lower will need to include some level of CDR, the choice of methods and the
37 scale and timing of their deployment will depend on the achievement of gross emission reductions, and
38 managing multiple sustainability and feasibility constraints, including political preferences and social
39 acceptability.

40 CDR refers to anthropogenic activities removing CO₂ from the atmosphere and durably storing it in
41 geological, terrestrial, or ocean reservoirs, or in products. It includes existing and potential
42 anthropogenic enhancement of biological, geochemical or chemical CO₂ sinks, but excludes natural
43 CO₂ uptake not directly caused by human activities (Annex I). Carbon Capture and Storage (CCS) and

FOOTNOTE ²² As a median value (5 to 95% range).

1 Carbon Capture and Utilisation (CCU) applied to fossil CO₂ do not count as removal technologies. CCS
2 and CCU can only be part of CDR methods if the CO₂ is biogenic or directly captured from ambient
3 air, and stored durably in geological reservoirs or products. {12.3}

4 There is a great variety of CDR methods and respective implementation options {Cross-Chapter Box 8
5 Figure 1 in Chapter 12}. Some of these methods (like afforestation and soil-carbon sequestration) have
6 been practiced for decades to millennia, although not necessarily with the intention to remove carbon
7 from the atmosphere. Conversely, for methods such as DACCS and BECCS, experience is growing but
8 still limited in scales. A categorisation of CDR methods can be based on several criteria, depending on
9 the highlighted characteristics. In this report, the categorisation is focused on the role of CDR methods
10 in the carbon cycle, i.e. on the removal process (*land-based biological; ocean-based biological;*
11 *geochemical; chemical*) and on the timescale of storage (*decades to centuries; centuries to millennia;*
12 *10 thousand years or longer*), the latter being closely linked to different carbon storage media. Within
13 one category (e.g., ocean-based biological CDR) options often differ with respect to other dynamic or
14 context-specific dimensions such as mitigation potential, cost, potential for co-benefits and adverse
15 side-effects, and technology readiness level. (Table TS.7; TS 5.6, 5.7) {12.3}

16 It is useful to distinguish between CO₂ removal from the atmosphere as the outcome of deliberate
17 activities implementing CDR options, and the net emissions outcome achieved with the help of CDR
18 deployment (i.e., gross emissions minus gross removals). As part of ambitious mitigation strategies at
19 global or national levels, gross CDR can fulfil three different roles in complementing emissions
20 abatement: (1) lowering net CO₂ or GHG emissions in the near-term; (2) counterbalancing ‘hard-to-
21 abate’ residual emissions like CO₂ from industrial activities and long-distance transport, or CH₄ and
22 nitrous oxide from agriculture, in order to help reach net zero CO₂ or GHG emissions in the mid-term;
23 (3) achieving net negative CO₂ or GHG emissions in the long-term if deployed at levels exceeding
24 annual residual emissions {2.7, 3.3, 3.4, 3.5}. These roles of CDR are not mutually exclusive: for
25 example, achieving net zero CO₂ or GHG emissions globally might involve individual developed
26 countries attaining net negative CO₂ emissions at the time of global net zero, thereby allowing
27 developing countries a smoother transition. {Cross-Chapter Box 8 Figure 2 in Chapter 12}

28 **END BOX TS.10 HERE**

1 **Table TS.7: Summary of status, costs, potentials, risk and impacts, co-benefits, trade-offs and spill over effects and the role in mitigation pathways for CDR**
2 **methods {12.3.2, 7.4} TRL = Technology Readiness Level**

CDR option	Status (TRL)	Cost (USD tCO ₂ ⁻¹)	Mitigation Potential (GtCO ₂ yr ⁻¹)	Risk and Impacts	Co-benefits	Trade-offs and spill over effects	Role in mitigation pathways	Section
Afforestation/Reforestation	(8-9)	0-240	0.5-10	Reversal of carbon removal through wildfire, disease, pests may occur. Reduced catchment water yield and lower groundwater level if species and biome are inappropriate.	Enhanced employment and local livelihoods, improved biodiversity, improved renewable wood products provision, soil carbon and nutrient cycling. Possibly less pressure on primary forest.	Inappropriate deployment at large scale can lead to competition for land with biodiversity conservation and food production.	Substantial contribution in IAMs and also in bottom-up sectoral studies.	{7.4}
Soil Carbon Sequestration in croplands and grasslands	(8-9)	45-100	0.6-9.3	Risk of increased nitrous oxide emissions due to higher levels of organic nitrogen in the soil; risk of reversal of carbon sequestration.	Improved soil quality, resilience and agricultural productivity.	Attempts to increase carbon sequestration potential at the expense of production. Net addition per hectare is very small; hard to monitor.	In development – not yet in global mitigation pathways simulated by IAMs in bottom-up studies: with medium contribution.	{7.4}
Peatland and coastal wetland restoration	(8-9)	Insufficient data	0.5-2.1	Reversal of carbon removal in drought or future disturbance. Risk of increased CH ₄ emissions.	Enhanced employment and local livelihoods, increased productivity of fisheries, improved biodiversity, soil carbon and nutrient cycling.	Competition for land for food production on some peatlands used for food production.	Not in IAMs but some bottom-up studies with medium contribution.	{7.4}
Agroforestry	(8-9)	Insufficient data	0.3-9.4	Risk that some land area lost from food production; requires very high skills.	Enhanced employment and local livelihoods, variety of products improved soil quality, more resilient systems.	Some trade off with agricultural crop production, but enhanced biodiversity, and resilience of system.	No data from IAMs, but in bottom-up sectoral studies with medium contribution.	{7.4}
Improved Forest management	(8-9)	Insufficient data	0.1-2.1	If improved management is understood as merely intensification involving increased fertiliser use and introduced species, then it could reduce biodiversity and increase eutrophication.	In case of sustainable forest management, it leads to enhanced employment and local livelihoods, enhanced biodiversity, improved productivity.	If it involves increased fertiliser use and introduced species it could reduce biodiversity and increase eutrophication and upstream GHG emissions.	No data from IAMs, but in bottom-up sectoral studies with medium contribution.	{7.4}
Biochar	(6-7)	10-345	0.3-6.6	Particulate and GHG emissions from production; biodiversity and carbon stock loss from unsustainable biomass harvest.	Increased crop yields and reduced non-CO ₂ emissions from soil; and resilience to drought.	Environmental impacts associated particulate matter; competition for biomass resource.	In development – not yet in global mitigation pathways simulated by IAMs.	{7.4}
DACCS	6	100-300 (84–386)	5-40	Increased energy and water use.	Water produced (solid sorbent DAC designs only).	Potentially increased emissions from water supply and energy generation.	In a few IAMs; DACCS complements other CDR methods.	{12.3}
BECCS	(5-6)	15-400	0.5-11	Inappropriate deployment at very large- scale leads to additional land and water use to grow biomass feedstock. Biodiversity and carbon stock loss if from unsustainable biomass harvest.	Reduction of air pollutants; fuel security, optimal use of residues, additional income, health benefits and if implemented well can enhance biodiversity.	Competition for land with biodiversity conservation and food production.	Substantial contribution in IAMs and bottom -up sectoral studies. Note-mitigation through avoided GHG emissions resulting from the bioenergy use is of the same magnitude as	{7.4}

CDR option	Status (TRL)	Cost (USD tCO ₂ ⁻¹)	Mitigation Potential (GtCO ₂ yr ⁻¹)	Risk and Impacts	Co-benefits	Trade-offs and spill over effects	Role in mitigation pathways	Section
							the mitigation from CDR (TS.5.6).	
Enhanced weathering	3-4	50-200 (24-578)	2-4 (<1-95)	Mining impacts; air quality impacts of rock dust when spreading on soil.	Enhanced plant growth, reduced erosion, enhanced soil carbon, reduced pH, soil water retention.	Potentially increased emissions from water supply and energy generation.	In a few IAMs; EW complements other CDR methods.	{12.3}
"Blue carbon" in coastal wetlands	2-3	Insufficient data	<1	If degraded or lost, coastal blue carbon ecosystems are expected to release most of their carbon back to the atmosphere; potential for sediment contaminants, toxicity, bioaccumulation and biomagnification in organisms; issues related to altering degradability of coastal plants; use of subtidal areas for tidal wetland carbon removal; effect of shoreline modifications on sediment redeposition and natural marsh accretion; abusive use of coastal blue carbon as means to reclaim land for purposes that degrade capacity for carbon removal.	Provide many non-climatic benefits and can contribute to ecosystem-based adaptation, coastal protection, increased biodiversity, reduced upper ocean acidification; could potentially benefit human nutrition or produce fertiliser for terrestrial agriculture, anti-methanogenic feed additive, or as an industrial or materials feedstock.		Not incorporated in IAMs, but in some bottom-up studies: small contribution.	{7.4, 12.3.1}
Ocean fertilisation	1-2	50-500	1-3	Nutrient redistribution, restructuring of the ecosystem, enhanced oxygen consumption and acidification in deeper waters, potential for decadal-to-millennial-scale return to the atmosphere of nearly all the extra carbon removed, risks of unintended side effects.	Increased productivity and fisheries, reduced upper ocean acidification.	Subsurface ocean acidification, deoxygenation; altered meridional supply of macronutrients as they are utilised in the iron-fertilised region and become unavailable for transport to, and utilisation in other regions, fundamental alteration of food webs, biodiversity.	No data.	{12.3.1}
Ocean alkalinity enhancement	1-2	40–260	1–100	Increased seawater pH and saturation states and may impact marine biota. Possible release of nutritive or toxic elements and compounds. Mining impacts.	Limiting ocean acidification.	Potentially increased emissions of CO ₂ and dust from mining, transport and deployment operations.	No data.	{12.3.1}

1 Range based on authors' estimates (as assessed from literature) are shown, with full literature ranges shown in brackets

1 **TS. 5.8 Demand-side aspects of mitigation**

2 The assessment of the social science literature and regional case studies reveals how social norms,
3 culture, and individual choices interact with infrastructure and other structural changes over time. This
4 provides new insight into climate change mitigation strategies, and how economic and social activity
5 might be organised across sectors to support emission reductions. To enhance well-being, people
6 demand services and not primary energy and physical resources per se. Focusing on demand for services
7 and the different social and political roles people play broadens the participation in climate action. (Box
8 TS.11)

9 **Demand-side mitigation and new ways of providing services can help *Avoid* and *Shift* final service**
10 **demands and *Improve* service delivery. Rapid and deep changes in demand make it easier for**
11 **every sector to reduce GHG emissions in the short and medium term (*high confidence*). {5.2, 5.3}**

12 **The indicative potential of demand-side strategies across all sectors to reduce emissions is 40-70%**
13 **by 2050 (*high confidence*).** Technical mitigation potentials compared to the International Energy
14 Agency's 2020 World Energy Outlook STEPS (Stated Policy Scenarios) baseline are up to 5.7 GtCO₂-eq for
15 building use and construction, 8 GtCO₂-eq for food demand, 6.5 GtCO₂-eq for land transport, and 5.2
16 GtCO₂-eq for industry. Mitigation strategies can be classified as *Avoid-Shift-Improve* (ASI) options,
17 that reflect opportunities for socio-cultural, infrastructural, and technological change. The greatest
18 *Avoid* potential comes from reducing long-haul aviation and providing short-distance low-carbon urban
19 infrastructures. The greatest *Shift* potential would come from switching to plant-based diets. The
20 greatest *Improve* potential comes from within the building sector, and in particular increased use of
21 energy efficient end-use technologies and passive housing. (Figure TS.20, Figure TS.21) {5.3.1, 5.3.2,
22 Figure 5.7, Figure 5.8, Table 5.1, Table SM 5.2}

23 **Socio-cultural and lifestyle changes can accelerate climate change mitigation (*medium***
24 ***confidence*).** Among 60 identified actions that could change individual consumption, individual
25 mobility choices have the largest potential to reduce carbon footprints. Prioritising car-free mobility by
26 walking and cycling and adoption of electric mobility could save 2 tCO₂-eq cap⁻¹ yr⁻¹. Other options
27 with high mitigation potential include reducing air travel, cooling setpoint adjustments, reduced
28 appliance use, shifts to public transit, and shifting consumption towards plant-based diets. {5.3.1,
29 5.3.1.2, Figure 5.8}

30

31 **START BOX TS.11 HERE**

32 **Box TS.11: A New Chapter in WG III AR6 Focusing on the Social Science of Demand, and** 33 **Social Aspects of Mitigation**

34 The WG III contribution to the Sixth Assessment Report of the IPCC (AR6) features a distinct chapter
35 on demand, services and social aspects of mitigation {5}. The scope, theories, and evidence for such an
36 assessment are addressed in Sections 5.1 and 5.4 within Chapter 5 and a Social Science Primer as an
37 Appendix to Chapter 5.

38 The literature on social science – from sociology, psychology, gender studies and political science for
39 example – and climate change mitigation is growing rapidly. A bibliometric search of the literature
40 identified 99,065 peer-reviewed academic papers, based on 34 search queries with content relevant to
41 Chapter 5. This literature is expanding by 15% per year, with twice as many publications in the AR6
42 period (2014-2020) as in all previous years.

43 The models of stakeholders' decisions assessed by IPCC have continuously evolved. From AR1 to
44 AR4, rational choice was the implicit assumption: agents with perfect information and unlimited

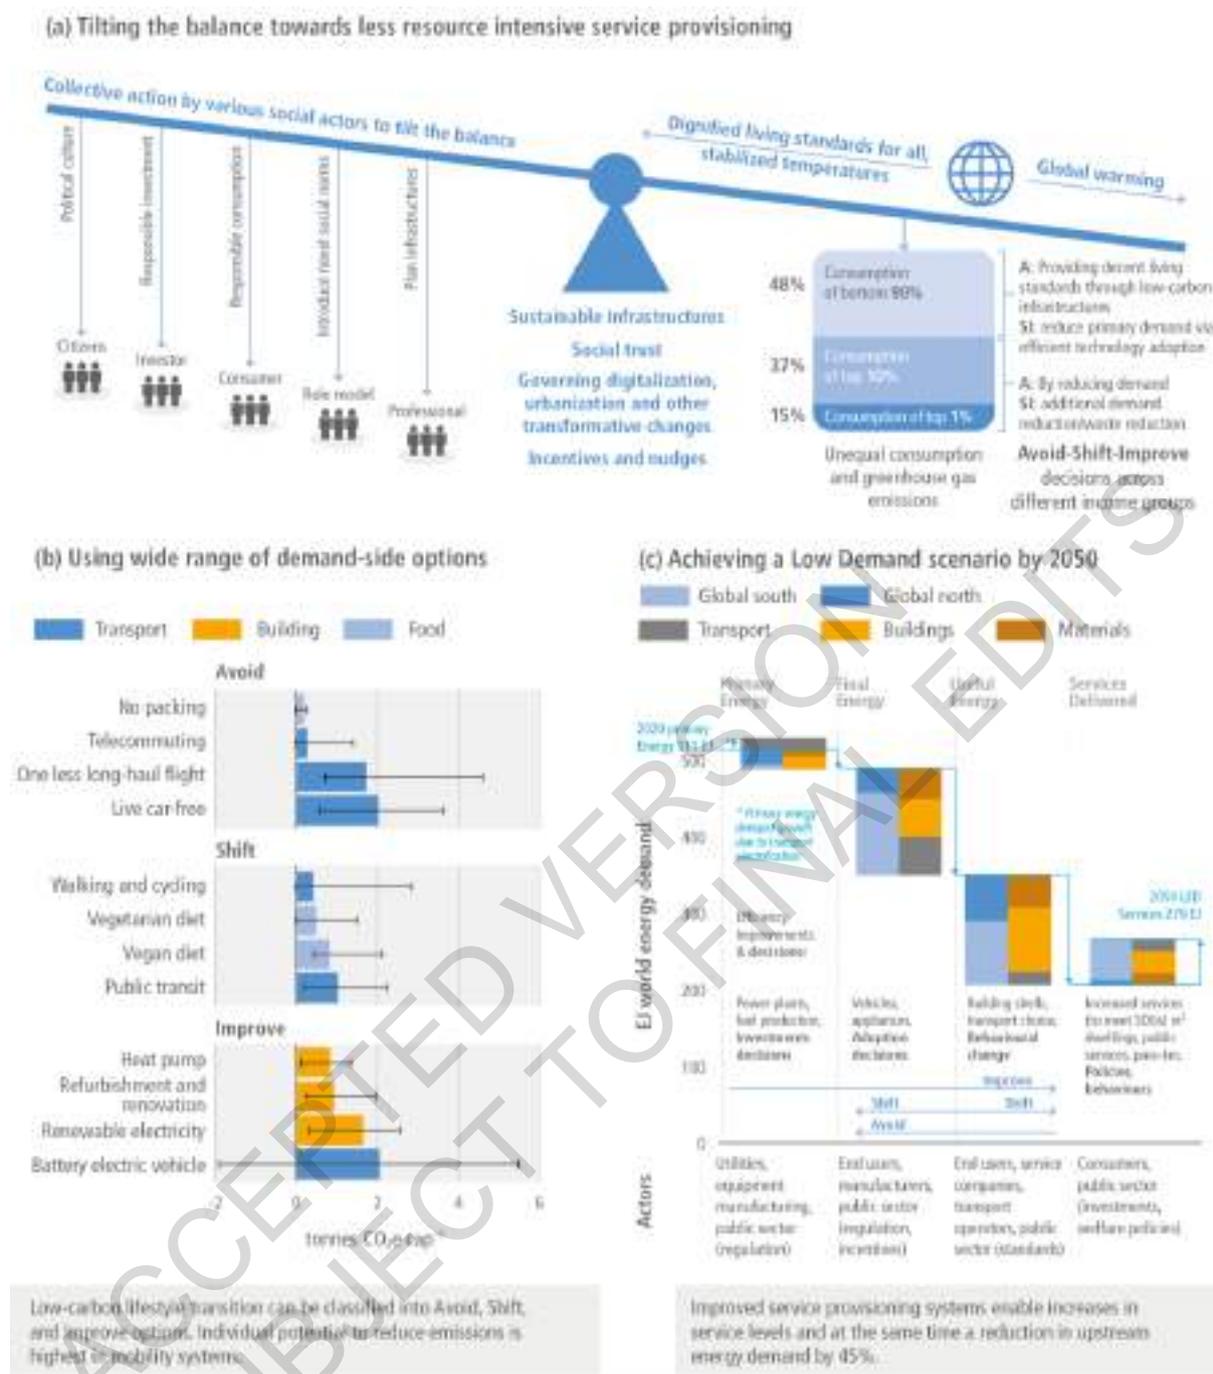

1 processing capacity maximising self-focused expected utility and differing only in wealth, risk attitude,
2 and time discount rate. AR5 introduced a broader range of goals (material, social, and psychological)
3 and decision processes (calculation-based, affect-based, and rule-based processes). However, its
4 perspective was still individual- and agency-focused, neglecting structural, cultural, and institutional
5 constraints and the influence of physical and social context.

6 A social science perspective is important in two ways. By adding new actors and perspectives, it (i)
7 provides more options for climate mitigation; and (ii) helps to identify and address important social and
8 cultural barriers and opportunities to socioeconomic, technological, and institutional change. Demand-
9 side mitigation involves five sets of social actors: individuals (e.g., consumption choices, habits),
10 groups and collectives (e.g., social movements, values), corporate actors (e.g., investments,
11 advertising), institutions (e.g., political agency, regulations), and infrastructure actors (e.g., very long-
12 term investments and financing). Actors either contribute to the status-quo of a global high-carbon,
13 consumption, and GDP growth-oriented economy, or help generate the desired change to a low-carbon
14 energy-services, well-being, and equity-oriented economy. Each set of actors has novel implications for
15 the design and implementation of both demand- and supply-side mitigation policies. They show
16 important synergies, making energy demand mitigation a dynamic problem where the packaging and/or
17 sequencing of different policies play a role in their effectiveness {5.5, 5.6}. Incremental interventions
18 change social practices, simultaneously affecting emissions and well-being. The transformative change
19 requires coordinated action across all five sets of actors (Table 5.4), using social science insights about
20 intersection of behaviour, culture, institutional and infrastructural changes for policy design and
21 implementation. *Avoid*, *Shift*, and *Improve* choices by individuals, households and communities support
22 mitigation {5.3.1.1, Table 5.1}. They are instigated by role models, changing social norms driven by
23 policies and social movements. They also require appropriate infrastructures designed by urban
24 planners and building and transport professionals, corresponding investments, and a political culture
25 supportive of demand side mitigation action.

26 **END BOX TS.11 HERE**

27

28 **Leveraging improvements in end-use service delivery through behavioural and technological**
29 **innovations, and innovations in market organisation, leads to large reductions in upstream**
30 **resource use (*high confidence*). Analysis of indicative potentials range from a factor 10- to 20-fold**
31 **improvement in the case of available energy (exergy) analysis, with the highest improvement potentials**
32 **at the end-user and service-provisioning levels. Realisable service level efficiency improvements could**
33 **reduce upstream energy demand by 45% in 2050. (Figure TS.20) {5.3.2, Figure 5.10}**

1
2 **Figure TS.20: Demand-side strategies for mitigation. Demand-side mitigation is about more than**
3 **behavioural change and transformation happens through societal, technological and institutional changes**
4 **{Figure 5.10, Figure 5.14}**
5
6

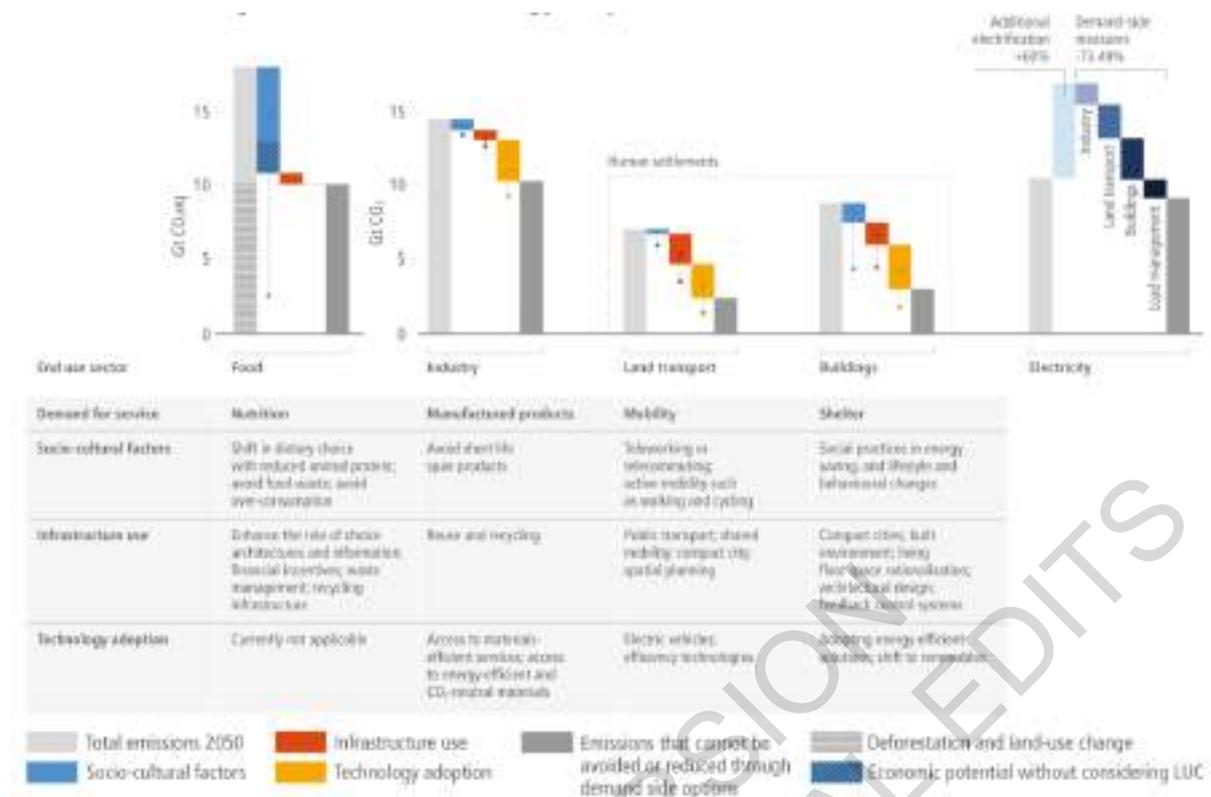

Figure TS.21: Demand-side mitigation can be achieved through changes in socio-cultural factors, infrastructure design and use, and technology adoption

Figure TS.21 legend: Mitigation response options related to demand for services have been categorised into three domains: ‘socio-cultural factors’, related to social norms, culture, and individual choices and behaviour; ‘infrastructure use’, related to the provision and use of supporting infrastructure that enables individual choices and behaviour; and ‘technology adoption’, which refers to the uptake of technologies by end users.

Potentials in 2050 are estimated using the International Energy Agency’s 2020 World Energy Outlook STEPS (Stated Policy Scenarios) as a baseline. This scenario is based on a sector-by-sector assessment of specific policies in place, as well as those that have been announced by countries by mid-2020. This scenario was selected due to the detailed representation of options across sectors and sub-sectors.

The heights of the coloured columns represent the potentials on which there is a high level of agreement in the literature, based on a range of case studies. The range shown by the dots connected by dotted lines represents the highest and lowest potentials reported in the literature which have low to medium levels of agreement.

The demand side potential of socio-cultural factors in the food system has two parts. The economic potential of direct emissions (mostly non-CO₂) demand reduction through socio-cultural factors alone is 1.9 GtCO₂eq without considering land use change by diversion of agricultural land from food production to carbon sequestration. If further changes in land use enabled by this change in demand are considered, the indicative potential could reach 7 GtCO₂eq.

The electricity panel presents separately the mitigation potential from changes in electricity demand and changes associated with enhanced electrification in end use sectors. Electrification increases electricity demand, while it is avoided through demand-side mitigation strategies. Load management refers to demand side flexibility that can be achieved through incentive design like time of use pricing/monitoring by artificial intelligence, diversification of storage facilities etc. NZE (IEA Net Zero Emissions by 2050 Scenario) is used to compute the impact of end use sector electrification, while the impact of demand side response options is based on bottom-up assessments.

Dark grey columns show the emissions that cannot be avoided through demand-side mitigation options.

The table indicates which demand-side mitigation options are included. Options are categorised according to: socio-cultural factors, infrastructure use, and technology adoption.

1 Figure SPM.7 covers potential of demand-side options for the year 2050. Figure SPM.8 covers both supply- and
2 demand-side options and their potentials for the year 2030.
3 {5.3, Figure 5.7, Supplementary Material 5.II}
4

5 **Decent living standards (DLS) and well-being for all (SDG 3) are achievable if high-efficiency low-**
6 **demand mitigation pathways are followed (medium confidence).** Minimum requirements of energy
7 use consistent with enabling *well-being for all* is between 20 and 50 GJ cap⁻¹ yr⁻¹ depending on the
8 context. (Figure TS.22) {5.2.2.1, 5.2.2.2, Box 5.3}

9 **Alternative service provision systems, for example those enabled through digitalisation, sharing**
10 **economy initiatives and circular economy initiatives, have to date made a limited contribution to**
11 **climate change mitigation (medium confidence).** While digitalisation through specific new products
12 and applications holds potential for improvement in service-level efficiencies, without public policies
13 and regulations, it also has the potential to increase consumption and energy use. Reducing the energy
14 use of data centres, networks, and connected devices is possible in managing low-carbon digitalisation.
15 Claims on the benefits of the circular economy for sustainability and climate change mitigation have
16 limited evidence. (Box TS.12, Box TS.14) {5.3.4, Figure 5.12, Figure 5.13}

17 18 **START BOX TS.12 HERE**

19 **Box TS.12: Circular Economy (CE)**

20 In AR6, the Circular Economy (CE) concept {Annex I} is highlighted as an increasingly important
21 mitigation approach that can help deliver human well-being by minimising waste of energy and
22 resources. While definitions of CE vary, its essence is to shift away from linear “make and dispose”
23 economic models to those that emphasize product longevity, reuse, refurbishment, recycling, and
24 material efficiency, thereby enabling more circular material systems that reduce embodied energy and
25 emissions. {5.3.4, 8.4, 8.5, 9.5, 11.3.3}

26 Whereas IPCC AR4 {WG III, Chapter 10} included a separate chapter on waste sector emissions and
27 waste management practices, and AR5 {WG III, Chapter 10} reviewed the importance of “reduce,
28 reuse, recycle” and related policies, AR6 focuses on how CE can reduce waste in materials production
29 and consumption by optimising materials’ end-use service utility. Specific examples of CE
30 implementations, policies, and mitigation potentials are included in chapters 5, 8, 9, 11 and 12. {5.3,
31 8.4, 9.5, 11.3, 12.6}

32 CE is shown to empower new social actors in mitigation actions, given that it relies on the synergistic
33 actions of producers, sellers, and consumers {11.3.3}. As an energy and resource demand-reduction
34 strategy, it is consistent with high levels of human well-being {5.3.4.3} and ensures better
35 environmental quality (Figure TS.22) {5.2.1}. It also creates jobs through increased sharing, reuse,
36 refurbishment, and recycling activities. Therefore, CE contributes to several SDGs, including Clean
37 Water and Sanitation (SDG6), Affordable Energy and Clean Energy (SDG7), Decent Work and
38 Economic Growth (SDG8), Responsible Production and Consumption (SDG12) and Climate Action
39 (SDG13). {11.5.3.2}

40 Emissions savings derive from reduced primary material production and transport. For example, in
41 buildings, lifetime extension, material efficiency, and reusable components reduce embodied emissions
42 by avoiding demand for structural materials {9.3, 9.5}. At regional scales, urban/industrial symbiosis
43 reduce primary material demand through byproduct exchange networks {11.3.3}. CE strategies also
44 exhibit enabling effects, such as material-efficient and circular vehicle designs that also improve fuel
45 economy {10.2.2.2}. There is growing interest in “circular bioeconomy” concepts applied to bio-based

1 materials {Box 12.2} and even a “circular carbon economy”, wherein carbon captured via CCU
2 {11.3.6} or CDR {3.4.6} is converted into reusable materials, which is especially relevant for the
3 transitions of economies dependent on fossil fuel revenue. {12.6}

4 While there are many recycling policies, CE-oriented policies for more efficient material use with
5 higher value retention are comparatively far fewer; these policy gaps have been attributed to
6 institutional failures, lack of coordination, and lack of strong advocates {5.3, 9.5.3.6, Box 11.5, Box
7 12.2}. Reviews of mitigation potentials reveal unevenness in the savings of CE applications and
8 potential risks of rebound effects {5.3}. Therefore, CE policies that identify system determinants
9 maximize potential emissions reductions, which vary by material, location, and application.

10 There are knowledge gaps for assessing CE opportunities within mitigation models due to CE’s many
11 cross-sectoral linkages and data gaps related to its nascent state {3.4.4}. Opportunity exists to bridge
12 knowledge from the Industrial Ecology field, which has historically studied CE, to the mitigation
13 modelling community for improved analysis of interventions and policies for AR7. For instance, a
14 global CE knowledge sharing platform is helpful for CE performance measurement, reporting and
15 accounting. {5.3, 9.5, 11.7}

16 **END BOX TS.12 HERE**

17

18 **Providing better services with less energy and resource input has high technical potential and is**
19 **consistent with providing well-being for all (*medium confidence*).** The assessment of 19 demand-
20 side mitigation options and 18 different constituents of well-being showed that positive impacts on well-
21 being outweigh negative ones by a factor of 11. {5.2, 5.2.3, Figure 5.6}

22 **Demand-side mitigation options bring multiple interacting benefits (*high confidence*).** Energy
23 services to meet human needs for nutrition, shelter, health, etc. are met in many different ways with
24 different emissions implications that depend on local contexts, cultures, geography, available
25 technologies, and social preferences. In the near term, many less-developed countries, and poor people
26 everywhere, require better access to safe and low-emissions energy sources to ensure decent living
27 standards and increase energy savings from service improvements by about 20-25%. (Figure TS.22)
28 {5.2, 5.4.5, Figure 5.3, Figure 5.4, Figure 5.5, Figure 5.6, Box 5.2, Box 5.3}

29 **Granular technologies and decentralized energy end-use, characterised by modularity, small unit**
30 **sizes and small unit costs, diffuse faster into markets and are associated with faster technological**
31 **learning benefits, greater efficiency, more opportunities to escape technological lock-in, and**
32 **greater employment (*high confidence*).** Examples include solar PV systems, batteries, and thermal
33 heat pumps. {5.3, 5.5, 5.5.3}

34 **Wealthy individuals contribute disproportionately to higher emissions and have a high potential**
35 **for emissions reductions while maintaining decent living standards and well-being (*high***
36 ***confidence*).** Individuals with high socio-economic status are capable of reducing their GHG emissions
37 by becoming role models of low-carbon lifestyles, investing in low-carbon businesses, and advocating
38 for stringent climate policies. {5.4.1, 5.4.3, 5.4.4, Figure 5.14}

39 **Demand-side solutions require both motivation and capacity for change (*high confidence*).**
40 Motivation by individuals or households worldwide to change energy consumption behaviour is
41 generally low. Individual behavioural change is insufficient for climate change mitigation unless
42 embedded in structural and cultural change. Different factors influence individual motivation and
43 capacity for change in different demographics and geographies. These factors go beyond traditional
44 socio-demographic and economic predictors and include psychological variables such as awareness,
45 perceived risk, subjective and social norms, values, and perceived behavioural control. Behavioural

1 nudges promote easy behaviour change, e.g., “*Improve*” actions such as making investments in energy
2 efficiency but fail to motivate harder lifestyle changes (*high confidence*). {5.4}

3 **Behavioural interventions, including the way choices are presented to end users (an intervention**
4 **practice known as choice architecture), work synergistically with price signals, making the**
5 **combination more effective (*medium confidence*).** Behavioural interventions through nudges, and
6 alternative ways of redesigning and motivating decisions, alone provide small to medium contributions
7 to reduce energy consumption and GHG emissions. Green defaults, such as automatic enrolment in
8 “green energy” provision, are highly effective. Judicious labelling, framing, and communication of
9 social norms can also increase the effect of mandates, subsidies, or taxes. {5.4, 5.4.1, Table 5.3, 5.3}

10 **Cultural change, in combination with new or adapted infrastructure, is necessary to enable and**
11 **realise many *Avoid and Shift* options (*medium confidence*).** By drawing support from diverse actors,
12 narratives of change can enable coalitions to form, providing the basis for social movements to
13 campaign in favour of (or against) societal transformations. People act and contribute to climate change
14 mitigation in their diverse capacities as consumers, citizens, professionals, role models, investors, and
15 policymakers. {5.4, 5.5, 5.6}

Figure TS.22: Demand side mitigation options, well-being and SDGs {Figure 5.6}

2

3

- 1 **Collective action as part of social or lifestyle movements underpins system change (*high***
2 ***confidence*)**. Collective action and social organising are crucial to shift the possibility space of public
3 policy on climate change mitigation. For example, climate strikes have given voice to youth in more
4 than 180 countries. In other instances, mitigation policies allow the active participation of all
5 stakeholders, resulting in building social trust, new coalitions, legitimising change, and thus initiate a
6 positive cycle in climate governance capacity and policies. {5.4.2, Figure 5.14}
- 7 **Transition pathways and changes in social norms often start with pilot experiments led by**
8 **dedicated individuals and niche groups (*high confidence*)**. Collectively, such initiatives can find
9 entry points to prompt policy, infrastructure, and policy reconfigurations, supporting the further uptake
10 of technological and lifestyle innovations. Individuals' agency is central as social change agents and
11 narrators of meaning. These bottom-up socio-cultural forces catalyse a supportive policy environment,
12 which enables changes. {5.5.2}
- 13 **The current effects of climate change, as well as some mitigation strategies, are threatening the**
14 **viability of existing business practices, while some corporate efforts also delay mitigation action**
15 **(*medium confidence*)**. Policy packages that include job creation programs can help to preserve social
16 trust, livelihoods, respect, and dignity of all workers and employees involved. Business models that
17 protect rent extracting behaviour may sometimes delay political action. Corporate advertisement and
18 brand building strategies may also attempt to deflect corporate responsibility to individuals or aim to
19 appropriate climate care sentiments in their own brand-building. {5.4.3, 5.6.4}
- 20 **Middle actors – professionals, experts, and regulators – play a crucial albeit underestimated and**
21 **underutilised role in establishing low-carbon standards and practices (*medium confidence*)**.
22 Building managers, landlords, energy efficiency advisers, technology installers, and car dealers
23 influence patterns of mobility and energy consumption by acting as middle actors or intermediaries in
24 the provision of building or mobility services and need greater capacity and motivation to play this role.
25 (Figure TS.20a) {5.4.3}
- 26 **Social influencers and thought leaders can increase the adoption of low-carbon technologies,**
27 **behaviours, and lifestyles (*high confidence*)**. Preferences are malleable and can align with a cultural
28 shift. The modelling of such shifts by salient and respected community members can help bring about
29 changes in different service provisioning systems. Between 10% and 30% of committed individuals are
30 required to set new social norms. {5.2.1, 5.4}

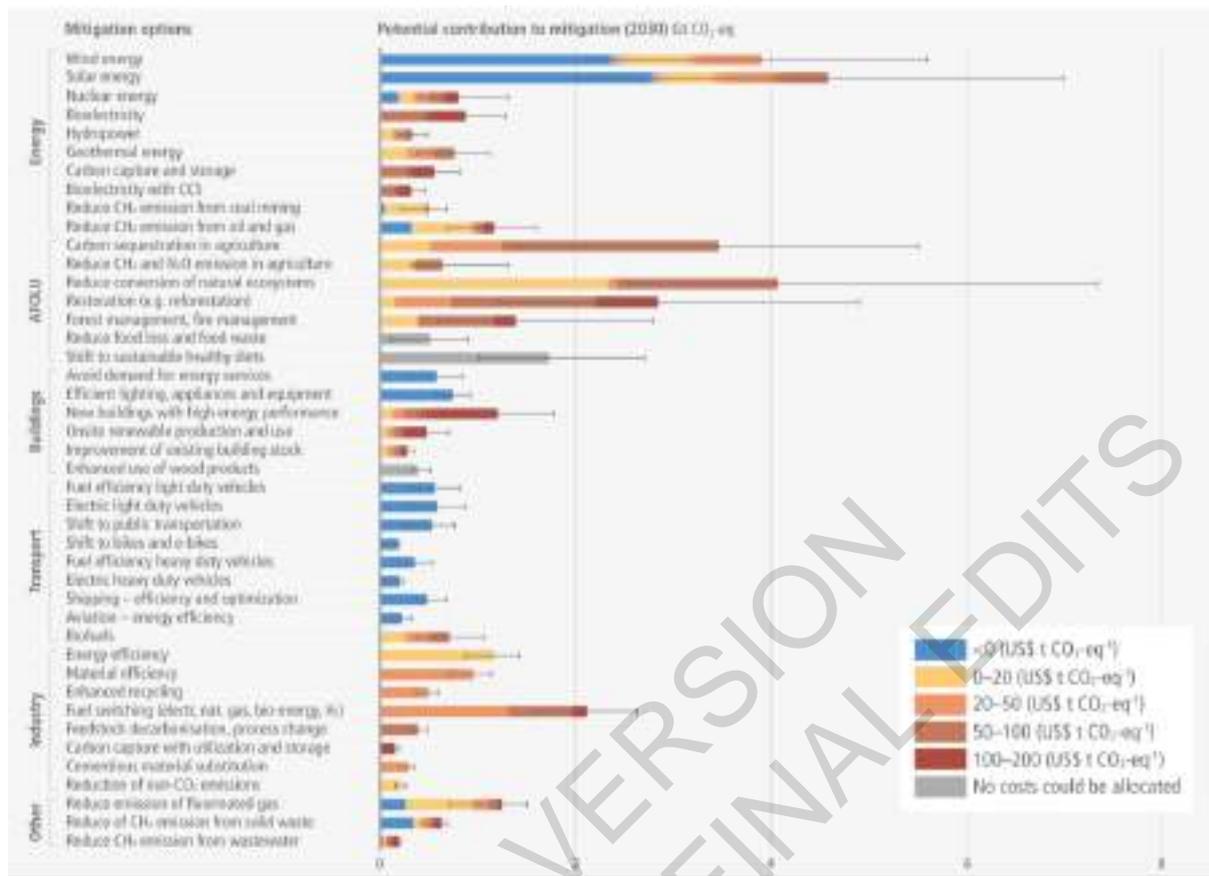

1 **TS. 5.9 Mitigation potential across sectors and systems**

2 **The total emission mitigation potential achievable by the year 2030, calculated based on sectoral**
3 **assessments, is sufficient to reduce global greenhouse gas emissions to half of the current (2019)**
4 **level or less (*high confidence*).** This potential – 31 to 44 GtCO₂-eq – requires the implementation of a
5 wide range of mitigation options. Options with mitigation costs lower than USD20 tCO₂⁻¹ make up
6 more than half of this potential and are available for all sectors. The market benefits of some options
7 exceed their costs. (Figure TS.23) {12.2, Table 12.3}

8 **Cross-sectoral considerations in mitigation finance are critical for the effectiveness of mitigation**
9 **action as well as for balancing the often conflicting social, developmental, and environmental**
10 **policy goals at the sectoral level (*medium confidence*).** True resource mobilisation plans that properly
11 address mitigation costs and benefits at sectoral level cannot be developed in isolation of their cross-
12 sectoral implications. There is an urgent need for multilateral financing institutions to align their
13 frameworks and delivery mechanisms including the use of blended financing to facilitate cross-sectoral
14 solutions as opposed to causing competition for resources among sectors. {12.6.4}

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1

2

3 **Figure TS.23: Overview of emission mitigation options and their cost and potential for the year 2030.**

4

5 **Figure TS.23 legend:** The mitigation potential of each option is the quantity of net greenhouse gas emission
6 reductions that can be achieved by a given mitigation option relative to specified emission baselines that reflects
7 what would be considered current policies in the period 2015-2019. Mitigation options may overlap or interact
8 and cannot simply be summed together.

9

10 The potential for each option is broken down into cost categories (see legend). Only monetary costs and
11 revenues are considered. If costs are less than zero, lifetime monetary revenues are higher than lifetime
12 monetary costs. For wind energy, for example, negative cost indicates that the cost is lower than that of fossil-
13 based electricity production. The error bars refer to the total potential for each option. The breakdown into cost
14 categories is subject to uncertainty. Where a smooth colour transition is shown, the breakdown of the potential
15 into cost categories is not well researched, and the colours indicate only into which cost category the potential
16 can predominantly be found in the literature.

16

17 {Figure SPM.8, 6.4, Table 7.3, Supplementary Material Table 9.2, Supplementary Material Table 9.3, 10.6,
18 11.4, Fig 11.13, 12.2, Supplementary Material 12.A.2.3}

18

19 **Carbon leakage is a cross-sectoral and cross-country consequence of differentiated climate policy**
20 **(robust evidence, medium agreement)**. Carbon leakage occurs when mitigation measures implemented
21 in one country/sector leads to increased emissions in other countries/sectors. Global commodity value
22 chains and associated international transport are important mechanisms through which carbon leakage
23 occurs. Reducing emissions from the value chain and transportation can offer opportunities to mitigate
24 three elements of cross-sectoral spill-overs and related leakage: 1) domestic cross-sectoral spill-overs
25 within the same country; 2) international spill-overs within a single sector resulting from substitution
26 of domestic production of carbon-intensive goods with their imports from abroad; and 3) international
27 cross-sectoral spill-overs among sectors in different countries. {12.6.3}

1 **TS. 6 Implementation and enabling conditions**

2 Chapters 13-16 address the enabling conditions that can accelerate or impede rapid progress on
3 mitigation. Chapters 13 and 14 focus on policy, governance and institutional capacity, and international
4 cooperation, respectively taking a national and international perspective; Chapter 15 focusses on
5 investment and finance; and Chapter 16 focusses on innovation and technology. The assessment of
6 social aspects of mitigation draws on material assessed in Chapter 5.

7 **TS. 6.1 Policy and Institutions**

8 **Long-term deep emission reductions, including the reduction of emissions to net zero, is best**
9 **achieved through institutions and governance that nurture new mitigation policies, while at the**
10 **same time reconsidering existing policies that support the continued emission of GHGs (*high***
11 ***confidence*).** To do so effectively, the scope of climate governance needs to include both direct efforts
12 to target GHG emissions and indirect opportunities to tackle GHG emissions that result from efforts
13 directed towards other policy objectives. {13.2, 13.5, 13.6, 13.7, 13.9}

14 **Institutions and governance underpin mitigation by providing the legal basis for action. This**
15 **includes setting up implementing organisations and the frameworks through which diverse actors**
16 **interact (*medium evidence, high agreement*).** Institutions can create mitigation and sectoral policy
17 instruments; policy packages for low-carbon system transition; and economy wide measures for
18 systemic restructuring. {13.2, 13.7, 13.9}

19 **Policies have had a discernible impact on mitigation for specific countries, sectors, and**
20 **technologies (*high confidence*), avoiding emissions of several GtCO₂-eq yr⁻¹ (*medium confidence*).**
21 Both market-based and regulatory policies have distinct, but complementary roles. The share of global
22 GHG emissions subject to mitigation policy has increased rapidly in recent years, but big gaps remain
23 in policy coverage, and the stringency of many policies falls short of what is needed to achieve the
24 desired mitigation outcomes. (Box TS.13) {13.6, Cross-Chapter Box 10 in Chapter 14}

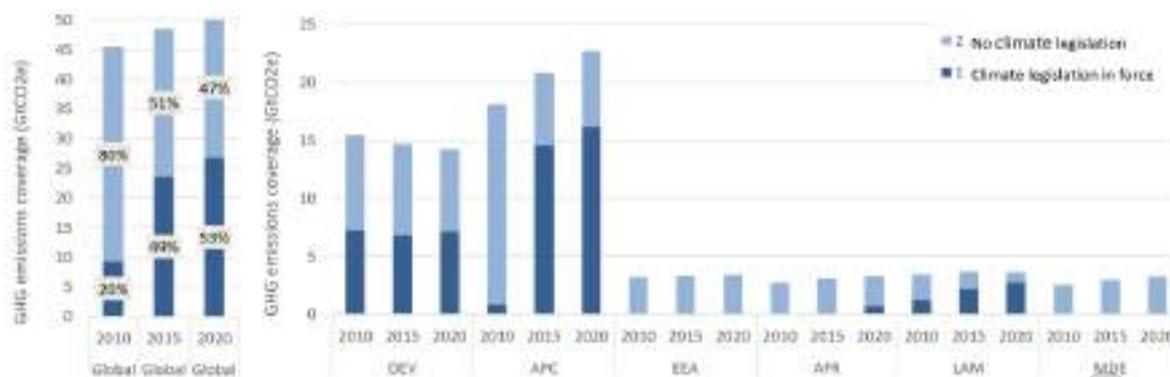

25 **Climate laws enable mitigation action by signalling the direction of travel, setting targets,**
26 **mainstreaming mitigation into sector policies, enhancing regulatory certainty, creating law-**
27 **backed agencies, creating focal points for social mobilisation, and attracting international finance**
28 **(*medium evidence, high agreement*).** By 2020, ‘direct’ climate laws primarily focused on GHG
29 reductions were present in 56 countries covering 53% of global emissions (see Figure TS.24). More
30 than 690 laws, including ‘indirect’ laws, however, may also have an effect on mitigation. Among direct
31 laws, ‘framework’ laws set an overarching legal basis for mitigation either by pursuing a target and
32 implementation approach, or by seeking to mainstream climate objectives through sectoral plans and
33 integrative institutions. (Figure TS.24) {13.2}

34 **Institutions can enable improved governance by coordinating across sectors, scales and actors,**
35 **building consensus for action, and setting strategies (*medium evidence, high agreement*).**
36 Institutions are more stable and effective when they are congruent with national contexts, leading to
37 mitigation-focused institutions in some countries and the pursuit of multiple objectives in others. Sub-
38 national institutions play a complementary role to national institutions by developing locally-relevant
39 visions and plans, addressing policy gaps or limits in national institutions, building local administrative
40 structures and convening actors for place-based decarbonisation. {13.2}

41 **Mitigation strategies, instruments and policies that fit with dominant ideas, values and belief**
42 **systems within a country or within a sector are more easily adopted and implemented (*medium***
43 ***confidence*).** Ideas, values and beliefs may change over time. Policies that bring perceived direct
44 benefits, such as subsidies, usually receive greater support. The awareness of co-benefits for the public
45 increases support of climate policies (*high confidence*). {13.2, 13.3, 13.4}

4

Panel b

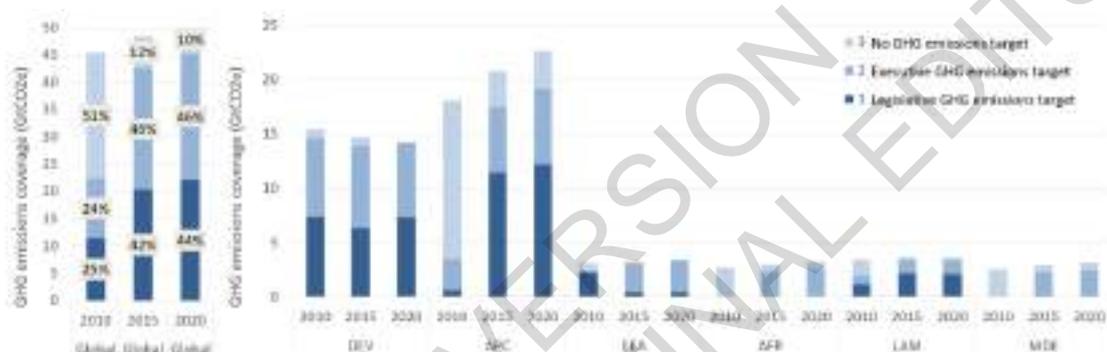

5
6

Figure TS.24: Prevalence of Legislation and Emissions Targets across Regions

7
8

Figure TS.24 legend: Panel a: Shares of global GHG emissions under national climate change legislations – in 2010, 2015 and 2020. Climate legislation is defined as an act passed by a parliament that includes the reduction of GHGs in its title or objectives.

Panel b: Shares of global GHG emissions under national climate emission targets – in 2010, 2015 and 2020. Emissions reductions targets were taken into account as a legislative target when they were defined in a law or as part of a country's submission under the Kyoto Protocol, or as an executive target when they were included in a national policy or official submissions under the UNFCCC. Targets were included if they were economy wide or included at least the energy sector. The proportion of national emissions covered are scaled to reflect coverage and whether targets are in GHG or CO₂ terms.

Emissions data used are for 2019. 2020 data was excluded as emissions shares across regions deviated from past patterns due to COVID-19. AR6 regions: DEV = Developed countries; APC = Asia and developing Pacific; EEA = Eastern Europe and West-Central Asia; AFR = Africa; LAM = Latin America and the Caribbean; MDE = Middle East. {Figure 13.1 and 13.2}

21
22

Climate governance is constrained and enabled by domestic structural factors, but it is still possible for actors to make substantial changes (*medium evidence, high agreement*). Key structural factors are domestic material endowments (such as fossil fuels and land-based resources); domestic political systems; and prevalent ideas, values and belief systems. Developing countries face additional material constraints in climate governance due to development challenges and scarce economic or natural resources. A broad group of actors influence how climate governance develop over time, including a range of civic organisations, encompassing both pro- and anti-climate action groups. {13.3, 13.4}

1 **Sub-national actors are important for mitigation because municipalities and regional**
2 **governments have jurisdiction over climate-relevant sectors such as land-use, waste and urban**
3 **policy. They are able to experiment with climate solutions and can forge partnerships with the**
4 **private sector and internationally to leverage enhanced climate action (*high confidence*). More**
5 **than 10,500 cities and nearly 250 regions representing more than 2 billion people have pledged largely**
6 **voluntary action to reduce emissions. Indirect gains include innovation, establishing norms and**
7 **developing capacity. However, sub-national actors often lack national support, funding, and capacity to**
8 **mobilize finance and human resources, and create new institutional competences. {13.5}**

9 **Climate litigation is growing and can affect the outcome and ambition of climate governance**
10 **(*medium evidence, high agreement*). Since 2015, at least 37 systemic cases have been initiated against**
11 **states that challenge the overall effort of a state to mitigate or adapt to climate change. If successful,**
12 **such cases can lead to an increase in a country's overall ambition to tackle climate change. Climate**
13 **litigation has also successfully challenged governments' authorisations of high-emitting projects setting**
14 **precedents in favour of climate action. Climate litigation against private sector and financial institutions**
15 **is also on the rise. {13.4}**

16 **The media shapes the public discourse about climate mitigation. This can usefully build public**
17 **support to accelerate mitigation action but may also be used to impede decarbonisation (*medium***
18 ***evidence, high agreement*). Global media coverage (across a study of 59 countries) has been growing,**
19 **from about 47,000 articles in 2016-17 to about 87,000 in 2020-21. Generally, the media representation**
20 **of climate science has increased and become more accurate over time. On occasion, the propagation of**
21 **scientifically misleading information by organized counter-movements has fuelled polarisation, with**
22 **negative implications for climate policy. {13.4}**

23 **Explicit attention to equity and justice is salient to both social acceptance and fair and effective**
24 **policymaking for mitigation (*high confidence*). Distributional implications of alternative climate**
25 **policy choices can be usefully evaluated at city, local and national scales as an input to policymaking.**
26 **It is anticipated that institutions and governance frameworks that enable consideration of justice and**
27 **just transitions can build broader support for climate policymaking. {13.2, 13.6, 13.8, 13.9}**

28 **Carbon pricing is effective in promoting implementation of low-cost emissions reductions (*high***
29 ***confidence*). While the coverage of emissions trading and carbon taxes has risen to over 20 percent of**
30 **global CO₂ emissions, both coverage and price are lower than is needed for deep reductions. Market**
31 **mechanisms ideally are designed to be effective as well as efficient, balance distributional goals and**
32 **find social acceptance. Practical experience has driven progress in market mechanism design, especially**
33 **of emissions trading schemes. Carbon pricing is limited in its effect on adoption of higher-cost**
34 **mitigation options, and where decisions are often not sensitive to price incentives such as in energy**
35 **efficiency, urban planning, and infrastructure (*robust evidence, medium agreement*). Subsidies have**
36 **been used to improve energy efficiency, encourage the uptake of renewable energy and other sector-**
37 **specific emissions saving options {13.6}**

38 **Carbon pricing is most effective if revenues are redistributed or used impartially (*high***
39 ***confidence*). A carbon levy earmarked for green infrastructures or saliently returned to taxpayers**
40 **corresponding to widely accepted notions of fairness increases the political acceptability of carbon**
41 **pricing. {5.6, Box 5.11}**

42 **Removing fossil fuel subsidies could reduce emissions by 1-10% by 2030 while improving public**
43 **revenue and macroeconomic performance (*robust evidence, medium agreement*). {13.6}**

44 **Regulatory instruments play an important role in achieving specific mitigation outcomes in**
45 **sectoral applications (*high confidence*). Regulation is effective in particular applications and often**
46 **enjoys greater political support, but tends to be more economically costly, than pricing instruments**

1 (*robust evidence, medium agreement*). Flexible forms of regulation (e.g., performance standards) have
2 achieved aggregate goals for renewable energy generation, vehicle efficiency and fuel standards, and
3 energy efficiency in buildings and industry. Infrastructure investment decisions are significant for
4 mitigation because they lock in high- or low- emissions trajectories over long periods. Information and
5 voluntary programs can contribute to overall mitigation outcomes (*medium evidence, high agreement*).
6 Designing for overlap and interactions among mitigation policies enhances their effectiveness. {13.6}

7 **National mitigation policies interact internationally with effects that both support and hinder**
8 **mitigation action (*medium evidence, high agreement*)**. Reductions in demand for fossil fuels tend to
9 negatively affect fossil fuel exporting countries. Creation of markets for emission reduction credits
10 tends to benefit countries able to supply credits. Policies to support technology development and
11 diffusion tend to have positive spill over effects. There is no consistent evidence of significant emissions
12 leakage or competitiveness effects between countries, including for emissions-intensive trade-exposed
13 industries covered by emission trading systems (*medium confidence*). {13.6}

14 **Policy packages are better able to support socio-technical transitions and shifts in development**
15 **pathways toward low carbon futures than are individual policies (*high confidence*)**. For best effect,
16 they need to be harnessed to a clear vision for change and designed with attention to local governance
17 context. Comprehensiveness in coverage, coherence to ensure complementarity, and consistency of
18 policies with the overarching vision and its objectives are important design criteria. Integration across
19 objectives occurs when a policy package is informed by a clear problem framing and identification of
20 the full range of relevant policy sub-systems. The climate policy landscape is outlined in Table TS.8,
21 which maps framings of desired national policy outcomes to policymaking approaches. {13.7, Figure
22 13.6}

23 **The co-benefits and trade-offs of integrating adaptation and mitigation are most usefully**
24 **identified and assessed prior to policy making rather than being accidentally discovered (*high***
25 ***confidence*)**. This requires strengthening relevant national institutions to reduce silos and overlaps,
26 increasing knowledge exchange at the country and regional levels, and supporting engagement with
27 bilateral and multilateral funding partners. Local governments are well placed to develop policies that
28 generate social and environmental co-benefits but to do so require legal backing and adequate capacity
29 and resources. {13.8}

30 **Climate change mitigation is accelerated when attention is given to integrated policy and economy**
31 **wide approaches, and when enabling conditions (*governance, institutions, behaviour and lifestyle,***
32 ***innovation, policy, and finance*) are present (*robust evidence, medium agreement*)**. Accelerating
33 climate mitigation includes simultaneously weakening high carbon systems and encouraging low
34 carbon systems; ensuring interaction between adjacent systems (e.g., energy and agriculture);
35 overcoming resistance to policies (e.g., from incumbents in high carbon emitting industries), including
36 by providing transitional support to the vulnerable and negatively affected by distributional impacts;
37 inducing changes in consumer practices and routines; providing transition support; and addressing
38 coordination challenges in policy and governance. Table TS.9 elucidates the complexity of
39 policymaking in driving sectoral transitions by summarising case studies of sectoral transitions from
40 Chapters 5-12. These real-world sectoral transitions reinforce critical lessons on policy integration.
41 (Table TS.9) {13.7, 13.9}

42 **Economy wide packages, including economic stimulus packages, can contribute to shifting**
43 **sustainable development pathways and achieving net zero outcomes whilst meeting short term**
44 **economic goals (*medium evidence, high agreement*)**. The 2008-9 Global Recession showed that
45 policies for sustained economic recovery go beyond short-term fiscal stimulus to include long-term
46 commitments of public spending on the low carbon economy, pricing reform, addressing affordability,
47 and minimising distributional impacts. COVID-19 spurred stimulus packages and multi-objective

1 recovery policies may also have potential to meet short-term economic goals while enabling longer-
2 term sustainability goals. (Table TS.8) {13.9}

Table TS.9: Case Studies of Integrated Policymaking for Sectoral Transitions1
2
3
4

Real world sectoral transitions reinforce critical lessons on policy integration: a high-level strategic goal (column A), the need for a clear sectoral outcome framing (column B), a carefully coordinated mix of policy instruments and governance actions (column C), and the importance of context-specific governance factors (column D). Illustrative examples, drawn from sectors, help elucidate the complexity of policymaking in driving sectoral transitions.

A. Illustrative Case	B. Objective	C. Policy mix	D. Governance Context	
			Enablers	Barriers
Shift in mobility service provision in Kolkata, India {Box 5.8}	<ul style="list-style-type: none"> - Improve system efficiency, sustainability and comfort - Shift public perceptions of public transport 	<ul style="list-style-type: none"> - Strengthen co-ordination between modes - Formalize and green auto-rickshaws - Procure fuel efficient, comfortable low floor AC buses - Ban cycling on busy roads - Deploy policy actors as change-agents, mediating between interest groups 	<ul style="list-style-type: none"> - Cultural norms around informal transport sharing, linked to high levels of social trust - Historically crucial role of buses in transit - App-cab companies shifting norms and formalizing mobility sharing - Digitalisation and safety on board 	<ul style="list-style-type: none"> - Complexity: multiple modes with separate networks and meanings - Pushback from equity-focused social movements against 'premium' fares, cycling ban
LPG Subsidy ("Zero Kero") Program, Indonesia {Box 6.3}	Decrease fiscal expenditures on kerosene subsidies for cooking	<ul style="list-style-type: none"> - Subsidize provision of Liquefied Petroleum Gas (LPG) cylinders and initial equipment - Convert existing kerosene suppliers to LPG suppliers 	<ul style="list-style-type: none"> - Provincial Government and industry support in targeting beneficiaries and implementation - Synergies in kerosene and LPG distribution infrastructures 	<ul style="list-style-type: none"> - Continued user preference for traditional solid fuels - Reduced GHG benefits as subsidy shifted between fossil fuels
Action Plan for Prevention and Control of Deforestation in the Legal Amazon, Brazil {Box 7.9}	Control deforestation and promote sustainable development	<ul style="list-style-type: none"> - Expand protected areas; homologation of indigenous lands - Improve inspections, satellite-based monitoring - Restrict public credit for enterprises and municipalities with high deforestation rates - Set up a REDD+ mechanism (Amazon Fund) 	<ul style="list-style-type: none"> - Participatory agenda-setting process - Cross-sectoral consultations on conservation guidelines - Mainstreaming of deforestation in government programs and projects 	<ul style="list-style-type: none"> - Political polarisation leading to erosion of environmental governance - Reduced representation and independence of civil society in decision-making bodies - Lack of clarity around land ownership
Climate smart cocoa (CSC) production, Ghana {Box 7.12}	<ul style="list-style-type: none"> - Promote sustainable intensification of cocoa production - Reduce deforestation - Enhance incomes and adaptive capacities 	<ul style="list-style-type: none"> - Distribute shade tree seedlings - Provide access to agronomic information and agro-chemical inputs - Design a multi-stakeholder program including MNCs, farmers and NGOs 	<ul style="list-style-type: none"> - Local resource governance mechanisms ensuring voice for smallholders - Community governance allowed adapting to local context - Private sector role in popularising CSC 	<ul style="list-style-type: none"> - Lack of secure tenure (tree rights) - Bureaucratic and legal hurdles to register trees - State monopoly on cocoa marketing, export
Coordination mechanism for joining fragmented urban policymaking	Integrate policymaking across objectives, towards low-carbon urban development	<ul style="list-style-type: none"> - Combine central targets and evaluation with local flexibility for initiating varied policy experiments - Establish a local leadership team for coordinating 	<ul style="list-style-type: none"> - Strong vertical linkages between central and local levels - Mandate for policy learning to inform national policy 	<ul style="list-style-type: none"> - Challenging starting point - low share of renewable energy high dependency on fossil fuels

A. Illustrative Case	B. Objective	C. Policy mix	D. Governance Context	
			Enablers	Barriers
in Shanghai, China {Box 8.3}		<ul style="list-style-type: none"> cross-sectoral policies involving multiple institutions Create a direct program fund for implementation and capacity-building 	<ul style="list-style-type: none"> Experience with mainstreaming mitigation in related areas (e.g., air pollution) 	<ul style="list-style-type: none"> Continued need for high investments in a developing context
Policy package for building energy efficiency, EU {Box SM 9.1}	Reduce energy consumption, integrating renewable energy and mitigating GHG emissions from buildings	<ul style="list-style-type: none"> Energy performance standards, set at nearly zero energy for new buildings Energy performance standards for appliances Energy performance certificates shown during sale Long Term Renovation Strategies 	<ul style="list-style-type: none"> Binding EU-level targets, directives and sectoral effort sharing regulations Supportive urban policies, coordinated through city partnerships Funds raised from allowances auctioned under the Emissions Trading Scheme (ETS) 	<ul style="list-style-type: none"> Inadequate local technical capacity to implement multiple instruments Complex governance structure leading to uneven stringency
African Electromobility- Trackless trams with solar in Bulawayo and e-motorbikes in Kampala {Box 10.4}	<ul style="list-style-type: none"> Leapfrog into a decarbonised transport future Achieve multiple social benefits beyond mobility provision 	<ul style="list-style-type: none"> Develop urban centres with solar at station precincts Public-private partnerships for financing Sanction demonstration projects for new electric transit and new electric motorbikes (for freight) 	<ul style="list-style-type: none"> 'Achieving SDGs' was an enabling policy framing Multi-objective policy process for mobility, mitigation and manufacturing Potential for funding through climate finance Co-benefits such as local employment generation 	<ul style="list-style-type: none"> Economic decline in the first decade of the 21st century Limited fiscal capacity for public funding of infrastructure Inadequate charging infrastructure for e-motorbikes

1 **START BOX TS.13 HERE**2 **Box TS.13: Policy Attribution – Methodologies for- and estimations of- the macro-level impact**
3 **of mitigation policies on indices of GHG mitigation**

4 Policy attribution examines the extent to which *GHG emission reductions*, the *proximate drivers of*
5 *emissions*, and the deployment of *technologies that reduce emissions* may be reasonably attributed to
6 policies implemented prior to the observed changes. Such policies include regulatory instruments such
7 as energy efficiency programmes or technical standards and codes, carbon pricing, financial support for
8 low-carbon energy technologies and efficiency, voluntary agreements, and regulation of land use
9 practices.

10 The vast majority of literature reviewed for this report examines the effect of particular instruments in
11 particular contexts {13.6, 14.3, 16.4}, and only a small number directly or plausibly infer global impacts
12 of policies. Policies also differ in design, scope, and stringency, may change over time as they require
13 amendments or new laws, and often partially overlap with other instruments. These factors complicate
14 analysis, because they give rise to the potential for double counting emissions reductions that have been
15 observed. These lines of evidence on the impact of polices include:

- 16 • **GHG Emissions** – Evidence from econometric assessments of the impact of policies in
17 countries which took on Kyoto Protocol targets; decomposition analyses that identify policy-
18 related, absolute reductions from historical levels in particular countries. {13.6.2, 14.3.3, Cross-
19 Chapter Box 10 in Chapter 14}
- 20 • **Proximate emission drivers** – trends in the factors that drive emissions including reduced rates
21 of deforestation {7.6.2}, industrial energy efficiency {Box 16.3}, buildings energy efficiency
22 {Figure 2.22}, and the policy-driven displacement of fossil fuel combustion by renewable
23 energy. (Box TS.13 Table 1, Box TS.13 Figure 1) {Chapters 2 and 6, Cross-Chapter Box 10 in
24 Chapter 14}.
- 25 • **Technologies** – the literature indicates unambiguously that the rapid expansion of low-carbon
26 energy technologies is substantially attributable to policy. {6.7.5, 16.5}

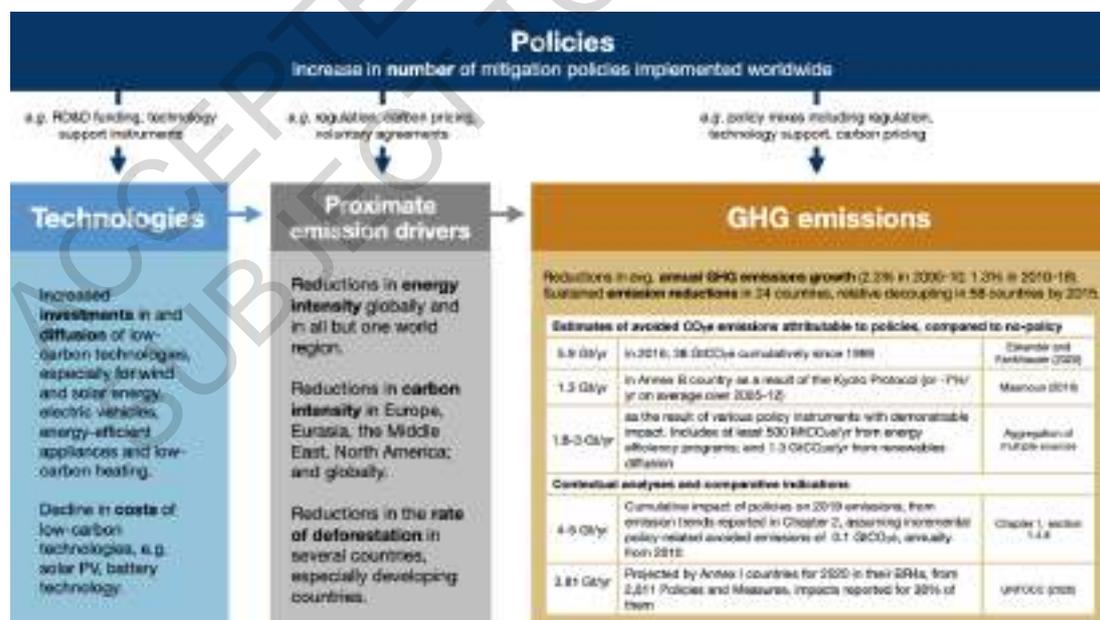

27 As illustrated in Box TS.13, Figure 1, these multiple lines of evidence indicate that point to policies
28 having had a discernible impact on mitigation for specific countries, sectors, and technologies (*high*
29 *confidence*), avoiding emissions of several GCO₂-eq yr⁻¹ globally (*medium confidence*).

1
2

Box TS.13 Table 1: The effects of policy on GHG emissions, drivers of emissions, and technology deployment

Sector	Effects on Emissions	Effects on Immediate Drivers	Effects on Low-carbon Technology
Energy supply {Chapter 6}	Carbon pricing, emissions standards, and technology support have led to declining emissions associated with the supply of energy	Carbon pricing and technology support have led to improvements in the efficiency of energy conversion	A variety of market-based instruments, especially technology support policies have led to high diffusion rates and cost reductions for renewable energy technologies.
AFOLU {Chapter 7}	Regulation of land-use rights and practices have led to falling aggregate AFOLU-sector emissions	Regulation of land-use rights and practices, payments for ecosystem service, and offsets have led to decreasing rates of deforestation (<i>medium confidence</i>)	
Buildings {Chapter 9}	Regulatory standards have led to reduced emissions from new buildings	Regulatory standards, financial support for building renovation and market-based instruments have led to improvements in building and building system efficiencies	Technology support and regulatory standards have led to adoption of low-carbon heating systems and high efficiency appliances
Transport {Chapter 10}	Vehicle standards, land-use planning, and carbon pricing have led to avoided emissions in ground transportation	Vehicle standard, carbon pricing, and support for electrification have led to automobile efficiency improvements	Technology support and emissions standards have increased diffusion rates and cost reductions for electric vehicles
Industry {Chapter 11}		Carbon pricing has led to efficiency improvements in industrial facilities.	

3 Note: Statements describe the effects of policies across those countries where policies are in place. Unless
4 otherwise noted, all findings are of *high confidence*

5
6 **Box TS.13, Figure 1: Policy impacts on key outcome indices: GHG emissions, proximate emission drivers,**
7 **and technologies, including several lines of evidence on GHG abatement attributable to policies. {Cross-**
8 **Chapter Box 10 Figure 1 in Chapter 14}**

9 **END BOX TS.13 HERE**

1 **TS. 6.2 International cooperation**

2 **International cooperation is having positive and measurable results (*high confidence*).** The Kyoto
3 Protocol led to measurable and substantial avoided emissions, including in 20 countries with Kyoto first
4 commitment period targets that have experienced a decade of declining absolute emissions. It also built
5 national capacity for GHG accounting, catalysed the creation of GHG markets, and increased
6 investments in low-carbon technologies. Other international agreements and institutions have led to
7 avoided CO₂ emissions from land-use practices, as well as avoided emissions of some non-CO₂
8 greenhouse gases. (*medium confidence*) {14.3, 14.5, 14.6}

9 **New forms of international cooperation have emerged since AR5 in line with an evolving**
10 **understanding of effective mitigation policies, processes, and institutions. Both new and pre-**
11 **existing forms of co-operation are vital for achieving climate mitigation goals in the context of**
12 **sustainable development (*high confidence*).** While previous IPCC assessments have noted important
13 synergies between the outcomes of climate mitigation and achieving sustainable development
14 objectives, there now appear to be synergies between the two processes themselves (*medium*
15 *confidence*). Since AR5, international cooperation has shifted towards facilitating national level
16 mitigation action through numerous channels, including through processes established under the
17 UNFCCC regime and through regional and sectoral agreements and organisations. {14.2, 14.3, 14.5,
18 14.6}

19 **Participation in international agreements and transboundary networks is associated with the**
20 **adoption of climate policies at the national and sub-national levels, as well as by non-state actors**
21 **(*high confidence*).** International cooperation helps countries achieve long-term mitigation targets when
22 it supports development and diffusion of low-carbon technologies, often at the level of individual
23 sectors, which can simultaneously lead to significant benefits in the areas of sustainable development
24 and equity (*medium confidence*). {14.2, 14.3, 14.5, 14.6}

25 **International cooperation under the UN climate regime took an important new direction with the**
26 **entry into force of the 2015 Paris Agreement, which strengthened the objective of the UN climate**
27 **regime, including its long-term temperature goal, while adopting a different architecture to that**
28 **of the Kyoto Protocol (*high confidence*).** The core national commitments under the Kyoto Protocol
29 were legally binding quantified emission targets for developed countries tied to well-defined
30 mechanisms for monitoring and enforcement. By contrast, the commitments under the Paris Agreement
31 are primarily procedural, extend to all parties, and are designed to trigger domestic policies and
32 measures, enhance transparency, and stimulate climate investments, particularly in developing
33 countries, and to lead iteratively to rising levels of ambition across all countries. Issues of equity remain
34 of central importance in the UN climate regime, notwithstanding shifts in the operationalisation of
35 ‘common but differentiated responsibilities and respective capabilities’ from Kyoto to Paris. {14.3}

36 **There are conflicting views on whether the Paris Agreement’s commitments and mechanisms will**
37 **lead to the attainment of its stated goals (*medium confidence*).** Arguments in support of the Paris
38 Agreement are that the processes it initiates and supports will in multiple ways lead, and indeed have
39 already led, to rising levels of ambition over time. The recent proliferation of national mid-century net
40 zero GHG targets can be attributed in part to the Paris Agreement. Moreover, its processes and
41 commitments will enhance countries’ abilities to achieve their stated level of ambition, particularly
42 among developing countries. Arguments against the Paris Agreement are that it lacks a mechanism to
43 review the adequacy of individual Parties’ nationally determined contributions (NDCs), that
44 collectively current NDCs are inconsistent in their level of ambition with achieving the Paris
45 Agreement’s long-term temperature goal, that its processes will not lead to sufficiently rising levels of
46 ambition in the NDCs, and that NDCs will not be achieved because the targets, policies and measures
47 they contain are not legally binding at the international level. To some extent, arguments on both sides

1 are aligned with different analytic frameworks, including assumptions about the main barriers to
2 mitigation that international cooperation can help overcome. The extent to which countries increase the
3 ambition of their NDCs and ensure they are effectively implemented will depend in part on the
4 successful implementation of the support mechanisms in the Paris Agreement, and in turn will
5 determine whether the goals of the Paris Agreement are met (*high confidence*). {14.2, 14.3, 14.4}

6 **International cooperation outside the UNFCCC processes and agreements provides critical**
7 **support for mitigation in particular regions, sectors and industries, for particular types of**
8 **emissions, and at the sub- and trans-national levels (*high confidence*).** Agreements addressing ozone
9 depletion, transboundary air pollution, and release of mercury are all leading to reductions in the
10 emissions of specific greenhouse gases. Cooperation is occurring at multiple governance levels
11 including cities. Transnational partnerships and alliances involving non-state and sub-national actors
12 are also playing a growing role in stimulating low-carbon technology diffusion and emissions
13 reductions (*medium confidence*). Such transnational efforts include those focused on climate litigation;
14 the impacts of these are unclear but promising. Climate change is being addressed in a growing number
15 of international agreements operating at sectoral levels, as well as within the practices of many
16 multilateral organisations and institutions. Sub-global and regional cooperation, often described as
17 climate clubs, can play an important role in accelerating mitigation, including the potential for reducing
18 mitigation costs through linking national carbon markets, although actual examples of these remain
19 limited. {14.2, 14.4, 14.5, 14.6}

20 **International cooperation will need to be strengthened in several key respects in order to support**
21 **mitigation action consistent with limiting temperature rise to well below 2°C in the context of**
22 **sustainable development and equity (*high confidence*).** Many developing countries' NDCs have
23 components or additional actions that are conditional on receiving assistance with respect to finance,
24 technology development and transfer, and capacity building, greater than what has been provided to
25 date. Sectoral and sub-global cooperation is providing critical support, and yet there is room for further
26 progress. In some cases, notably with respect to aviation and shipping, sectoral agreements have
27 adopted climate mitigation goals that fall far short of what would be required to achieve the long-term
28 temperature goal of the Paris Agreement. Moreover, there are cases where international cooperation
29 may be hindering mitigation efforts, namely evidence that trade and investment agreements, as well as
30 agreements within the energy sector, impede national mitigation efforts (*medium confidence*).
31 International cooperation is emerging but so far fails to fully address transboundary issues associated
32 with solar radiation modification and carbon dioxide removal. {14.2, 14.3, 14.4, 14.5, 14.6, Cross-
33 Working Group Box 4 in Chapter 14}

35 **TS. 6.3 Societal aspects of mitigation**

36 **Social equity reinforces capacity and motivation for mitigating climate change (*medium***
37 ***confidence*).** Impartial governance such as fair treatment by law-and-order institutions, fair treatment
38 by gender, and income equity, increases social trust, thus enabling demand-side climate policies. High
39 status (often high carbon) item consumption may be reduced by taxing absolute wealth without
40 compromising well-being. {5.2, 5.4.2, 5.6}

41
42 **Policies that increase the political access and participation of women, racialised, and marginalised**
43 **groups, increase the democratic impetus for climate action (*high confidence*).** Including more
44 differently situated knowledge and diverse perspectives makes climate mitigation policies more
45 effective. {5.2, 5.6}

1 **Greater contextualisation and granularity in policy approaches better addresses the challenges**
2 **of rapid transitions towards zero-carbon systems (*high confidence*)**. Larger systems take more time
3 to evolve, grow, and change compared to smaller ones. Creating and scaling up entirely new systems
4 takes longer than replacing existing technologies and practices. Late adopters tend to adopt faster than
5 early pioneers. Obstacles and feasibility barriers are high in the early transition phases. Barriers decrease
6 as a result of technical and social learning processes, network building, scale economies, cultural
7 debates, and institutional adjustments. {5.5, 5.6}

8
9 **Mitigation policies that integrate and communicate with the values people hold are more**
10 **successful (*high confidence*)**. Values differ between cultures. Measures that support autonomy, energy
11 security and safety, equity and environmental protection, and fairness resonate well in many
12 communities and social groups. Changing from a commercialised, individualised, entrepreneurial
13 training model to an education cognizant of planetary health and human well-being can accelerate
14 climate change awareness and action. {5.4.1, 5.4.2}

15
16 **Changes in consumption choices that are supported by structural changes and political action**
17 **enable the uptake of low-carbon choices (*high confidence*)**. Policy instruments applied in
18 coordination can help to accelerate change in a consistent desired direction. Targeted technological
19 change, regulation, and public policy can help in steering digitalisation, the sharing economy, and
20 circular economy towards climate change mitigation. (Box TS.12, Box TS.14) {5.3, 5.6}

21
22 **Complementarity in policies helps in the design of an optimal demand-side policy mix (*medium***
23 ***confidence*)**. In the case of energy efficiency, for example, this may involve CO₂ pricing, standards and
24 norms, and information feedback. {5.3, 5.4, 5.6}

1 **TS. 6.4 Investment and finance**

2 **Finance to reduce net GHG emissions and enhance resilience to climate impacts is a critical**
3 **enabling factor for the low carbon transition. Fundamental inequities in access to finance as well**
4 **as finance terms and conditions, and countries' exposure to physical impacts of climate change**
5 **overall, result in a worsening outlook for a global just transition (*high confidence*).** Decarbonising
6 the economy requires global action to address fundamental economic inequities and overcome the
7 climate investment trap that exists for many developing countries. For these countries the costs and
8 risks of financing often represent a significant challenge for stakeholders at all levels. This challenge is
9 exacerbated by these countries' general economic vulnerability and indebtedness. The rising public
10 fiscal costs of mitigation, and of adapting to climate shocks, is affecting many countries and worsening
11 public indebtedness and country credit ratings at a time when there were already significant stresses on
12 public finances. The COVID-19 pandemic has made these stresses worse and tightened public finances
13 still further. Other major challenges for commercial climate finance include: the mismatch between
14 capital and investment needs, home bias²³ considerations, differences in risk perceptions for regions, as
15 well as limited institutional capacity to ensure safeguards are effective. (*high confidence*) {15.2, 15.6.3}

16 **Investors, central banks, and financial regulators are driving increased awareness of climate risk.**
17 **This increased awareness can support climate policy development and implementation (*high***
18 ***confidence*).** {15.2, 15.6} Climate-related financial risks arise from physical impacts of climate change
19 (already relevant in the short term), and from a disorderly transition to a low carbon economy.
20 Awareness of these risks is increasing, leading also to concerns about financial stability. Financial
21 regulators and institutions have responded with multiple regulatory and voluntary initiatives to assess
22 and address these risks. Yet despite these initiatives, climate-related financial risks remain greatly
23 underestimated by financial institutions and markets, limiting the capital reallocation needed for the
24 low-carbon transition. Moreover, risks relating to national and international inequity – which act as a
25 barrier to the transformation – are not yet reflected in decisions by the financial community. Stronger
26 steering by regulators and policy makers has the potential to close this gap. Despite the increasing
27 attention of investors to climate change, there is limited evidence that this attention has directly
28 impacted emission reductions. This leaves high uncertainty, both near-term (2021-30) and longer-term
29 (2021-50), on the feasibility of an alignment of financial flows with the Paris Agreement goals (*high*
30 *confidence*). {15.2, 15.6}

31 **Progress on the alignment of financial flows with low GHG emissions pathways remains slow.**
32 **There is a climate financing gap which reflects a persistent misallocation of global capital (*high***
33 ***confidence*).** {15.2, 15.3}. Persistently high levels of both public and private fossil-fuel related financing
34 continue to be of major concern despite promising recent commitments. This reflects policy
35 misalignment, the current perceived risk-return profile of fossil fuel-related investments, and political
36 economy constraints (*high confidence*). Estimates of climate finance flows²⁴ exhibit highly divergent
37 patterns across regions and sectors and a slowing growth {15.3}. When the perceived risks are too high,
38 the misallocation of abundant savings persists and investors refrain from investing in infrastructure and
39 industry in search of safer financial assets, even earning low or negative real returns. (*high confidence*)
40 {15.2, 15.3}

41

FOOTNOTE ²³ Most of climate finance stays within national borders, especially private climate flows (over 90%). The reasons for this range from national policy support, differences in regulatory standards, exchange rate, political and governance risks, to information market failures.

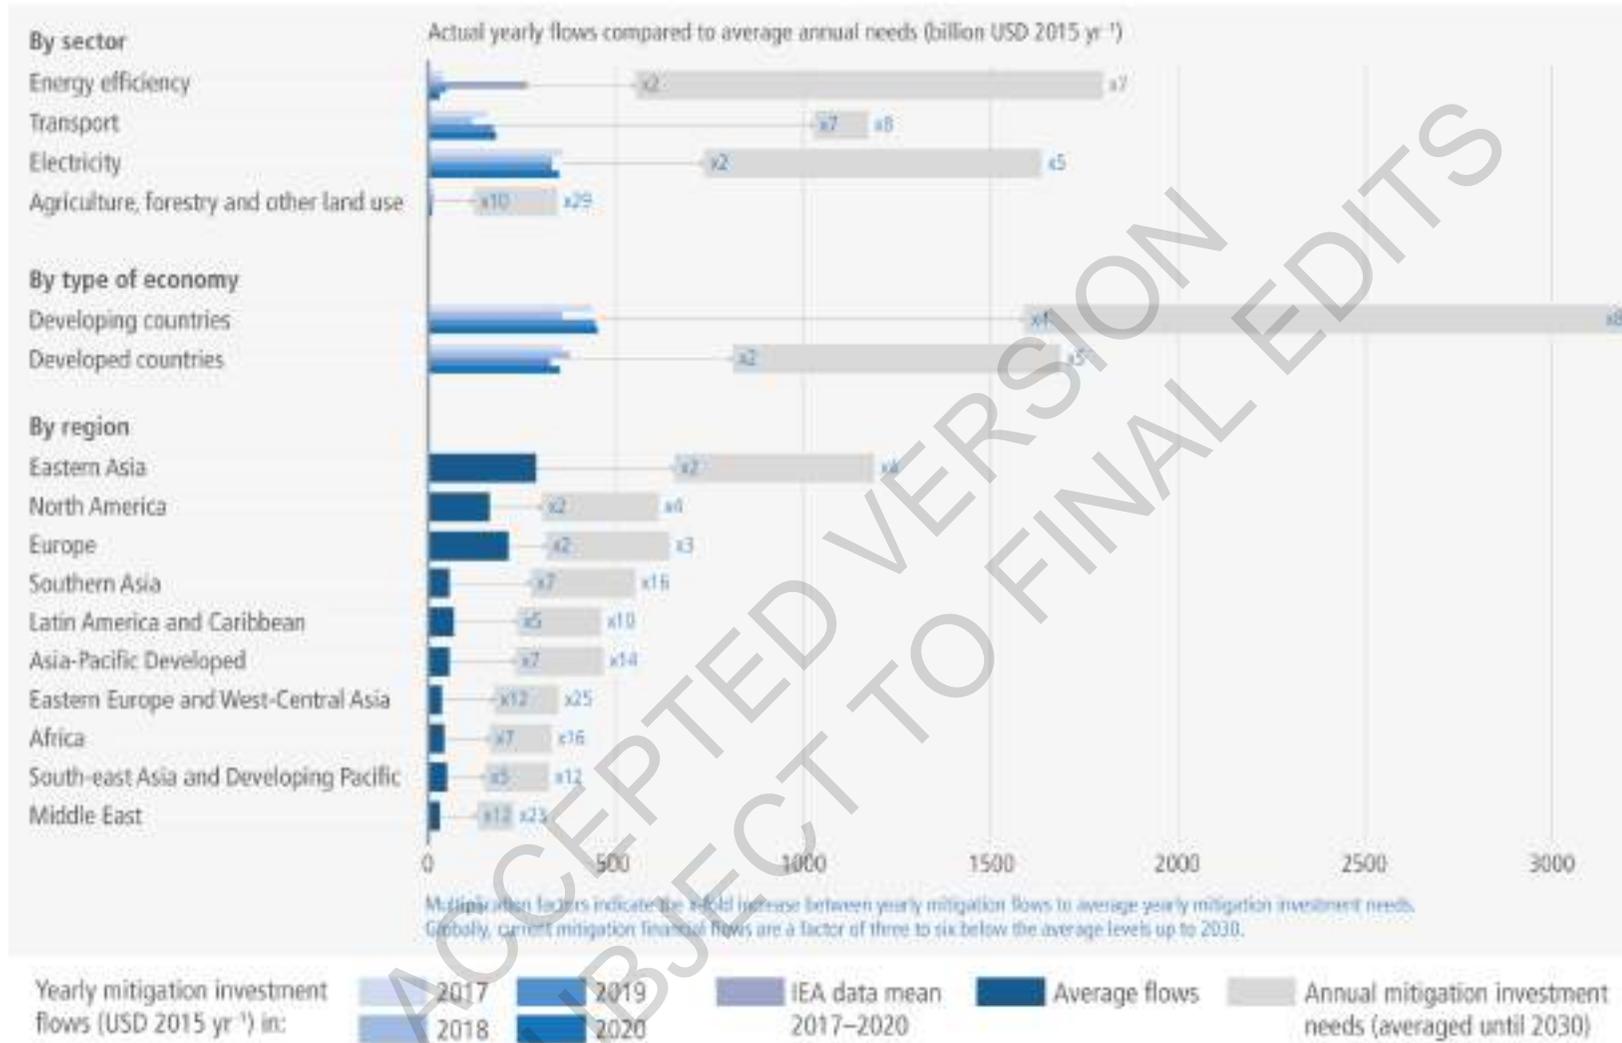

FOOTNOTE ²⁴ Climate finance flows refers to local, national, or transnational financing from public, private, and alternative sources, to support mitigation and adaptation actions addressing climate change.

1 **Global climate finance is heavily focused on mitigation (more than 90% on average between 2017-**
2 **2020) (*high confidence*) {15.4, 15.5}.** This is despite the significant economic effects of climate
3 change's expected physical impacts, and the increasing awareness of these effects on financial stability.
4 To meet the needs for rapid deployment of mitigation options, global mitigation investments are
5 expected to need to increase by the factor of three to six (*high confidence*). The gaps represent a major
6 challenge for developing countries, especially Least Developed Countries (LDCs), where flows have to
7 increase by the factor of four to eight for specific sectors like AFOLU, and for specific groups with
8 limited access to, and high costs of, climate finance (*high confidence*) (Figure TS.25) {15.4, 15.5}. The
9 actual size of sectoral and regional climate financing gaps is only one component driving the magnitude
10 of the challenge. Financial and economic viability, access to capital markets, appropriate regulatory
11 frameworks, and institutional capacity to attract and facilitate investments and ensure safeguards are
12 decisive to scaling-up funding. Soft costs for regulatory environment and institutional capacity,
13 upstream funding needs as well as R&D and venture capital for development of new technologies and
14 business models are often overlooked despite their critical role to facilitate the deployment of scaled-
15 up climate finance (*high confidence*). {15.4.1, 15.5.2}

4

Figure TS.25: Mitigation investment flows fall short of investment needs across all sectors and types of economy, particularly in developing countries.

1
2 **Figure TS.25 legend:** Breakdown of average mitigation investment flows and investment needs until 2030
3 (USD billion). Given the multiple sources and lack of harmonised methodologies, the data presented here can be
4 considered only as indicative of the size and pattern of investment gaps. For full information of sources see
5 chapter 15 Figure 15.4. Mitigation investment flows and investment needs shown by sector (energy efficiency,
6 transport, electricity, and agriculture, forestry and land use), by type of economy, and by region (see Annex II
7 Part I Section 1 for the classification schemes for countries and areas). Blue bars display data on mitigation
8 investment flows for four years: 2017, 2018, 2019 and 2020 by sector and by type of economy. For the regional
9 breakdown, the annual average mitigation investment flows for 2017-2019 are shown. The grey bars show the
10 minimum and maximum level of global annual mitigation investment needs in the assessed scenarios averaged
11 until 2030. Multiplication factors show the ratio of global average yearly mitigation investment needs (averaged
12 until 2030) and current yearly mitigation flows (averaged for 2017-2020). The lower multiplication factor refers
13 to the lower end of the range of investment needs. The upper multiplication factor refers to the upper range of
14 investment needs. Data on mitigation investment flows does not include technical assistance (i.e., policy and
15 national budget support or capacity building) and other non-technology deployment financing. Adaptation
16 pegged transactions are also excluded. Data on mitigation investment needs does not include needs for
17 infrastructure investment or investment related to meeting the SDGs. {15.3, 15.4, 15.5, Table 15.2, Table 15.3,
18 Table 15.4}

19
20 **The relatively slow implementation of commitments by countries and stakeholders in the financial**
21 **sector to scale up climate finance reflects neither the urgent need for ambitious climate action,**
22 **nor the economic rationale for ambitious climate action (*high confidence*).** Delayed climate
23 investments and financing – and limited alignment of investment activity with the Paris Agreement –
24 will result in significant carbon lock-ins, stranded assets, and other additional costs. This will
25 particularly impact urban infrastructure and the energy and transport sectors (*high confidence*). A
26 common understanding of debt sustainability and debt transparency, including negative implications of
27 deferred climate investments on future GDP, and how stranded assets and resources may be
28 compensated, has not yet been developed (*medium confidence*). {15.6}

29 **There is a mismatch between capital availability in the developed world and the future emissions**
30 **expected in developing countries (*high confidence*).** This emphasizes the need to recognize the
31 explicit and positive social value of global cross-border mitigation financing. A significant push for
32 international climate finance access for vulnerable and poor countries is particularly important given
33 these countries' high costs of financing, debt stress and the impacts of ongoing climate change (*high*
34 *confidence*). {15.2, 15.3.2.3, 15.5.2, 15.6.1, 15.6.7}

35 **Innovative financing approaches could help reduce the systemic under-pricing of climate risk in**
36 **markets and foster demand for investment opportunities aligned with the Paris Agreement goals.**
37 **Approaches include de-risking investments, robust 'green' labelling and disclosure schemes, in**
38 **addition to a regulatory focus on transparency and reforming international monetary system**
39 **financial sector regulations (*medium confidence*).** Green bond markets and markets for sustainable
40 finance products have grown significantly since AR5 and the landscape continues to evolve.
41 Underpinning this evolution is investors' preference for scalable and identifiable low-carbon investment
42 opportunities. These relatively new labelled financial products will help by allowing a smooth
43 integration into existing asset allocation models. (*high confidence*) Green bond markets and markets for
44 sustainable finance products have also increased significantly since AR5, but challenges nevertheless
45 remain, in particular there are concerns about 'greenwashing' and the limited application of these
46 markets to developing countries (*high confidence*). {15.6.2, 15.6.6}

47 **New business models (e.g., pay-as-you-go) can facilitate the aggregation of small-scale financing**
48 **needs and provide scalable investment opportunities with more attractive risk-return profiles**
49 (*high confidence*). Support and guidance for enhancing transparency can promote capital markets'

1 climate financing by providing quality information to price climate risks and opportunities. Examples
2 include SDG and environmental, social and governance (ESG) disclosure, scenario analysis and climate
3 risk assessments, including the Task Force on Climate-Related Financial Disclosures (TCFD). The
4 outcome of these market-correcting approaches on capital flows cannot be taken for granted, however,
5 without appropriate fiscal, monetary and financial policies. Mitigation policies will be required to
6 enhance the risk-weighted return of low emission and climate resilient options, accelerate the
7 emergence and support for financial products based on real projects, such as green bonds, and phase
8 out fossil fuel subsidies. Greater public-private cooperation can also encourage the private sector to
9 increase and broaden investments, within a context of safeguards and standards, and this can be
10 integrated into national climate change policies and plans (*high confidence*). {15.1, 15.2.4, 15.3.1,
11 15.3.2, 15.3.3, 15.5.2, 15.6.1, 15.6.2, 15.6.6, 15.6.7, 15.6.8}

12 **Ambitious global climate policy coordination and stepped-up public climate financing over the**
13 **next decade (2021–2030) can help redirect capital markets and overcome challenges relating to**
14 **the need for parallel investments in mitigation. It can also help address macroeconomic**
15 **uncertainty and alleviate developing countries’ debt burden post-COVID-19 (*high confidence*).**
16 Providing strong climate policy signals helps guide investment decisions. Credible signalling by
17 governments and the international community can reduce uncertainty for financial decision-makers and
18 help reduce transition risk. In addition to indirect and direct subsidies, the public sector’s role in
19 addressing market failures, barriers, provision of information, and risk sharing can encourage the
20 efficient mobilisation of private sector finance (*high confidence*). {15.2, 15.6.1, 15.6.2} The mutual
21 benefits of coordinated support for climate mitigation and adaptation in the next decade for both
22 developed and developing regions could potentially be very high in the post-COVID era. Climate
23 compatible stimulus packages could significantly reduce the macro-financial uncertainty generated by
24 the pandemic and increase the sustainability of the world economic recovery. {15.2, 15.3.2.3, 15.5.2,
25 15.6.1, 15.6.7} Political leadership and intervention remain central to addressing uncertainty, which is
26 a fundamental barrier for the redirection of financial flows. Existing policy misalignments – for example
27 in fossil fuel subsidies – undermine the credibility of public commitments, reduce perceived transition
28 risks and limit financial sector action (*high confidence*). {15.2, 15.3.3, 15.6.1, 15.6.2, 15.6.3}

29 **The greater the urgency of action to remain on a 1.5°C pathway, the greater need for parallel**
30 **investment decisions in upstream and downstream parts of the value chain (*high confidence*).**
31 Greater urgency also reduces the lead times to build trust in regulatory frameworks. Consequently,
32 many investment decisions will need to be made based on the long-term global goals. This highlights
33 the importance of trust in political leadership which, in turn, affects risk perception and ultimately
34 financing costs (*high confidence*). {15.6.1, 15.6.2}

35 **Accelerated international cooperation on finance is a critical enabler of a low-carbon and just**
36 **transition (*very high confidence*).** Scaled-up public grants for adaptation and mitigation and funding
37 for low-income and vulnerable regions, especially in Sub-Saharan Africa, may have the highest returns.
38 key options include: increased public finance flows from developed to developing countries beyond
39 USD100 billion-a-year; shifting from a direct lending modality towards public guarantees to reduce
40 risks and greatly leverage private flows at lower cost; local capital markets development; and, changing
41 the enabling operational definitions. A coordinated effort to green the post-pandemic recovery is also
42 essential in countries facing much higher debt costs. (*high confidence*) {15.2, 15.6}

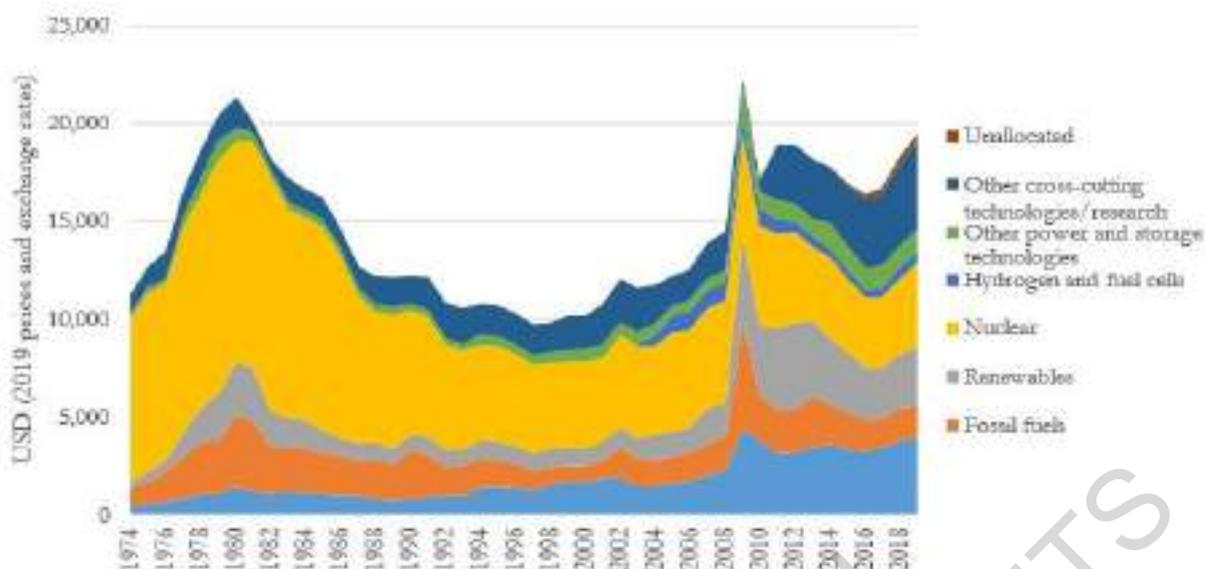

43

1 **TS. 6.5 Innovation, technology development and transfer**

2 **Innovation in climate mitigation technologies has seen enormous activity and significant progress**
3 **in recent years. Innovation has also led to, and exacerbated, trade-offs in relation to sustainable**
4 **development.** Innovation can leverage action to mitigate climate change by reinforcing other
5 interventions. In conjunction with other enabling conditions innovation can support system transitions
6 to limit warming and help shift development pathways. The currently widespread implementation of
7 solar PV and LED lighting, for instance, could not have happened without technological innovation.
8 Technological innovation can also bring about new and improved ways of delivering services that are
9 essential to human well-being (*high confidence*) {16.1, 16.3, 16.4, 16.6}. At the same time as delivering
10 benefits, innovation can result in trade-offs that undermine both progress on mitigation and progress
11 towards other sustainable development goals. Trade-offs include negative externalities – for instance
12 greater environmental pollution and social inequalities – rebound effects leading to lower net emission
13 reductions or even increases in emissions, and increased dependency on foreign knowledge and
14 providers (*high confidence*). Effective governance and policy have the potential to avoid and minimise
15 such misalignments (*medium evidence, high agreement*). {16.2, 16.3, 16.4, 16.5.1, 16.6}

16 **A systemic view of innovation to direct and organize the processes has grown over the last decade.**
17 **This systemic view of innovation takes into account the role of actors, institutions, and their**
18 **interactions and can inform how innovation systems that vary across technologies, sectors and**
19 **countries, can be strengthened (*high confidence*) {16.2, 16.3, 16.5}.** Where a systemic view of
20 innovation has been taken, it has enabled the development and implementation of indicators that are
21 better able to provide insights in innovation processes. This, in turn, has enabled the analysis and
22 strengthening of innovation systems. Traditional quantitative innovation indicators mainly include
23 R&D investments and patents. Figure TS.26 illustrates that energy-related RD&D has risen slowly in
24 the last two decades, and that there has been a reorientation of the portfolio of funded energy
25 technologies. Systemic indicators of innovation, however, go well beyond these approaches. They
26 include structural innovation system elements including actors and networks, as well as indicators for
27 how innovation systems function, such as access to finance, employment in relevant sectors, and
28 lobbying activities {16.3.4, Table 16.7}. For example, in Latin America, monitoring systemic
29 innovation indicators for the effectiveness of agroecological mitigation approaches has provided
30 insights on the appropriateness and social alignment of new technologies and practices {Box 16.5}.
31 Climate-energy-economy models, including integrated assessment models, generally employ a stylised
32 and necessarily incomplete view of innovation, and have yet to incorporate a systemic representation
33 of innovation systems. {16.2.4, Box 16.1}

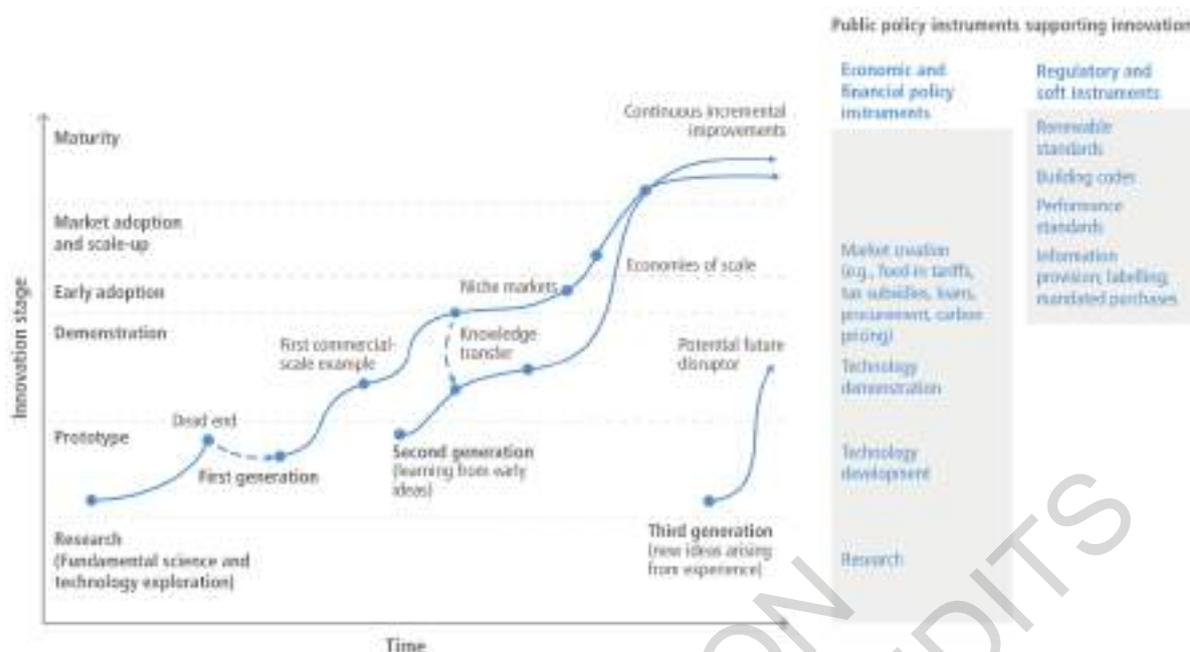

34

1
2 **Figure TS.26: Fraction of public energy research, development and demonstration (RD&D (spending by**
3 **technology over time for IEA (largely OECD) countries between 1974 and 2018. {Box 16.3 Figure 1}**

4
5 **A systemic perspective on technological change can provide insights to policymakers supporting**
6 **their selection of effective innovation policy instruments (*high confidence*) {16.4, 16.5}. A**
7 combination of scaled-up innovation investments with demand-pull interventions can achieve faster
8 technology unit cost reductions and more rapid scale-up than either approach in isolation. These
9 innovation policy instruments would nonetheless have to be tailored to local development priorities, to
10 the specific context of different countries, and to the technology being supported. The timing of
11 interventions and any trade-offs with sustainable development also need to be addressed. Public R&D
12 funding and support as well as innovation procurement have shown to be valuable for fostering
13 innovation in small to medium cleantech firms (Figure TS.27) {16.4.4.3}. Innovation outcomes of
14 policy instruments not necessarily aimed at innovation, such as feed-in tariffs, auctions, emissions
15 trading schemes, taxes and renewable portfolio standards, vary from negligible to positive for climate
16 change mitigation. Some specific designs of environmental taxation can also result in negative
17 distributional outcomes {16.4.4}. Most of the available literature and evidence on innovation systems
18 come from industrialised countries and larger developing countries. However, there is a growing body
19 of evidence from developing countries and small island developing states (SIDS). {16.4, 16.5, 16.7}

20

1
2 **Figure TS.27: Technology innovation process and the (illustrative) roles of different public policy**
3 **instruments (on the right-hand side). {Figure 16.1}**

4 **Figure TS.27 legend:** Note that, demand pull instruments in the regulatory instrument category, for instance,
5 can also shape the early stages of the innovation process. Their position on the latter stages is highlighted in this
6 figure just because typically these instruments have been introduced in latter stages of the development of the
7 technology. {16.4.4}

8 **Experience and analyses show that technological change is inhibited if technological innovation**
9 **system functions are not adequately fulfilled; this inhibition occurs more often in developing**
10 **countries (*high confidence*).** Examples of such functions are knowledge development, resource
11 mobilisation, and activities that shape the needs, requirements and expectations of actors within the
12 innovation system (guidance of the search). Capabilities play a key role in these functions, the build-up
13 of which can be enhanced by domestic measures, but also by international cooperation. For instance,
14 innovation cooperation on wind energy has contributed to the accelerated global spread of this
15 technology. As another example, the policy guidance by the Indian government, which also promoted
16 development of data, testing capabilities and knowledge within the private sector, has been a key
17 determinant of the success of an energy-efficiency programme for air conditioners and refrigerators in
18 India. {16.3, 16.5, 16.6, Cross-Chapter Box 12 in Chapter 16, Box 16.3}

19 **Consistent with innovation system approaches, the sharing of knowledge and experiences**
20 **between developed and developing countries can contribute to addressing global climate and the**
21 **SDGs. The effectiveness of such international cooperation arrangements, however, depends on**
22 **the way they are developed and implemented (*high confidence*).** The effectiveness and sustainable
23 development benefits of technology sharing under market conditions appears to be determined primarily
24 by the complexity of technologies, local capabilities and the policy regime. This suggests that the
25 development of planning and innovation capabilities remains necessary, especially in least-developed
26 countries and SIDS. International diffusion of low-emission technologies is also facilitated by
27 knowledge spill overs from regions engaged in clean R&D (*medium confidence*). {16.2}

28 **The evidence on the role of intellectual property rights (IPR) in innovation is mixed. Some**
29 **literature suggests that it is a barrier while other sources suggests that it is an enabler to the**
30 **diffusion of climate-related technologies (*medium confidence*).** There is agreement that countries
31 with well-developed institutional capacity may benefit from a strengthened IPR regime, but that

1 countries with limited capabilities might face greater barriers to innovation as a consequence. This
2 enhances the continued need for capacity building. Ideas to improve the alignment of the global IPR
3 regime and addressing climate change include specific arrangements for least-developed countries,
4 case-by-case decision-making and patent-pooling institutions. {16.2.3, 16.5, Box 16.10}

5 **Although some initiatives have mobilised investments in developing countries, gaps in innovation**
6 **cooperation remain, including in the Paris Agreement instruments. These gaps could be filled by**
7 **enhancing financial support for international technology cooperation, by strengthening**
8 **cooperative approaches, and by helping build suitable capacity in developing countries across all**
9 **technological innovation system functions (*high confidence*). The implementation of current**
10 arrangements of international cooperation for technology development and transfer, as well as capacity
11 building, are insufficient to meet climate objectives and contribute to sustainable development. For
12 example, despite building a large market for mitigation technologies in developing countries, the lack
13 of a systemic perspective in the implementation of the Clean Development Mechanism, operational
14 since the mid-2000s, has only led to some technology transfer, especially to larger developing countries,
15 but limited capacity building and minimal technology development (*medium confidence*). In the current
16 climate regime, a more systemic approach to innovation cooperation could be introduced by linking
17 technology institutions, such as the Technology Mechanism, and financial actors, such as the financial
18 mechanism. {16.5.3}

19 **Countries are exposed to sustainable development challenges in parallel with the challenges that**
20 **relate to climate change. Addressing both sets of challenges simultaneously presents multiple and**
21 **recurrent obstacles that systemic approaches to technological change could help resolve, provided**
22 **they are well managed (*high confidence*). Obstacles include both entrenched power relations**
23 dominated by vested interests that control and benefit from existing technologies, and governance
24 structures that continue to reproduce unsustainable patterns of production and consumption (*medium*
25 *confidence*). Studies also highlight the potential of cultural factors to strongly influence the pace and
26 direction of technological change. Sustainable solutions require adoption and mainstreaming of locally
27 novel technologies that can meet local needs, and simultaneously address the SDGs. Acknowledging
28 the systemic nature of technological innovation – which involve many levels of actors, stages of
29 innovation and scales – can lead to new opportunities to shift development pathways towards
30 sustainability. {16.4, 16.5, 16.6}

31 **Strategies for climate change mitigation can be most effective in accelerating transformative**
32 **change when actions taken to strengthen one set of enabling conditions also reinforce and**
33 **strengthen the effectiveness of other enabling conditions (*medium confidence*). Applying transition**
34 or system dynamics to decisions can help policy makers take advantage of such high-leverage
35 intervention points, address the specific characteristics of technological stages, and respond to societal
36 dynamics. Inspiration can be drawn from the global unit cost reductions of solar PV, which were
37 accelerated by a combination of factors interacting in a mutually reinforcing way across a limited group
38 of countries (*high confidence*). {Box 16.2, Cross-Chapter Box 12 in Chapter 16}. Transitions can be
39 accelerated by policies appropriately targeted, which may be grouped in different ‘pillars of policy’.
40 The relative importance of different ‘pillars’ differs according to stage of the transition. (see Figure
41 TS.28) {1.2.3}

42

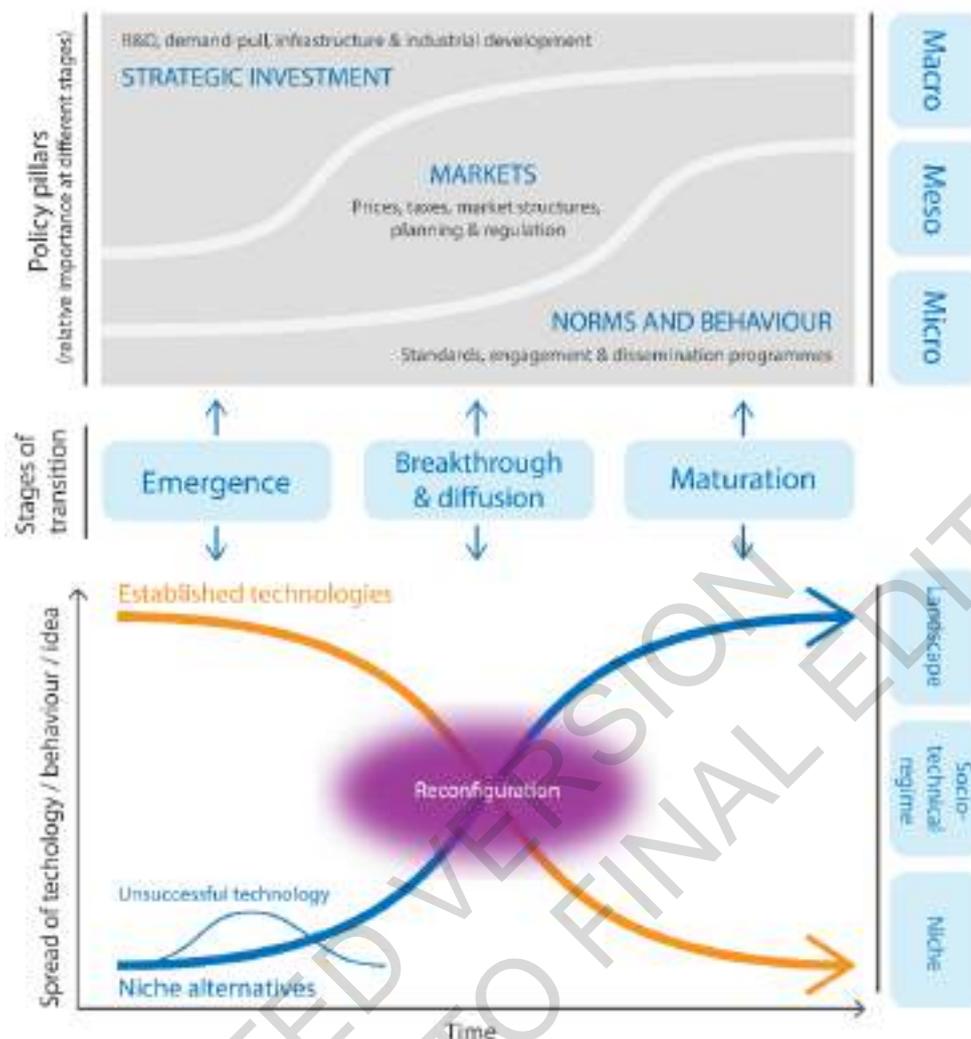

Figure TS.28: Transition dynamics: levels, policies and processes. {Figure 1.7}

The relative importance of different ‘pillars of policy’ differs according to stage of the transition. The lower panel illustrates growth of innovative technologies or practices, which if successful, emerge from niches into an S-shape dynamic of exponential growth. The diffusion stage often involves new infrastructure and reconfiguration of existing market and regulatory structures. During the phase of more widespread diffusion, growth levels off to linear, then slows as the industry and market matures. The processes displace incumbent technologies/practices which decline, initially slowly but then at an accelerating pace. Many related literatures identify three main levels with different characteristics, most generally termed *micro*, *meso* and *macro*.

Better and more comprehensive data on innovation indicators can provide timely insights for policy makers and policy design locally, nationally and internationally, especially for developing countries, where such insights are often missing. Data needed include those that can show the strength of technological, sectoral and national innovation systems. It is also necessary to validate current results and generate insights from theoretical frameworks and empirical studies for developing countries’ contexts. Innovation studies on adaptation and mitigation other than energy and ex-post assessments of the effectiveness of various innovation-related policies and interventions, including R&D, would also provide benefits. Furthermore, methodological developments to improve the ability of IAMs to capture energy innovation system dynamics and the relevant institutions and policies (including design and implementation), would allow for more realistic assessment. {16.2, 16.3, 16.7}

1 START BOX TS.14 HERE**2 Box TS.14 Digitalisation**

3 Digital technologies can promote large increases in energy efficiency through coordination and an
4 economic shift to services, but they can also greatly increase energy demand because of the energy used
5 in digital devices (*high confidence*). {Cross-Chapter Box 11 in Chapter 16, 16.2}

6 Digital devices, including servers, increase pressure on the environment due to the demand for rare
7 metals and end-of-life disposal. The absence of adequate governance in many countries can lead to
8 harsh working conditions and unregulated disposal of electronic waste. Digitalisation also affects firms'
9 competitiveness, the demand for skills, and the distribution of, and access to resources. The existing
10 digital divide, especially in developing countries, and the lack of appropriate governance of the digital
11 revolution can hamper the role that digitalisation could play in supporting the achievement of stringent
12 mitigation targets. At present, the understanding of both the direct and indirect impacts of digitalisation
13 on energy use, carbon emissions and potential mitigation is limited (*medium confidence*).

14 The digital transformation is a megatrend that is fundamentally changing all economies and societies,
15 albeit in very different ways depending on the level of development of a given country and on the nature
16 of its economic system. Digital technologies have significant potential to contribute to decarbonisation
17 due to their ability to increase energy and material efficiency, make transport and building systems less
18 wasteful, and improve the access to services for consumers and citizens. Yet, if left unmanaged, the
19 digital transformation will probably increase energy demand, exacerbate inequities and the
20 concentration of power, leaving developing economies with less access to digital technologies behind,
21 raise ethical issues, reduce labour demand and compromise citizens' welfare. Appropriate governance
22 of the digital transformation can ensure that digitalisation works as an enabler, rather than as a barrier
23 and further strain in decarbonisation pathways. Governance can ensure that digitalisation not only
24 reduces GHG emissions intensity but also contributes to reducing absolute GHG emission, constraining
25 run-away consumption. {Cross-Chapter Box 11 in Chapter 16, 16.2}

26 Digital technologies have the potential to reduce energy demand in all end-use sectors through steep
27 improvements in energy efficiency. This includes material input savings and increased coordination as
28 they allow the use of fewer inputs to perform a given task. Smart appliances and energy management,
29 supported by choice architectures, economic incentives and social norms, effectively reduce energy
30 demand and associated GHG emissions by 5-10% while maintaining equal service levels. Data centres
31 can also play a role in energy system management, for example by waste heat utilisation where district
32 heat systems are close by; temporal and spatial scheduling of electricity demand can provide about 6%
33 of the total potential demand response. {5.5, Cross-Chapter Box 11 Table 1 in Chapter 16}

34 Digital technologies, analytics and connectivity consume large amounts of energy implying higher
35 direct energy demand and related carbon emissions. Global energy demand from digital appliances
36 reached 7.14 EJ in 2018. The demand for computing services increased by 550% between 2010 and
37 2018 and is now estimated at 1% of global electricity consumption. Due to efficiency improvements,
38 the associated energy demand increased only modestly, by about 6% from 2000 to 2018. {Box 9.5}

39 System-wide effects endanger energy and GHG emission savings. Rising demand can diminish energy
40 savings, and also produce run-away effects associated with additional consumption and GHG emissions
41 if left unregulated. Savings are varied in smart and shared mobility systems, as ride hailing increases
42 GHG emissions due to deadheading, whereas shared pooled mobility and shared cycling reduce GHG
43 emissions, as occupancy levels and/or weight per person kilometre transported improve. Systemic
44 effects have wider boundaries of analysis and are more difficult to quantify and investigate but are
45 nonetheless very relevant. Systemic effects tend to have negative impacts, but policies and adequate
46 infrastructures and choice architectures can help manage and contain these. {5.3, 5.4, 5.6}

1 **END BOX TS.14 HERE**

2 **TS. 7 Mitigation in the context of sustainable development**

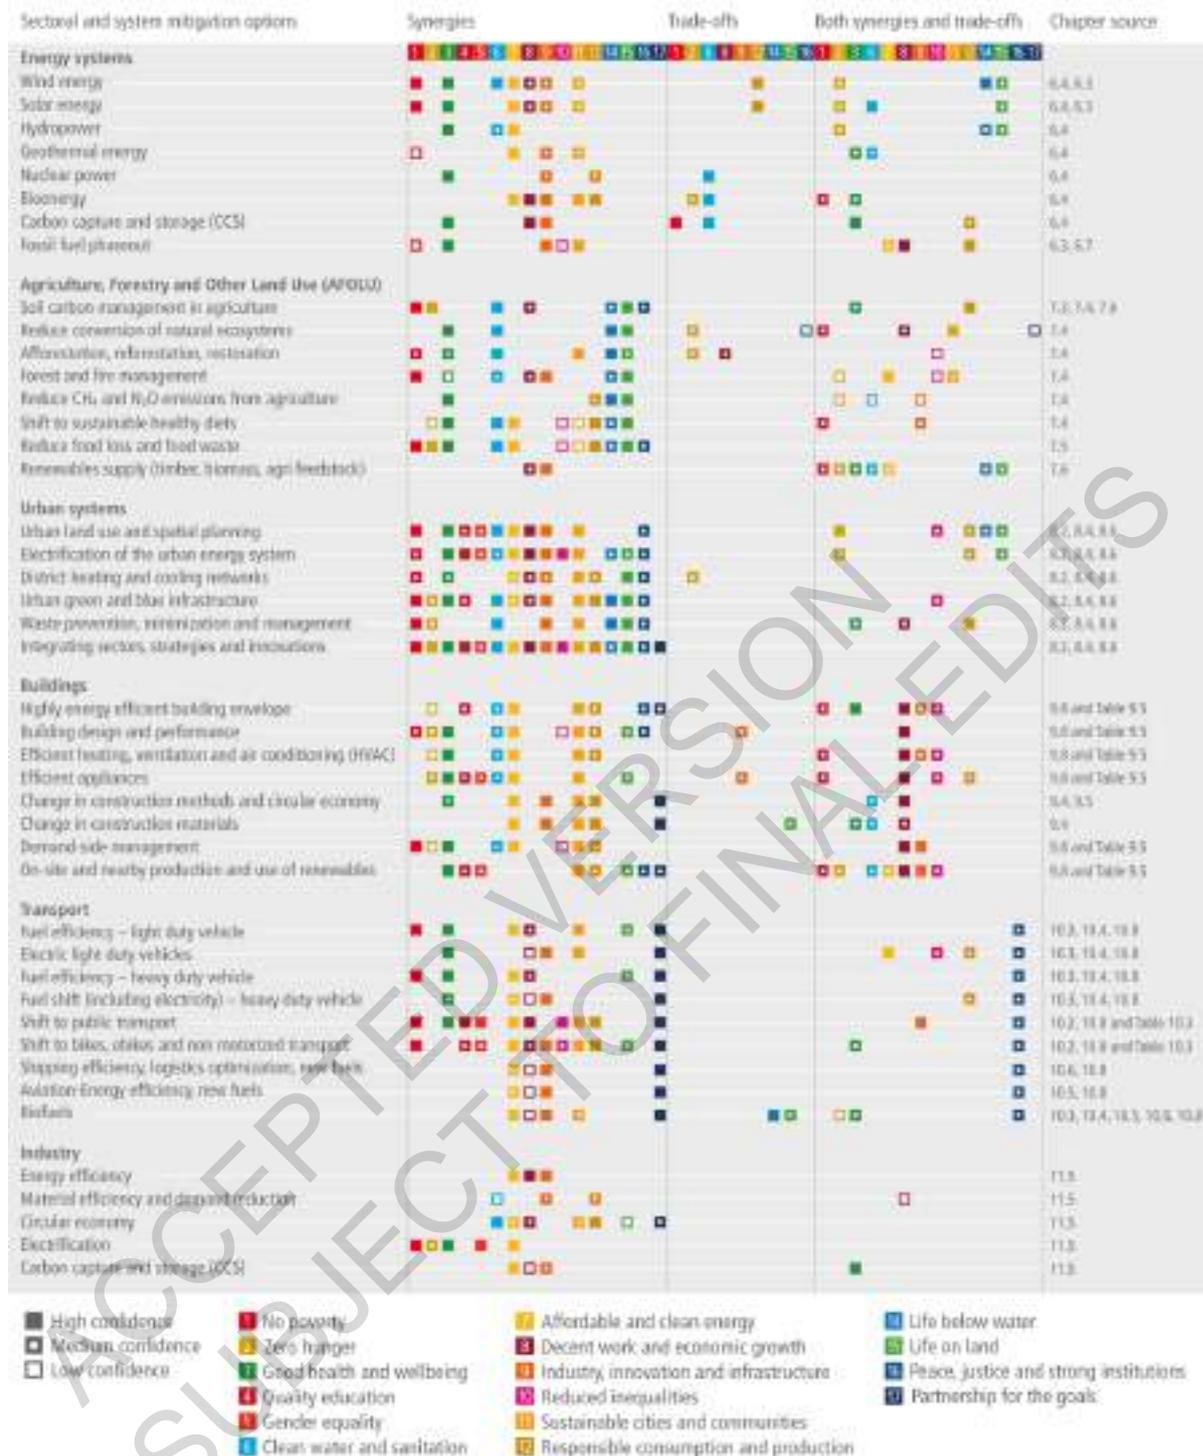

3 Accelerating climate mitigation *in the context of sustainable development* involves not only expediting
4 the pace of change but also addressing the underlying drivers of vulnerability and emissions.
5 Addressing these drivers can enable diverse communities, sectors, stakeholders, regions and cultures to
6 participate in just, equitable and inclusive processes that improve the health and well-being of people
7 and the planet. Looking at climate change from a justice perspective also means placing the emphasis
8 on: i) the protection of vulnerable populations from the impacts of climate change, ii) mitigating
9 the effects of low-carbon transformations, and iii) ensuring an equitable decarbonised world (*high*
10 *confidence*). {17.1}

11 **The SDG framework²⁵ can serve as a template to evaluate the long-term implications of mitigation**
12 **on sustainable development and vice versa (*high confidence*). Understanding the co-benefits and**
13 **trade-offs associated with mitigation is key to understanding how societies prioritise among the**
14 **various sectoral policy options (*medium confidence*). Areas with anticipated trade-offs include food**
15 **and biodiversity, energy affordability/access, and mineral resource extraction. Areas with anticipated**
16 **co-benefits include health, especially regarding air pollution, clean energy access and water availability.**
17 **The possible implementation of the different sectoral mitigation options therefore depends on**
18 **how societies prioritise mitigation versus other products and services: not least, how societies prioritise**
19 **food, material well-being, nature conservation and biodiversity protection, as well as considerations**
20 **such as their future dependence on CDR. Figure TS.29 summarises the assessment of where key**
21 **synergies and trade-offs exist between mitigation options and the SDGs. (Figure TS.29, Figure TS.31,**
22 **Table TS.7) {12.3, 12.4, 12.5, 12.6.1, Figure 3.39, Figure 17.1}**

23 **The beneficial and adverse impacts of deploying climate-change mitigation and adaptation**
24 **responses are highly context-specific and scale-dependent. There are synergies and trade-offs**
25 **between adaptation and mitigation as well as synergies and trade-offs with sustainable**
26 **development (*high confidence*). Strong links also exists between sustainable development,**
27 **vulnerability and climate risks, as limited economic, social and institutional resources often result in**
28 **low adaptive capacities and high vulnerability, especially in developing countries. Resource limitations**
29 **in these countries can similarly weaken the capacity for climate mitigation and adaptation. The move**
30 **towards climate-resilient societies requires transformational or deep systemic change. This has**
31 **important implications for countries' sustainable development pathways (*medium evidence, high***
32 **agreement). (Box TS.3, Figure TS.29) {4.5, Figure 4.9, 17.3.3}**

33

FOOTNOTE ²⁵ The 17 SDGs are at the heart of the UN 2030 Agenda for Sustainable Development, adopted by all United Nations Member States in 2015.

1 **Figure TS.29: Mitigation options have synergies with many Sustainable Development Goals, but there are**
 2 **trade-offs associated with some options especially when implemented at scale. The synergies and trade-**
 3 **offs vary widely and depend on the context**

4
 5 **Figure TS.29 legend:** Figure TS.29 presents a summary of the chapter-level qualitative assessment of the
 6 synergies and trade-offs for selected mitigation options. Overlaps may exist in the mitigation options assessed
 7 and presented by sector and system, and interlinkages with the SDGs might differ depending on the application
 8 of that option by sector. Interactions of mitigation options with the SDGs are context-specific and dependent on
 9 the scale of implementation. For some mitigation options, these scaling and context-specific issues imply that
 10 there are both synergies and trade-offs in relation to specific SDGs. The SDGs are displayed as coloured

1 squares. They indicate whether a synergy, trade-off or both synergies and trade-offs exist between the SDG and
2 the mitigation option. Confidence levels are indicated through the solidity of the squares. A solid square
3 indicates high confidence, a partially filled square indicates medium confidence, and an outlined square
4 indicates low confidence. The final column in the figure provides a line of sight to the chapters that provide
5 details on context-specificity and scale of implementation. {6.3, 6.4, 6.7, 7.3, 7.4, 7.5, 7.6, 8.2, 8.4, 8.6, 9.4, 9.5,
6 9.8, Table 9.5, 10.3, 10.4, 10.5, 10.6, 10.8, 11.5, Table 10.3, 17.3, Figure 17.1, Supplementary Material
7 Table 17.1, Annex II Part IV Section 12}
8

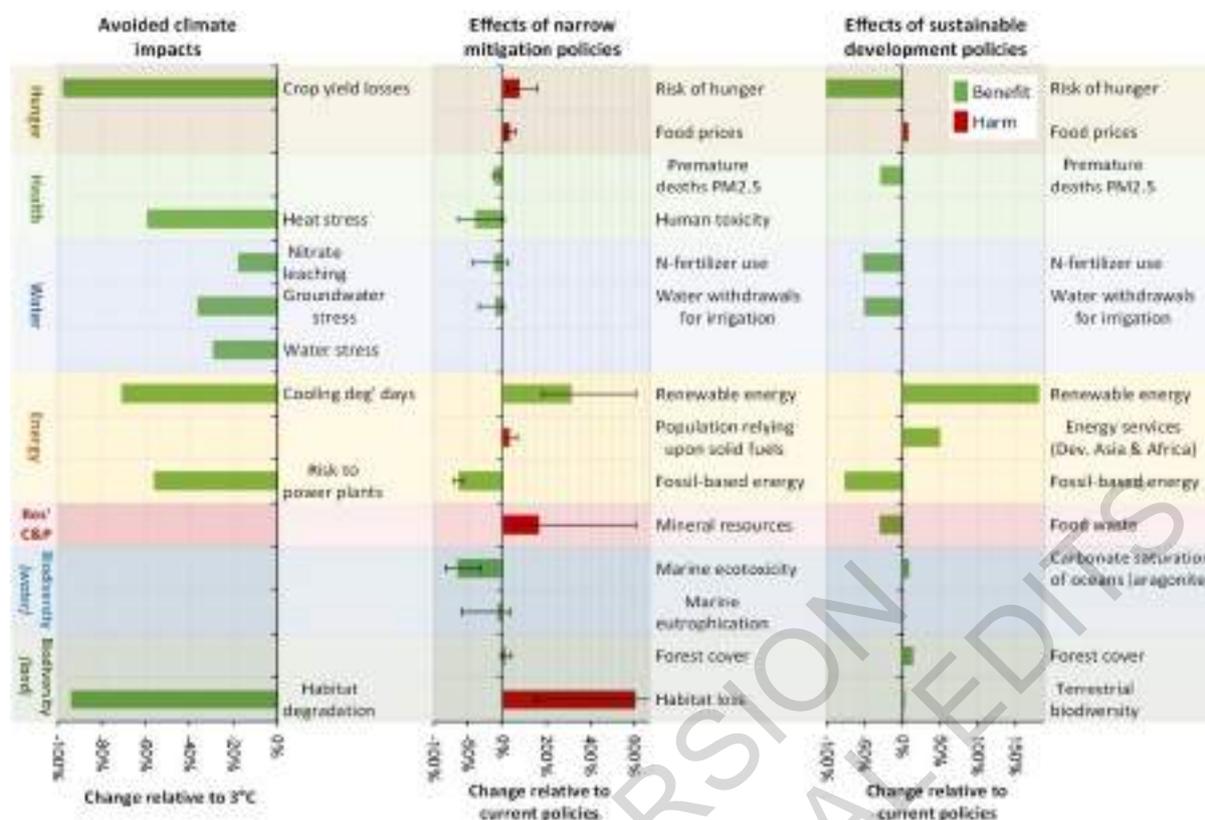

9 **Many of the potential trade-offs between mitigation and other sustainable development outcomes**
10 **depend on policy design and can be compensated or avoided with additional policies and**
11 **investments, or through policies that integrate mitigation with other SDGs (*high confidence*).**
12 Targeted SDG policies and investments, for example in the areas of healthy nutrition, sustainable
13 consumption and production, and international collaboration, can support climate change mitigation
14 policies and resolve or alleviate trade-offs. Trade-offs can also be addressed by complementary policies
15 and investments, as well as through the design of cross-sectoral policies integrating mitigation with the
16 SDGs, and in particular: good health and well-being (SDG 3), zero hunger and nutrition (SDG 2),
17 responsible consumption and production (SDG 12), reduced inequalities (SDG 10) and life on land
18 (SDG 15). (Figure TS.29, Figure TS.30) {3.7}

19 ***Decent living standards, which encompasses many SDG dimensions, are achievable at lower***
20 ***energy use than previously thought (*high confidence*).*** Mitigation strategies that focus on lowering
21 demand for energy and land-based resources exhibit reduced trade-offs and negative consequences for
22 sustainable development relative to pathways involving either high emissions and climate impacts or
23 pathways with high consumption and emissions that are ultimately compensated by large quantities of
24 BECCS. Figure TS.30 illustrates how, in the case of pathways *likely* limiting warming to 1.5°C,
25 sustainable development policies can lead to overall benefits compared to mitigation policies alone.
26 (Figure TS.22, Figure TS.30) {3.7, 5.2}

27 **The timing of mitigation actions and their effectiveness will have significant consequences for**
28 **broader sustainable development outcomes in the longer term (*high confidence*).** Ambitious
29 mitigation can be considered a precondition for achieving the SDGs. {3.7}

30 **Adopting coordinated cross-sectoral approaches to climate mitigation can target synergies and**
31 **minimise trade-offs, both between sectors and between sustainable development objectives (*high***
32 ***confidence*).** This requires integrated planning using multiple-objective-multiple-impact policy
33 frameworks. Strong inter-dependencies and cross-sectoral linkages create both opportunities for
34 synergies and need to address trade-offs related to mitigation options and technologies. This can only
35 be done if coordinated sectoral approaches to climate change mitigation policies are adopted that
36 mainstream these interactions and ensure local people are involved in the development of new products,
37 as well as production and consumption practices. For instance, there can be many synergies in urban
38 areas between mitigation policies and the SDGs but capturing these depends on the overall planning of
39 urban structures and on local integrated policies such as combining affordable housing and spatial
40 planning with walkable urban areas, green electrification and clean renewable energy (*medium*
41 *confidence*). Integrated planning and cross-sectoral alignment of climate change policies are also
42 particularly evident in developing countries' NDCs under the Paris Agreement, where key priority
43 sectors such as agriculture and energy are closely aligned with the proposed mitigation and adaptation
44 actions and the SDGs. {12.6.2, Supplementary Material Table 17.1, 17.3.3}

The feasibility of deploying response options is shaped by barriers and enabling conditions across geophysical, environmental-ecological, technological, economic, socio-cultural, and institutional dimensions (high confidence). Accelerating the deployment of response options depends on reducing or removing barriers across these dimensions, as well on establishing and strengthening enabling conditions. Feasibility is context-dependent, and also depends on the scale and the speed of implementation. For example: the institutional, legal and administrative capacity to support deployment varies across countries; the feasibility of options that involve large-scale land use changes is highly context dependent; spatial planning has a higher potential in early stages of urban development; the geophysical potential of geothermal is site specific; and cultural and local conditions may either inhibit or enable demand-side responses. Figure TS.31 summarises the assessment of barriers and enablers for a broad range of sector specific, and cross sectoral response options. (Box TS.15) {6.4, 7.4, 8.5, 9.10, 10.8, 12.3}

1

2

3 **Figure TS.31 Geophysical, environmental-ecological, technological, economic, socio-cultural and**
 4 **institutional factors can enable or act as barriers to the deployment of response options**

5 **Figure TS.31 legend:** chapter-level assessment for selected mitigation options. Overlaps may exist in the
 6 mitigation options assessed and presented by sector and system, and feasibility might differ depending on the
 7 demarcation of that option in each sector. Chapters 6, 8, 9, 10, and 12 assess mitigation response options across
 8 six feasibility dimensions: *geophysical, environmental-ecological, technological, economic, socio-cultural and*
 9 *institutional*. AFOLU (Ch7) and industry (Ch11) are not included because of the heterogeneity of options in
 10 these sectors. For each dimension, a set of feasibility indicators was identified. Examples of indicators include
 11 impacts on land use, air pollution, economic costs, technology scalability, public acceptance and political
 12 acceptance (see Box TS.15, and Annex II Part IV Section 11 for a detailed explanation). An indicator could
 13 refer to a barrier or an enabler to implementation, or could refer to both a barrier or an enabler, depending on the
 14 context, speed, and scale of implementation. Dark blue bars indicate the extent of enablers to deployment within
 15 each dimension. This is shown relative to the maximum number of possible enablers, as indicated by the light
 16 blue shading. Dark orange bars indicate the extent of barriers to deployment within each dimension. This is
 17 shown relative to the maximum number of possible barriers, as indicated by light orange shading. A light grey
 18 dot indicates that there is limited or no evidence to assess the option. A dark grey dot indicates that one of the
 19 feasibility indicators within that dimension is not relevant for the deployment of the option. The relevant
 20 sections in the underlying chapters include references to the literature on which the assessment is based and
 21 indicate whether the feasibility of an option varies depending on context (e.g., region), scale (e.g., small,
 22 medium, full scale), speed (e.g., implementation in 2030 versus 2050) and warming level (e.g., 1.5°C versus
 23 2°C). {6.4, 8.5, 9.10, 10.8, 12.3, Annex II Part IV Section 11}

24 **Alternative mitigation pathways are also associated with different feasibility challenges (*high***
 25 ***confidence*)**. These challenges are multi-dimensional, context-dependent, malleable to policy and to

1 technological and societal trends. They can also be reduced by putting in place appropriate enabling
2 conditions. Figure TS.32 highlights the dynamic and transient nature of feasibility risks. These risks are
3 transient and concentrated in the decades before mid-century. Figure TS.32 also illustrates how different
4 feasibility dimensions pose differentiated challenges: for example, institutional feasibility challenges
5 are shown as *unprecedented* for a high proportion of scenarios, in line with the qualitative literature,
6 but moving from 2030 to 2050 and 2100 these challenges decrease.

7 **The feasibility challenges associated with mitigation pathways are predominantly *institutional***
8 **and *economic* rather than *technological* and *geophysical* (*medium confidence*).** The rapid pace of
9 technological development and deployment in mitigation scenarios is not incompatible with historical
10 records, but rather, institutional capacity is a key limiting factor for a successful transition. Emerging
11 economies appear to have highest feasibility challenges in the short- to medium- term. This suggests
12 a key role of policy and technology as enabling factors. (Figure TS.32) {3.8}

13 **Pathways relying on a broad portfolio of mitigation strategies are more robust and resilient (*high***
14 ***confidence*).** Portfolios of technological solutions reduce the feasibility risks associated with the low
15 carbon transition. (Figure TS.31, Figure TS.32, Box TS.15) {3.8}

ACCEPTED VERSION
SUBJECT TO FINAL EDITING

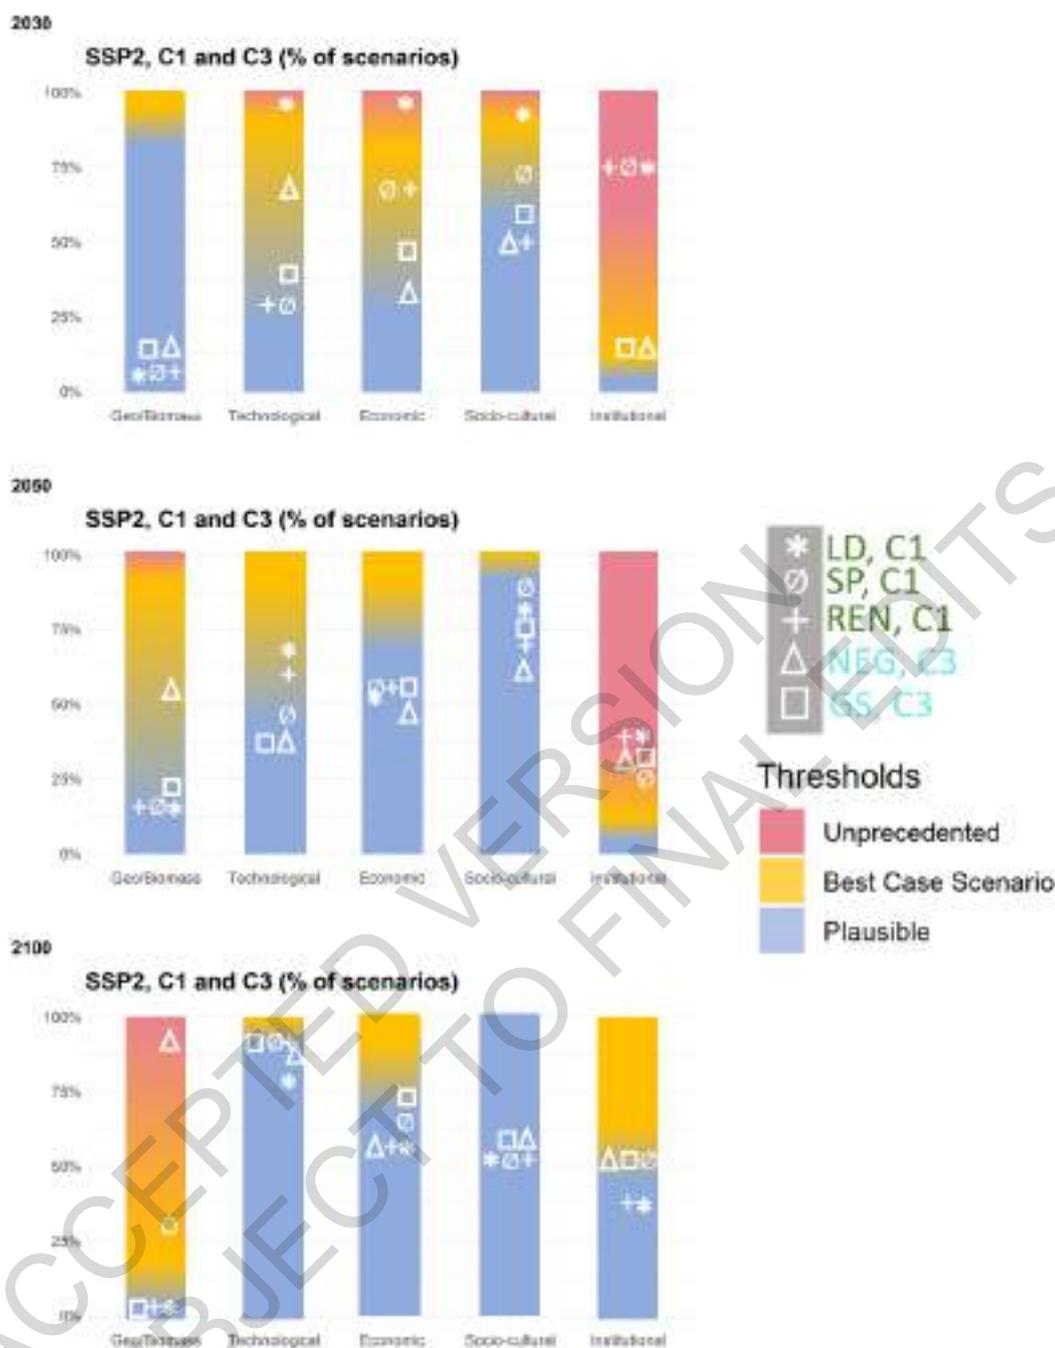

Figure TS.32: The feasibility of mitigation scenarios

Figure TS.32 legend: Figure shows the proportion scenarios in the AR6 scenarios database – falling within the warming level classifications C1 and C3 (C1: below 1.5°C, no or limited overshoot; C3: likely below 2°C) – that exceed threshold values in 2030, 2050 and 2100 for five dimensions of feasibility (See Box TS.5, Box TS.15). The feasibility dimensions shown are: *geophysical, technological, economic, socio-cultural and institutional*. The thresholds shown are: i) *plausible* – range of values based on past historical trends or other peer reviewed assessments; ii) *best case scenario* – range of values assuming major political support or technological breakthrough; iii) *unprecedented* – values going beyond those observed or reported in peer reviewed assessments. Overlaid are the Illustrative Mitigation Pathways consistent with SSP2 (LD, SP, Ren: C1 category; Neg, GS: C3 category). The positioning of the illustrative pathways is simply indicative of the general trade-offs over time and across the feasibility dimensions it is not determined mathematically.

(Box TS.5) {3.8}

1
2 **START BOX TS.15 HERE**

3 **Box TS.15: A harmonised approach to assessing feasibility**

4 The assessment of feasibility in this report aims to identify barriers and enablers to the deployment of
5 mitigation options and pathways. The assessment organises evidence to support policy decisions, and
6 decisions on actions, that would improve the feasibility of mitigation options and pathways by removing
7 relevant barriers and by strengthening enablers of change.

8 *The feasibility of mitigation response options*

9 Mitigation response options are assessed against six dimensions of feasibility. Each dimension
10 comprises a key set of indicators that can be evaluated by combining various strands of literature.
11 {Annex II Part IV Section 11, Table 6.1 }

12 **Box TS.15 Table.1: Feasibility dimensions and indicators to assess the barriers and enablers of**
13 **implementing mitigation options**

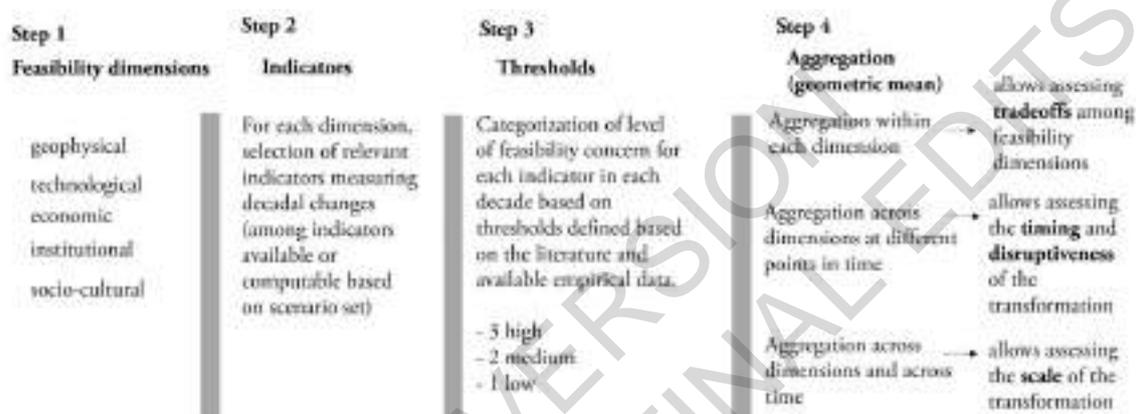

Feasibility dimension	Indicators
Geophysical feasibility	Availability of required geophysical resources: <ul style="list-style-type: none"> • Physical potential • Geophysical resource availability • Land use
Environmental-ecological feasibility	Impacts on environment: <ul style="list-style-type: none"> • Air pollution • Toxic waste, ecotoxicity and eutrophication • Water quantity and quality • Biodiversity
Technological feasibility	Extent to which the technology can be implemented at scale soon <ul style="list-style-type: none"> • Simplicity • Technology scalability • Maturity and technology readiness
Economic feasibility	Financial costs and economic effects <ul style="list-style-type: none"> • Costs now, in 2030 and in the long term • Employment effects and economic growth
Socio-cultural feasibility	Public engagement and support, and social impacts: <ul style="list-style-type: none"> • Public acceptance • Effects on health and well-being • Distributional effects
Institutional feasibility	Institutional conditions that affect the implementation of the response option <ul style="list-style-type: none"> • Political acceptance • Institutional capacity and governance, cross-sectoral coordination • Legal and administrative capacity

15 The assessment – undertaken by the sectoral chapters in this report – evaluates to what extent each
16 indicator (listed in Box TS.15 Table.1) would be an enabler or barrier to implementation using a scoring
17 methodology (described in detail in Annex II Part IV Section 11). When appropriate, it is also indicated
18 whether the feasibility of an option varies across context, scale, time and temperature goal. The resulting
19 scores provide insight into the extent to which each feasibility dimension enables or inhibits the
20 deployment of the relevant option. It also provides insight into the nature of the effort needed to reduce
21 or remove barriers thereby improving the feasibility of individual options. {Annex II Part IV Section
22 11}
23

1 *The feasibility of mitigation scenarios*

2 Scenarios provide internally consistent projections of emission reduction drivers and help contextualize
3 the scale of deployment and interactions of mitigation strategies. Recent research has proposed and
4 operationalised frameworks for the feasibility assessment of mitigation scenarios. In this report the
5 feasibility assessment of scenarios uses an approach that involves developing a set of multi-dimensional
6 metrics capturing the *timing*, *disruptiveness* and the *scale* of the transformative change within five
7 dimensions: *geophysical*, *technological*, *economic*, *socio-cultural* and *institutional*, as illustrated in
8 Box TS.15 Figure 1.

9 More than 20 indicators were chosen to represent feasibility dimensions that could be related to scenario
10 metrics. Thresholds of feasibility risks of different intensity were obtained through empirical analysis
11 of historical data and assessed literature. Details of indicators, thresholds, and how they were applied is
12 reported in Annex II Part IV Section 11. {3.8}

13
14 **Box TS.15 Figure 1: Steps involved in evaluating the feasibility of scenarios {Figure 3.41}**

15 Note: In this approach the *environmental-ecological* dimension is captured through different scenarios'
16 categories.

17 **END BOX TS.15 HERE**

18
19 **A wide range of factors have been found to enable sustainability transitions, ranging from**
20 **technological innovations to shifts in markets, and from policies and governance arrangements**
21 **to shifts in belief systems and market forces (*high confidence*).** Many of these factors have come
22 together in a co-evolutionary process that has unfolded globally, internationally and locally over several
23 decades (*low evidence, high agreement*). Those same conditions that may serve to impede the transition
24 (i.e., organisational structure, behaviour, technological lock-in) can also 'flip' to enable both the
25 transition and the framing of sustainable development policies to create a stronger basis for policy
26 support (*high confidence*). It is important to note that strong shocks to these systems, including
27 accelerating climate change impacts, economic crises and political changes, may provide crucial
28 openings for accelerated transitions to sustainable systems. For example, re-building more sustainably
29 after an extreme event, or renewed public debate about the drivers of social and economic vulnerability
30 to multiple stressors (*medium confidence*). {17.4}

31 **While transition pathways will vary across countries it is anticipated that they will be challenging**
32 **in many contexts (*high confidence*).** Climate change is the result of decades of unsustainable
33 production and consumption patterns, as well as governance arrangements and political economic
34 institutions that lock in resource-intensive development patterns (*high confidence*). Resource shortages,
35 social divisions, inequitable distributions of wealth, poor infrastructure and limited access to advanced

1 technologies and skilled human resources can constrain the options and capacity of developing
2 countries to achieve sustainable and just transitions (*medium evidence, high agreement*) {17.1.1}.
3 Reframing development objectives and shifting development pathways towards sustainability can help
4 transform these patterns and practices, allowing space to transform unsustainable systems (*medium*
5 *evidence, high agreement*). {1.6, Cross-Chapter Box 5 in Chapter 4, 17.1, 17.3}

6 **The landscape of transitions to sustainable development is changing rapidly, with multiple**
7 **transitions already underway. This creates the room to manage these transitions in ways that**
8 **prioritise the needs of workers in vulnerable sectors (e.g., land, energy) to secure their jobs and**
9 **maintain secure and healthy lifestyles (*medium evidence, high agreement*). {17.3.2}**

10
11 **Actions aligning sustainable development, climate mitigation and partnerships can support**
12 **transitions. Strengthening different stakeholders’ “response capacities” to mitigate and adapt to**
13 **a changing climate will be critical for a sustainable transition (*high confidence*). {17.1}**

14
15 **Accelerating the transition to sustainability will be enabled by explicit consideration being given**
16 **to the principles of justice, equality and fairness (*high confidence*). {5.2, 5.4, 5.6, 13.2, 13.6, 13.8,**
17 **13.9,17.4}**

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1 Executive Summary

2 **Global greenhouse gas (GHG) emissions continued to rise to 2019: the aggregate reductions**
3 **implied by current Nationally Determined Contributions (NDCs) to 2030 would still make it**
4 **impossible to limit warming to 1.5°C with no or limited overshoot, and would only be compatible**
5 **with likely limiting warming below 2°C if followed by much steeper decline, hence limiting**
6 **warming to either level implies accelerated mitigation actions at all scales** (*robust evidence, high*
7 *agreement*). Since the IPCC's Fifth Assessment Report (AR5), important changes that have emerged
8 include the specific objectives established in the Paris Agreement of 2015 (for temperature, adaptation
9 and finance), rising climate impacts, and higher levels of societal awareness and support for climate
10 action. The growth of global GHG emissions has slowed over the past decade, and delivering the
11 updated NDCs to 2030 would turn this into decline, but the implied global emissions by 2030 exceed
12 pathways consistent with 1.5°C by a large margin, and are near the upper end of the range of modelled
13 pathways which keep temperatures likely below 2°C. Continuing investments in carbon-intensive
14 activities at scale will heighten the multitude of risks associated with climate change and impede societal
15 and industrial transformation towards low carbon development. Meeting the long-term temperature
16 objective in the Paris Agreement therefore implies a rapid turn to an accelerating decline of GHG
17 emissions towards 'net zero', which is implausible without urgent and ambitious action at all scales.
18 The unprecedented COVID-19 pandemic has had far-reaching impacts on the global economic and
19 social system, and recovery will present both challenges and opportunities for climate mitigation. {1.2,
20 1.3, 1.5, 1.6, Chapters 3 and 4}.

21 **While there are some trade-offs, effective and equitable climate policies are largely compatible**
22 **with the broader goal of sustainable development and efforts to eradicate poverty as enshrined in**
23 **the 17 Sustainable Development Goals (SDGs)** (*robust evidence, high agreement*). Climate mitigation
24 is one of many goals that societies pursue in the context of sustainable development, as evidenced by
25 the wide range of the SDGs. Climate mitigation has synergies and/or trade-offs with many other SDGs.
26 There has been a strong relationship between development and GHG emissions, as historically both per
27 capita and absolute emissions have risen with industrialisation. However, recent evidence shows
28 countries can grow their economies while reducing emissions. Countries have different priorities in
29 achieving the SDGs and reducing emissions as informed by their respective national conditions and
30 capabilities. Given the differences in GHG emissions contributions, degree of vulnerabilities and
31 impacts, as well as capacities within and between nations, equity and justice are important
32 considerations for effective climate policy and for securing national and international support for deep
33 decarbonisation. Achieving sustainable global development and eradicating poverty as enshrined in the
34 17 SDGs would involve effective and equitable climate policies at all levels from local to global scale.
35 Failure to address questions of equity and justice over time can undermine social cohesion and stability.
36 International co-operation can enhance efforts to achieve ambitious global climate mitigation in the
37 context of sustainable development. {1.4, 1.6, Chapters 2, 3, 4, 5, 13 and 17}.

38 **The transition to a low carbon economy depends on a wide range of closely intertwined drivers**
39 **and constraints, including policies and technologies where notable advances over the past decade**
40 **have opened up new and large-scale opportunities for deep decarbonisation, and for alternative**
41 **development pathways which could deliver multiple social and developmental goals** (*robust*
42 *evidence, medium agreement*). Drivers for and constraints against low carbon societal transition
43 comprise *economic and technological* factors (the means by which services such as food, heating and
44 shelter are provided and for whom, the emissions intensity of traded products, finance, and investment),
45 *socio-political issues* (political economy, equity and fairness, social innovation and behaviour change),
46 and *institutional factors* (legal framework and institutions, and the quality of international cooperation).
47 In addition to being deeply intertwined all the factors matter to varying degrees, depending on prevailing

1 social, economic, cultural and political context. They often exert both push and pull forces at the same
2 time, within and across different scales. The development and deployment of innovative technologies
3 and systems at scale are important for achieving deep decarbonisation. In recent years, the cost of
4 several low carbon technologies has declined sharply, alongside rapid deployment. Over twenty
5 countries have also sustained emission reductions, and many more have accelerated energy efficiency
6 and/or land-use improvements. Overall, however the global contribution is so far modest, at a few
7 billion tonnes (tCO_{2e}) of avoided emissions annually. {1.3, 1.4, Chapters 2, 4,13,14}.

8 **Accelerating mitigation to prevent dangerous anthropogenic interference within the climate**
9 **system will require the integration of broadened assessment frameworks and tools that combine**
10 **multiple perspectives, applied in a context of multi-level governance** (*robust evidence, medium*
11 *agreement*). Analysing a challenge on the scale of fully decarbonising our economies entails integration
12 of multiple analytic frameworks. Approaches to risk assessment and resilience, established across IPCC
13 Working Groups, are complemented by frameworks for probing the challenges in implementing
14 mitigation. *Aggregate Frameworks* include cost-effectiveness analysis towards given objectives, and
15 cost-benefit analysis, both of which have been developing to take fuller account of advances in
16 understanding risks and innovation, the dynamics of emitting systems and of climate impacts, and
17 welfare economic theory including growing consensus on long-term discounting. *Ethical frameworks*
18 consider the fairness of processes and outcomes which can help ameliorate distributional impacts across
19 income groups, countries and generations. *Transition and transformation frameworks* explain and
20 evaluate the dynamics of transitions to low-carbon systems arising from interactions amongst levels,
21 with inevitable resistance from established socio-technical structures. *Psychological, behavioural and*
22 *political frameworks* outline the constraints (and opportunities) arising from human psychology and the
23 power of incumbent interests. A comprehensive understanding of climate mitigation must combine
24 these multiple frameworks. Together with established risk frameworks, collectively these help to
25 explain potential synergies and trade-offs in mitigation, imply a need for a wide portfolio of policies
26 attuned to different actors and levels of decision-making, and underpin ‘just transition’ strategies in
27 diverse contexts. {1.2.2, 1.7, 1.8}.

28 **The speed, direction and depth of any transition will be determined by choices in the,**
29 **environmental, technological, economic, socio-cultural and institutional realms** (*robust evidence,*
30 *high agreement*). Transitions in specific systems can be gradual or rapid and disruptive. The pace of a
31 transition can be impeded by ‘lock-in’ generated by existing physical capital, institutions, and social
32 norms. The interaction between power, politics and economy is central in explaining why broad
33 commitments do not always translate to urgent action. At the same time, attention to and support for
34 climate policies and low carbon societal transition has generally increased, as the impacts have become
35 more salient. Both public and private financing and financial structures strongly affect the scale and
36 balance of high and low carbon investments. COVID-19 has strained public finances, and integrating
37 climate finance into ongoing recovery strategies, nationally and internationally, can accelerate the
38 diffusion of low carbon technologies and also help poorer countries to minimise future stranded assets.
39 Societal & behavioural norms, regulations and institutions are essential conditions to accelerate low
40 carbon transitions in multiple sectors, whilst addressing distributional concerns endemic to any major
41 transition. {1.3.3, Cross-Chapter Box 1 in this chapter, 1.4, 1.8, Chapters 2-4 and 15}.

42 **Achieving the global transition to a low-carbon, climate-resilient and sustainable world requires**
43 **purposeful and increasingly coordinated planning and decisions at many scales of governance**
44 **including local, subnational, national and global levels** (*robust evidence, high agreement*).
45 Accelerating mitigation globally would imply strengthening policies adopted to date, expanding the
46 effort across options, sectors, and countries, and broadening responses to include more diverse actors
47 and societal processes at multiple – including international – levels. Effective governance of climate
48 change entails strong action across multiple jurisdictions and decision-making levels, including regular

1 evaluation and learning. Choices that cause climate change as well as the processes for making and
2 implementing relevant decisions involve a range of non-nation state actors such as cities, businesses,
3 and civil society organisations. At global, national and subnational levels, climate change actions are
4 interwoven with and embedded in the context of much broader social, economic and political goals.
5 Therefore, the governance required to address climate change has to navigate power, political,
6 economic, and social dynamics at all levels of decision making. Effective climate-governing
7 institutions, and openness to experimentation on a variety of institutional arrangements, policies and
8 programmes can play a vital role in engaging stakeholders and building momentum for effective climate
9 action. {1.4, 1.9, Chapters 8, 15, 17}.

10

11 **1.1 Introduction**

12 This Report (WGIII) aims to assess new literature on climate mitigation including implications for
13 global sustainable development. In this Sixth Assessment Cycle the IPCC has also published three
14 Special Reports¹ all of which emphasise the rising threat of climate change and the implications for
15 more ambitious mitigation efforts at all scales. At the same time, the Paris Agreement (PA) and the UN
16 2030 Agenda for Sustainable Development with its 17 Sustainable Development Goals (SDGs), both
17 adopted in 2015, set out a globally agreed agenda within which climate mitigation efforts must be
18 located. Along with a better understanding of the physical science basis of climate change (AR6 WGI),
19 and vulnerabilities, impacts, and adaptation (AR6 WGII), the landscape of climate mitigation has
20 evolved substantially since Fifth Assessment Report (AR5).

21 Since AR5, (IPCC 2014a) climate mitigation policies around the world have grown in both number
22 and shape (Chapter 13). However, while the average rate of annual increase of CO₂ emissions has
23 declined (Section 1.3.2) GHG emissions globally continued to rise, underlining the urgency of the
24 mitigation challenge (Chapters 2, 3). Over twenty countries have cut absolute emissions alongside
25 sustained economic growth, but the scale of mitigation action across countries remains varied and
26 generally much slower than the pace required to meet the goals of the Paris Agreement (Section 1.3.2
27 in this chapter and Section 2.7.2 in Chapter 2). Per-capita GHG emissions between countries even at
28 similar stages of economic development (based on GDP per capita) vary by a factor of three (Figure
29 1.6) and by more than two on consumption basis (Section 2.3 in Chapter 2).

30 The Special Report on 1.5°C underlined that humanity is now living with the “unifying lens of the
31 Anthropocene” (SR 1.5 IPCC 2018a, 52 & 53), that requires a sharpened focus on the impact of human
32 activity on the climate system and the planet more broadly given ‘planetary boundaries’ (Steffen et al.
33 2015) including interdependencies of climate change and biodiversity (Dasgupta 2021). Recent
34 literature assessed by WGs I and II of this AR6 underlines the urgency of climate action as cumulative
35 CO₂ emissions, along with other greenhouse gases, drives the temperature change. Across AR6, global
36 temperature changes are defined relative to the period 1850-1900, as in SR1.5 and collaboration with
37 WGI enabled the use of AR6-calibrated emulators to assure consistency across the three Working
38 Groups. The remaining ‘carbon budgets’ (see Annex I) associated with 1.5°C and 2°C temperature
39 targets equate to about one (for 1.5°C) to three (for 2°C) decades of current emissions, as from 2020,
40 but with significant variation depending on multiple factors including other gases (Figure 2.7 in Chapter

FOOTNOTE¹ These are the ‘Special Report on the impacts of global warming of 1.5°C above pre-industrial levels and related global greenhouse gas emission pathways, in the context of strengthening the global response to the threat of climate change, sustainable development, and efforts to eradicate poverty’ (hereafter SR1.5, 2018) (IPCC 2018b); the ‘Special Report on Climate Change and Land’ (SRCL) (IPCC 2019c); and the ‘Special Report on the Ocean and Cryosphere in a Changing Climate’ (SROCC) (IPCC 2019b).

2; Cross-Working Group Box 1 in Chapter 3). For an outline of the WGIII approach to mitigation scenarios, emission pathways implied by the Paris goals, and timing of peak and ‘net zero’ (Annex I and FAQ 1.3), see Section 1.5, and Chapter 3.

Strong differences remain in responsibilities for, and capabilities to, take climate action within and between countries. These differences, as well as differences in the impact of climate change, point to the role of collective action in achieving urgent and ambitious global climate mitigation in the context of sustainable development, with attention to issues of equity and fairness as highlighted in several chapters of the report (Chapters 4, 5, 14, 15, 17).

Innovation and industrial development of key technologies in several relevant sectors have transformed prospects for mitigation at much lower cost than previously assessed (Chapters 2 and 6–12). Large reductions in the cost of widely-available renewable energy technologies, along with energy efficient technologies and behavioural changes (Chapters 5 and 9–11), can enable societies to provide services with much lower emissions. However, there are still significant differences in the ability to access and utilise low carbon technologies across the world (Chapter 4, 15, 16). New actors, including cities, businesses, and numerous non-state transnational alliances have emerged as important players in the global effort to tackle climate change (Chapters 13–16).

Along with continued development of concepts, models and technologies, there have been numerous insights from both the successes and failures of mitigation action that can inform future policy design and climate action. However, to date, policies and investments are still clearly inadequate to put the world in line with the PA’s aims (Chapters 13, 15).

The greater the inertia in emission trends and carbon-intensive investments, the more that CO₂ will continue to accumulate (Hilaire et al. 2019; IPCC 2019a). Overall, the literature points to the need for a more dynamic consideration of intertwined challenges concerning the transformation of key GHG emitting systems: to minimise the trade-offs, and maximise the synergies, of delivering deep decarbonisation whilst enhancing sustainable development.

This Chapter introduces readers to the AR6 WGIII Report and provides an overview of progress and challenges, in three parts. Part A, introduces the climate mitigation challenge, provides key findings and developments since previous assessment, and reviews the main drivers for, and constraints against accelerated climate action. Part B provides an assessment of the key frameworks for understanding the climate mitigation challenge covering broad approaches like sustainable development and more specific economic, political and ethical framings. Part C briefly highlights the role of governance for steering and coordinating efforts to accelerate globally effective and equitable climate mitigation, notes the gaps in knowledge that have been identified in the process of assessment and provides a road map to the rest of the Report.

1.2 Previous Assessments

1.2.1 Key findings from Previous Assessment Reports

Successive WGIII IPCC Assessments have emphasised the importance of climate mitigation along with the need to consider broader societal goals especially sustainable development. Key insights from AR5 and the subsequent three Special Reports (IPCC 2019b, 2018b, 2019c) are summarised below.

AR5 projected that in baseline scenarios (i.e. based on prevailing trends without explicit additional mitigation efforts), Agriculture, Forestry and Other Land Uses (AFOLU) would be the only sector where emissions could fall by 2100, with some CO₂ removal (IPCC 2014b, p. 17). Direct CO₂ emissions from energy were projected to double or even triple by 2050 (IPCC 2014b, p. 20) due to global

1 population and economic growth, resulting in global mean surface temperature increases in 2100 from
2 3.7°C to 4.8°C compared to pre-industrial levels. AR5 noted that mitigation effort and the costs
3 associated with ambitious mitigation differ significantly across countries, and in ‘globally cost-
4 effective’ scenarios, the biggest reductions (relative to projections) occur in the countries with the
5 highest future emissions in the baseline scenarios (IPCC 2014b, p. 17). Since most physical capital (e.g.
6 power plants, buildings, transport infrastructure) involved in GHG emissions is long-lived, the timing
7 of the shift in investments and strategies will be crucial (IPCC 2014b, p. 18).

8 A key message from recent Special Reports is the urgency to mitigate GHG emissions in order to avoid
9 rapid and potentially irreversible changes in natural and human systems (IPCC 2019b, 2018b, 2019a).
10 Successive IPCC reports have drawn upon increasing sophistication of modelling tools to project
11 emissions in the absence of ambitious decarbonisation action, as well as the emission pathways that
12 meet long term temperature targets. The SR1.5 examined pathways limiting warming to 1.5°C,
13 compared to historical baseline of 1850-1900, finding that “in pathways with no or limited overshoot
14 of 1.5°C, global net anthropogenic CO₂ emissions decline by about 45% from 2010 levels by 2030,
15 reaching net zero around 2050” (2045–2055 interquartile range); with ‘overshoot’ referring to higher
16 temperatures, then brought down by 2100 through ‘net negative’ emissions. It found this would require
17 rapid and far-reaching transitions in energy, land, urban and infrastructure (including transport and
18 buildings), and industrial systems (*high confidence*) (IPCC 2018b).

19 SR1.5 found that the Nationally Determined Contributions (NDCs) as declared under the Paris
20 Agreement (PA) would not limit warming to 1.5 C; despite significant updates to NDCs in 2020/21,
21 this remains the case though delivery of these more ambition NDCs would somewhat enhance the
22 prospects for staying below 2°C (Section 1.3.3).

23 AR5 WGIII and the Special Reports analysed economic costs associated with climate action. The
24 estimates vary widely depending on the assumptions made as to how ordered the transition is,
25 temperature target, technology availability, the metric or model used, among others (Chapter 6).
26 Modelled direct mitigation costs of pathways to 1.5°C, with no/limited overshoot, span a wide range,
27 but were typically 3-4 times higher than in pathways to 2°C (*high confidence*), before taking account
28 of benefits, including significant reduction in loss of life and livelihoods, and avoided climate impacts
29 (IPCC 2018b).

30 Successive IPCC Reports highlight a strong connection between climate mitigation and sustainable
31 development. Climate mitigation and adaptation goals have synergies and trade-offs with efforts to
32 achieve sustainable development, including poverty eradication. A comprehensive assessment of
33 climate policy therefore involves going beyond a narrow focus on specific mitigation and adaptation
34 options to incorporate climate issues into the design of comprehensive strategies for equitable
35 sustainable development. At the same time, some climate mitigation policies can run counter to
36 sustainable development and eradicating poverty, which highlights the need to consider trade-offs
37 alongside benefits. Examples include synergies between climate policy and improved air quality,
38 reducing premature deaths and morbidity (IPCC 2014b Fig SPM.6; AR6 WG1 sections 6.6.3 and 6.7.3),
39 but there would be trade-offs if policy raises net energy bills, with distributional implications. The
40 Special Report on Climate Change and Land (SRCCL) also emphasises important synergies and trade-
41 offs, bringing new light on the link between healthy and sustainable food consumption and emissions
42 caused by the agricultural sector. Land-related responses that contribute to climate change adaptation
43 and mitigation can also combat desertification and land degradation and enhance food security (IPCC
44 2019a).

45 Previous ARs have detailed the contribution of various sectors and activities to global GHG emissions.
46 When indirect emissions (mainly from electricity, heat and other energy conversions) are included, the
47 four main consumption (end-use) drivers are industry, AFOLU, buildings and transport (Chapter 2,

1 Figure 2.14), though the magnitude of these emissions can vary widely between countries. These –
2 together with the energy and urban systems which feed and shape end-use sectors – define the sectoral
3 chapters in this AR6 WGIII report.

4 Estimates of emissions associated with production and transport of internationally traded goods were
5 first presented in AR5 WGIII, which estimated the ‘embodied emission transfers’ from upper-middle-
6 income countries to industrialised countries through trade at about 10 percent of CO₂ emissions in each
7 of these groups (IPCC 2014a Fig TS.5). The literature on this and discussion on their accounting has
8 grown substantially since then (Chapters 2 & 8).

9 The atmosphere is a shared global resource and an integral part of the “global commons”. In the
10 depletion/restoration of this resource, myriad actors at various scales are involved, for instance,
11 individuals, communities, firms and states. *Inter alia*, international cooperation to tackle ozone
12 depletion and acid rain offer useful examples. AR5 noted that greater cooperation would ensue if
13 policies are perceived as fair and equitable by all countries along the spectrum of economic
14 development—implying a need for equitable sharing of the effort. A key takeaway from AR5 is that
15 climate policy involves value judgement and ethics. (IPCC 2014a Box TS.1 “*People and countries have*
16 *rights and owe duties towards each other. These are matters of justice, equity, or fairness. They fall*
17 *within the subject matter of moral and political philosophy, jurisprudence, and economics.” p. 37).
18 International cooperation and collective action on climate change alongside local, national, regional and
19 global policies will be crucial to solve the problem, and this report notes cooperative approaches beyond
20 simple ‘global commons’ framings (Chapters 13, 14).*

21 AR5 (all Working Group Reports) also underlined that climate policy inherently involves risk and
22 uncertainty (in nature, economy, society and individuals). To help evaluate responses, there exists a rich
23 suite of analytical tools, for example, cost-benefit analysis, cost-effectiveness analysis, multi-criteria
24 analysis, expected utility theory and catastrophe and risk models. All have pros and cons, and have been
25 further developed in subsequent literature and AR6 (next section).

26 Recent Assessments (IPCC 2014a, 2018b) began to consider the role of individual behavioural choices
27 and cultural norms in driving energy and food patterns. Notably, SR1.5 (Section 4.4.3 in Chapter 4)
28 outlined emerging evidence on the potential for changes in behaviour, lifestyle and culture to contribute
29 to decarbonisation (and lower the cost); for the first time, AR6 devotes a whole chapter (Chapter 5) to
30 consider these and other underlying drivers of energy demand, food choices and social aspects.

31 **1.2.2 Developments in Climate Science, Impacts and Risk**

32 The assessment of the Physical Science Basis (IPCC WGI AR6) documents sustained and widespread
33 changes in the atmosphere, cryosphere, biosphere and ocean, providing unequivocal evidence of a world
34 that has warmed, associated with rising atmospheric CO₂ concentrations reaching levels not experienced
35 in at least the last 2 million years. Aside from temperature, other clearly discernible, human-induced
36 changes beyond natural variations include declines in Arctic Sea ice and glaciers, thawing of
37 permafrost, and a strengthening of the global water cycle (WG1 SPM A.2, B.3 and B.4). Oceanic
38 changes include rising sea level, acidification, deoxygenation, and changing salinity (WG1 SPM B.3).
39 Over land, in recent decades, both frequency and severity have increased for hot extremes but decreased
40 for cold extremes; intensification of heavy precipitation is observed in parallel with a decrease in
41 available water in dry seasons, along with an increased occurrence of weather conditions that promote
42 wildfires.

43 In defining the objective of international climate negotiations as being to ‘prevent dangerous
44 anthropogenic interference’ (Article 2 UNFCCC 1992), the UNFCCC underlines the centrality of risk
45 framing in considering the threats of climate change and potential response measures. Against the
46 background of ‘unequivocal’ (AR4) evidence of human-induced climate change, and the growing

1 experience of direct impacts, the IPCC has sought to systematise a robust approach to risk and risk
2 management.

3 In AR6 the IPCC employs a common risk framing across all three working groups and provides
4 guidance for more consistent and transparent usage (AR6 WGI Cross-Chapter Box 3 in Chapter 1; AR6
5 WGII 1.4.1; IPCC risk guidance). AR6 defines risk as “the potential for adverse consequences for
6 human or ecological systems, recognising the diversity of values and objectives associated with such
7 systems” (Annex I), encompassing risks from both potential impacts of climate change and human
8 responses to it (Reisinger et al. 2020). The risk framing includes steps for identifying, evaluating, and
9 prioritising current and future risks; for understanding the interactions among different sources of risk;
10 for distributing effort and equitable sharing of risks; for monitoring and adjusting actions over time
11 while continuing to assess changing circumstances; and for communications among analysts, decision-
12 makers, and the public.

13 Climate change risk assessments face challenges including a tendency to mis-characterise risks and pay
14 insufficient attention to the potential for surprises (Weitzman 2011; Aven and Renn 2015; Stoerk et al.
15 2018). Concepts of resilience and vulnerability provide overlapping, alternative entry points to
16 understanding and addressing the societal challenges caused and exacerbated by climate change (AR6,
17 WGII, Chapter 1.2.1).

18 AR6 WGII devotes a full chapter (17) to ‘Decision-Making Options for Managing Risk’, detailing the
19 analytic approaches and drawing upon the *Cynefin* classification of Known, Knowable, Complex and
20 Chaotic systems (17.3.1). With deep uncertainty, risk management often aims to identify specific
21 combinations of response actions and enabling institutions that increase the potential for favourable
22 outcomes despite irreducible uncertainties (AR6 WGII Chapter 17 Cross-Chapter Box DEEP; also
23 (Marchau et al. 2019; Doukas and Nikas 2020).

24 Literature trying to quantify the cost of climate damages has continued to develop. Different
25 methodologies systematically affect outcomes, with recent estimates based on empirical approaches –
26 econometric measurements based on actual impacts – ‘categorically higher than estimates from other
27 approaches’ (Cross-Working Group Box ECONOMIC in WGII Chapter 16, Section 16.6.2). This, along
28 with other developments strengthen foundations for calculating a ‘social cost of carbon’. This informs
29 a common metric for comparing different risks and estimating benefits compared to the costs of GHG
30 reductions and other risk-reducing options (Section 1.7.1); emissions mitigation itself also involves
31 multiple uncertainties, which alongside risks can also involve potential opportunities (Section 1.7.3).

32 Simultaneously, the literature increasingly emphasises the importance of multi-objective risk
33 assessment and management (e.g., representative key risks in WGII Chapter 16), which may or may
34 not correlate with any single estimate of economic value (AR6 WGII 1.4.1; IPCC risk guidance). Given
35 the deep uncertainties and risks, the goals established (notably in the Paris Agreement and SDGs) reflect
36 negotiated outcomes informed by the scientific assessment of risks.

37

38 **1.3 The Multilateral Context, Emission Trends and Key Developments**

39 Since AR5, there have been notable multilateral efforts which help determine the context for current
40 and future climate action. This section summarises key features of this evolving context.

41 **1.3.1 The 2015 Agreements**

42 In 2015 the world concluded four major agreements that are very relevant to climate action. These
43 include: the Paris Agreement under the 1992 United Nations Framework Convention on Climate

1 Change (UNFCCC), the UN agreements on Disaster Risk Reduction (Sendai) and Finance for
2 Development (Addis Ababa), and the Sustainable Development Goals (SDGs).

3 **The Paris Agreement (PA).** The Paris Agreement aims to “hold the increase in the global average
4 temperature to well below 2°C above pre-industrial levels and pursuing efforts to limit the temperature
5 increase to 1.5°C above pre-industrial levels” (UNFCCC 2015), alongside goals for adaptation (IPCC
6 WGII), and ‘aligning financial flows’ (below), so as “to strengthen the global response to the threat of
7 climate change, in the context of sustainable development and efforts to eradicate poverty.”

8 The Paris Agreement is predicated on encouraging progressively ambitious climate action from all
9 countries on the basis of Nationally Determined Contributions (Rajamani 2016; Cléménçon 2016). The
10 NDC approach requires countries to set their own level of ambitions for climate change mitigation but
11 within a collaborative and legally binding process to foster ambition towards the agreed goals (Falkner
12 2016a; Bodansky 2016). The PA entered into force in November 2016 and as of February 2021 it has
13 190 Parties (out of 197 Parties to the UNFCCC).

14 The PA also underlines “the principle of common but differentiated responsibilities and respective
15 capabilities, in the light of different national circumstances” (PA Article 2 para 2), and correspondingly
16 that “developed country Parties should continue taking the lead by undertaking economy-wide absolute
17 emission reductions”. It states that developing country Parties should continue enhancing their
18 mitigation efforts, and are encouraged to move over time towards economy-wide emission reduction or
19 limitation targets in the light of different national circumstances.

20 The Paris Agreement’s mitigation goal implies “to achieve a balance between anthropogenic emissions
21 by sources and removals by sinks of greenhouse gases in the second half of this century” (PA Article 4
22 para 1). The Paris Agreement provides for 5-yearly stocktakes in which Parties have to take collective
23 stock on progress towards achieving its purposes and its long-term goal in the light of equity and
24 available best science (PA Article 14). The first global stocktake is scheduled for 2023. (PA Article 14
25 para 3).

26 The Paris Agreement aims to make ‘finance flows consistent with a pathway towards low greenhouse
27 gas emissions and climate-resilient development’ (PA Article 2.1C). In keeping with the acknowledged
28 context of global sustainable development and poverty eradication, and the corresponding aims of
29 aligning finance and agreed differentiating principles as indicated above, “...the developed country
30 parties are to assist developing country parties with financial resources” (PA Article 9). The Green
31 Climate Fund (GCF), an operating entity of the UNFCCC Financial Mechanism to finance mitigation
32 and adaptation efforts in developing countries (GCF 2020), was given an important role in serving the
33 Agreement and supporting PA goals.. The GCF gathered pledges worth USD 10.3 billion, from
34 developed and developing countries, regions, and one city (Paris) (Antimiani et al. 2017; Bowman and
35 Minas 2019). Financing has since increased but remains short of the goal to mobilise USD100 billion
36 by 2020 (Chapter 15).

37 Initiatives contributing to the Paris Agreement goals include the Non-State Actor Zone for Climate
38 Action (NAZCA or now renamed as Global Climate Action) portal, launched at COP20 (December
39 2014) in Lima, Peru, to support city-based actions for mitigating climate change (Mead 2015) and
40 Marrakech Partnership for Global Climate Action which is a UNFCCC-backed series of events intended
41 to facilitate collaboration between governments and the cities, regions, businesses and investors that
42 must act on climate change.

43 Details of the Paris Agreement, evaluation of the Kyoto Protocol, and other key multilateral
44 developments since AR5 relevant to climate mitigation including the CORSIA aviation agreement
45 adopted under ICAO, the IMO shipping strategy, and the Kigali Amendment to the Montreal Protocol
46 on HFCs, are discussed in Chapter 14.

1 **SDGs.** In September 2015, the UN endorsed a universal agenda – ‘Transforming our World: the 2030
2 Agenda for Sustainable Development’. The agenda adopted 17 non-legally-binding SDGs and 169
3 targets to support people, peace, prosperity, partnerships and the planet. While climate change is
4 explicitly listed as SDG13, the pursuit of the implementation of the UNFCCC is relevant for a number
5 of other goals including SDG 7 (clean energy for all), 9 (sustainable industry), and 11 (sustainable
6 cities), 12 (responsible consumption and production) as well as those relating to life below water (14)
7 and on land (15) (Biermann et al. 2017). Mitigation actions could have multiple synergies and trade-
8 offs across the SDGs (Chapter 17; Pradhan et al. 2017) and their net effects depend on the pace and
9 magnitude of changes, the specific mitigation choices and the management of the transition. This
10 suggests that mitigation must be pursued in the broader context of sustainable development as explained
11 in Section 1.6

12 **Finance.** The Paris Agreement’s finance goal (above) reflects a broadened focus, beyond the costs of
13 climate adaptation and mitigation, to recognising that a structural shift towards low carbon climate-
14 resilient development pathways requires large scale investments that engage the wider financial system
15 (15.1 and 15.2.4). The SR1.5C report estimated that 1.5°C pathways would require *increased investment*
16 of 0.5-1% of global GDP between now and 2050, which is up to 2.5% of global savings / investment
17 over the period. For low- and middle-income countries, SDG-compatible infrastructure investments in
18 the most relevant sectors are estimated to be around 4-5% of their GDP, and ‘infrastructure investment
19 paths compatible with full decarbonisation in the second half of the century need not cost more than
20 more-polluting alternatives’ (Rozenberg and Fay 2019).

21 The parallel 2015 UN Addis Ababa Conference on Finance for Development, and its resulting Action
22 Agenda, aims to ‘address the challenge of financing ... to end poverty and hunger, and to achieve
23 sustainable development in its three dimensions through promoting inclusive economic growth,
24 protecting the environment, and promoting social inclusion.’ The Conference recognises the significant
25 potential of regional co-operation and provides a forum for discussing the solutions to common
26 challenges faced by developing countries (15.6.4).

27 Alongside this, private and blended climate finance is increasing but is still short of projected
28 requirements consistent with Paris Agreement goals (15.3.2.1). The financing gap is particularly acute
29 for adaptation projects, especially in vulnerable developing countries. From a macro-regulatory
30 perspective, there is growing recognition that substantial financial value may be at risk from changing
31 regulation and technology in a low-carbon transition, with potential implications for global financial
32 stability (15.6.3). To date, the most significant governance development is the Financial Stability
33 Board’s Task Force on Climate-related Financial Disclosure (TCFD) and its recommendations that
34 investors and companies consider climate change risks in their strategies and capital allocation, so
35 investors can make informed decisions (TCFD 2018), welcomed by over 500 financial institutions and
36 companies as signatories, albeit with patchy implementation (1.4. 4; 15.6.3).

37 **Talanoa Dialogue and Just Transition.** As mandated at Paris COP21 and launched at COP23, the
38 ‘Talanoa Dialogue’ (UNFCCC 2018a) emphasised holistic approaches across multiple economic
39 sectors for climate change mitigation. At COP24 also, the Just Transition Silesia Declaration, focusing
40 on the need to consider social aspects in designing policies for climate change mitigation was signed
41 by 56 heads of state (UNFCCC 2018b). This underlined the importance of aiming for a ‘just transition’
42 in terms of reducing emissions, at the same time preserving livelihoods and managing economic risks
43 for countries and communities that rely heavily on emissions-intensive technologies for domestic
44 growth (Markkanen and Anger-Kraavi 2019), and for maintaining ecosystem integrity through nature-
45 based solutions.

1 1.3.2 Global and regional emissions

2 Global GHG emissions have continued to rise since AR5, though the average rate of emissions growth
3 slowed, from 2.4% (from 2000-2010) to 1.3% for 2010-2019 (Figure 1.1). After a period of
4 exceptionally rapid growth from 2000 as charted in AR5, global fossil-fuel- and industry-related (FFI)
5 CO₂ emissions almost plateaued between 2014 and 2016 (while the global economy continued to
6 expand (World Bank 2020), but increased again over 2017-19, the average annual growth rate for all
7 GHGs since 2014 being around 0.8% yr⁻¹ (IPCC/EDGAR emissions database). Important driving
8 factors include population and GDP growth, as illustrated in panels (b) and (c) respectively. The pause
9 in emissions growth reflected interplay of strong energy efficiency improvements and low-carbon
10 technology deployment, but these did not expand fast enough to offset the continued pressures for
11 overall growth at global level (UNEP 2018a; IEA 2019a). However, since 2013/14, the decline in global
12 emissions intensity (GHG/GDP) has accelerated somewhat, and global emissions growth has averaged
13 slightly slower than population growth (Figure 1.1d), which if sustained would imply a peak of global
14 CO₂ (GHG) emissions per-capita, at about 5tCO₂/person (/7tCO₂e/person) respectively.

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

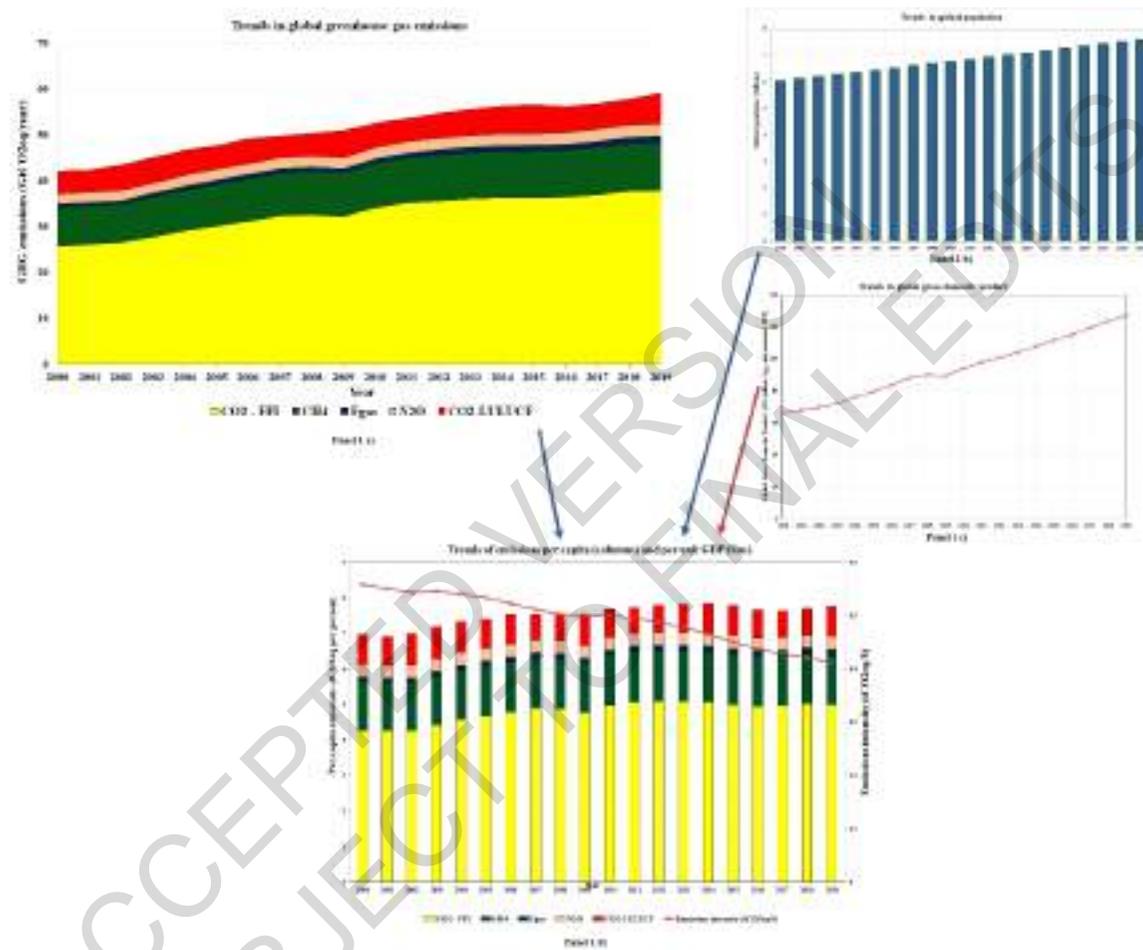

Figure 1.1: Global emission trends since 2000 by groups of gases: absolute, per-capita, and intensity

Note: Shows CO₂ from fossil fuel combustion and industrial processes (FFI); CO₂ from Agriculture, Forestry and Other Land use (AFOLU); methane (CH₄); nitrous oxide (N₂O); fluorinated gases (F-gases). Gases reported in Gt CO₂eq converted based on AR6 global warming potentials with 100-year time horizon (GWP-100).

1
2
3
4

1 Due to its much shorter lifetime, methane has disproportionate impact on near-term temperature, and is
2 estimated to account for almost a third of the warming observed to date (AR6 WG1 SPM; WG-III Chapter
3 2, Figure 2.4). Methane reductions could be particularly important in relation to near- and medium-term
4 temperatures, including through counteracting the impact of reducing short-lived aerosol pollutants which
5 have an average cooling effect.²

6 The land-use component of CO₂ emissions has different drivers and particularly large uncertainties (Chapter
7 2, Figures 2.2, 2.5), hence is shown separately. Also, compared to AR5, new evidence showed that the
8 AFOLU CO₂ estimates by the global models assessed in this report are not necessarily comparable with
9 national GHG inventories, due to different approaches to estimate the 'anthropogenic' CO₂ sink. Possible
10 ways to reconcile these discrepancies are discussed in Chapter 7.

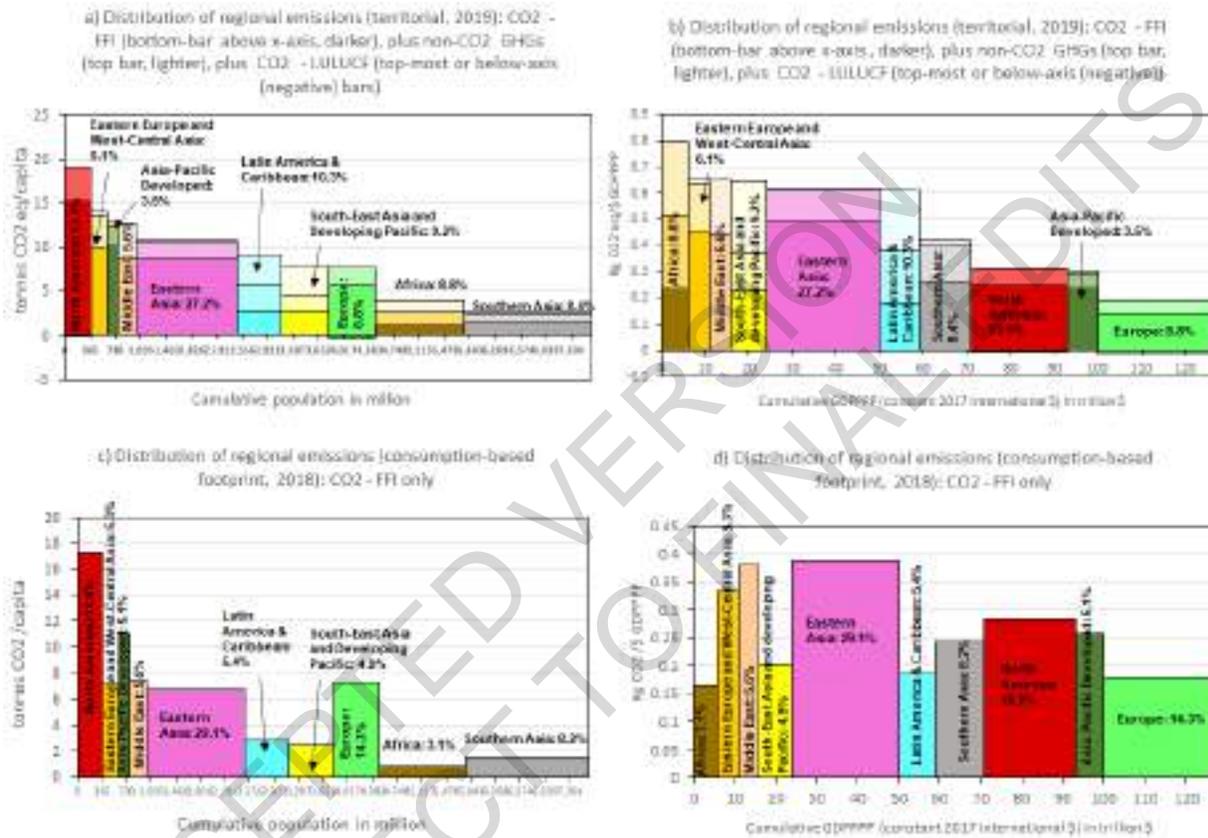

11 Regional trends have varied. Emissions from most countries continued to grow, but in absolute terms, 32
12 countries reduced energy-and-industry-CO₂ emissions for at least a decade, and 24 reduced overall GHG
13 (CO₂-eq) emissions over the same period, but only half of them by more than 10% over the period in each
14 case (Chapter 2).³ In total, developed country emissions barely changed from 2010, whilst those from the
15 rest of the world grew.

16 Figure 1.2 shows the distribution of regional CO₂ (GHG emissions) (a) per capita and (b) per GDP based
17 on purchasing power parity (GDP_{PPP}) of different country groupings in 2019. Plotted against population and
18 GDP respectively, the area of each block is proportional to the region's emissions. Compared to the
19 equivalent presentations in 2004 (AR4, SPM.3) and 2010 (AR5, Figure 1.8), East Asia now forms
20 substantially the biggest group, whilst at about 8/(10tCO₂eq) per person, its emissions per-capita remain
21 about half that of north America. In contrast, a third of the world's population, in southern Asia and Africa,
22 emit on average under 2 (2.5tCO₂eq) per person, little more than in the previous Assessments. Particularly
23 for these regions there continue to be substantial differences in the GDP, life expectancy and other measures
24 of wellbeing (see Figure 1.6).

FOOTNOTE² Indeed, cooling effects of anthropogenic aerosols (organic carbon, black carbon, sulphates, nitrates), which are also important components of local air pollution (Myhre et al. 2013; WGI SPM D1.7) may in global average be of similar magnitude to warming from methane at present. Mitigation which reduces such aerosol masking could thereby increase global temperatures, and reducing methane emissions would offset this much more rapidly than reducing CO₂ because of its relatively short lifetime, with the combined effects which could counterbalance each other (WGI SPM D1.7). Methane is thus particularly important in determining whether or when 1.5C is reached for example.

FOOTNOTE 3 With some exclusions for countries which were very small or undergoing economic collapse: Energy-and Industry-CO₂ emissions in 2018 were below 2010 levels in 32 developed countries, but only in 24 when including other GHGs. Reductions were by less than 10% in half these countries. Data from Chapter 2: see (2.2.3) and Figure 2.11 for panel of countries that have sustained territorial emission reductions longer than 10 years, as analysed in Lamb et al. (2021), and decomposition analysis of national trends in Xia et al. (2021). The previously rising trend of 'outsourced/embodyed emissions' associated with goods imported into developed countries peaked in 2006, but detailed data on this are only available EEI-CO₂, to 2018 (Section 2.3 in Chapter 2). See Chapter 3 for reduction rates associated with 1.5 and 2°C.

- 1 *Emissions per unit GDP* are much less diverse than per-capita, and have also converged significantly.
- 2 Poorer countries tend to show higher energy/ emissions per unit GDP partly because of higher reliance on
- 3 basic industries, and this remains the case, though in general their energy/GDP has declined faster.
- 4 Many developed country regions are net importers of energy-intensive goods, and emissions are affected
- 5 by the accounting of such ‘embodied emissions’. Panels (c) and (d) show results (only available for CO₂,
- 6 to 2018) on the basis of consumption-footprints which include emissions embodied in traded goods. This
- 7 makes modest changes to the relative position of different regions (for further discussion see Chapter 2).

8

 20 **Emissions from international aviation and shipping (2.4% of the total GHG emissions) are not included.**

1 While extreme poverty has fallen in more than half of the world’s economies in recent years, nearly one-
2 fifth of countries faced poverty rates above 30% in 2015 (below USD1.90 a day), reflecting large income
3 inequality (Laborde Debuquet and Martin 2017; Rozenberg and Fay 2019). Diffenbaugh and Burke (2019)
4 find that global warming already has increased global economic inequality, even if between-country
5 inequalities have decreased over recent decade. The distributional implications between regional groups
6 of different in the ‘shared socioeconomic pathways (SSPs)’ diverge according to the scenario (Frame et al.
7 2019).

8 An important recent development has been commitments by many countries, now covering a large majority
9 of global emissions, to reach net zero CO₂ or greenhouse gas emissions (Chapter 3).⁴ Furthermore, globally,
10 net zero targets (whether CO₂ or GHG) have been adopted by about 823 cities and 101 regions (Chapter 8).

11 **1.3.3 Some Other Key Trends and Developments**

12 The **COVID-19 pandemic** profoundly impacted economy and human society, globally and within
13 countries. As detailed in Cross-Chapter Box 1, some of its impacts will be long lasting, permanent even,
14 and there are also lessons relevant to climate change. The direct impact on emissions projected for rest of
15 this decade are modest, but the necessity for economic recovery packages creates a central role for
16 government-led investment, and may change the economic fundamentals involved for some years to come.

17 The COVID-19 aftermath consequently also changes the economic context for mitigation (Sections 15.2
18 and 15.4 in Chapter 15). Many traditional forms of economic analysis (expressed as general equilibrium)
19 assume that available economic resources are fully employed, with limited scope for beneficial economic
20 ‘multiplier effects’ of government-led investment. After COVID-19 however, no country is in this state.
21 Very low interest rates amplify opportunities for large-scale investments which could bring ‘economic
22 multiplier’ benefits, especially if they help to build the industries and infrastructures for further clean
23 growth (Hepburn et al. 2020). However, the capability to mobilise low interest finance vary markedly across
24 countries and large public debts - including bringing some developing countries close to default - undermine
25 both the political appetite and feasibility of large-scale clean investments. In practice the current orientation
26 of COVID-19 recovery packages is very varied, pointing to a very mixed picture about whether or not
27 countries are exploiting this opportunity (Cross-Chapter Box 1).

28

29 **START CROSS-CHAPTER BOX 1 HERE**

30 **Cross-chapter Box 1 The COVID-19 crisis: lessons, risks and opportunities for mitigation**

31 Authors: Diana Ürge-Vorsatz (Hungary), Lilia Caiado Couto (Brazil), Felix Creutzig (Germany), Dipak
32 Dasgupta (India), Michael Grubb (United Kingdom), Kirsten Halsnaes (Denmark), Siir Kilkis (Turkey),
33 Alexandre Koberle (Brazil), Silvia Kreibiehl (Germany), Jan Minx (Germany), Peter Newman (Australia),
34 Chukwumerije Okereke (Nigeria/ United Kingdom)

35 The COVID-19 pandemic triggered the deepest global economic contraction as well as CO₂ emission
36 reductions since the Second World War (Section 2.2.2.1 in Chapter 2; AR6 WGI Box 6.1 in Chapter 6) (Le
37 Quéré et al. 2020b;). While emissions and most economies are expected to rebound in 2021-2022 (IEA
38 2021), some impacts of the pandemic (eg. aspects of economy, finance and transport-related emission

FOOTNOTE⁴ Continually updated information on net-zero commitments is available at <https://www.zerotracker.net>

1 drivers) may last far longer. COVID-19 pushed more than 100 million people back into extreme poverty,
2 and reversed progress towards some other SDGs including health, life expectancy and child literacy (UN
3 DESA 2021). Health impacts and the consequences of deep economy-wide shocks may last many years
4 even without significant future recurrence (Section 15.6.3 in Chapter 15). These changes, as well as the
5 pandemic response actions, bring both important risks as well as opportunities for accelerating mitigation
6 (Chapters 1, 5, 10 and 15).

7 **Lessons.** Important lessons can be drawn from the pandemic to climate change including the value of
8 forward-looking risk management, the role of scientific assessment, preparatory action and international
9 process and institutions (1.3, Chapter 5). There had been long-standing warnings of pandemic risks, and
10 precursors – with both pandemic and climate risks being identified by social scientists as ‘uncomfortable
11 knowledge’, or ‘unknown knowns’ which tend to be marginalised in practical policy (Rayner 2012;
12 Sarewitz 2020). This echoes long-standing climate literature on potential ‘high impact’ events, including
13 those *perceived* as low probability (Dietz 2011; Weitzman 2011). The costs of preparatory action, mainly
14 in those countries that had suffered from earlier pandemics were negligible in comparison, suggesting the
15 importance not just of knowledge but its effective communication and embodiment in society (Chapter 5).
16 (Klenert et al. 2020) offer five early lessons for climate policy, concerning: the cost of delay; the bias in
17 human judgement; the inequality of impacts; the need for multiple forms of international cooperation; and
18 finally, ‘transparency in value judgements at the science-policy interface’.

19 **Emissions and behavioural changes.** Overall, global CO₂ FFI emissions declined by about 5.8% (5.1% to
20 6.3%) from 2019 to 2020, or about 2.2 (1.8-2.4) GtCO₂ in total (Section 2.2.2 in Chapter 2). Analysis from
21 previous economic crises suggest significant rebound in emissions without policy-induced structural shifts
22 (2.2.2.1; Figure 2.5) (Jaeger et al. 2020). Initial projections suggest the COVID aftermath may reduce
23 emissions by 4-5% over 2025 - 2030 (Shan and Et.al 2020; Reilly et al. 2021), below a ‘no-pandemic’
24 baseline The long-term impacts on behaviour, technology and associated emissions remain to be seen, but
25 may be particularly significant in transport - lockdowns reduced mobility-related emissions, alongside two
26 major growth areas: electronic communications replacing many work and personal travel requirements
27 (Section 4.4.3.4 in Chapter 4 and Chapter 10); and, revitalised local active transport and e-micromobility
28 (Earley and Newman 2021). Temporary ‘clear skies’ may also have raised awareness of the potential
29 environment and health co-benefits of reduced fossil fuel use particularly in urban areas (Section 8.7 in
30 Chapter 8), with evidence also indicating that air pollution itself amplified vulnerability to COVID-19 (Wu
31 et al. 2020; Gudka et al. 2020). The significant impacts on passenger aviation are projected to extend not
32 just through behavioural changes, but also fleet changes from retiring older planes, and reduced new orders
33 indicating expectations of reduced demand and associated GHG emissions until 2030 (Section 5.1.2 in
34 Chapter 5 and Section 10.5 in Chapter 10; AR6 WGI Box 6.1 in Chapter 6). However, air cargo has
35 recovered more rapidly (IATA 2020), possibly enhanced by online ordering.

36 **Fiscal, growth and inequality impacts.** Aspects of the global and regional economic crises from COVID-
37 19 may prevail much longer than the crisis itself, potentially compromising mitigation. Most countries have
38 undertaken unprecedented levels of short-term public expenditures. The IMF projects sovereign debt to
39 GDP to have increased by 20% in advanced economies and 10% in emerging economies by the end of 2021
40 (IMF 2020). This is likely to slow economic growth, and may squeeze financial resources for mitigation
41 and relevant investments for many years to come (15.2.3, 15.6.3). COVID-19 further lowered interest rates
42 which should facilitate low carbon investment, but pandemic responses have increased sovereign debt
43 across countries in all income bands (IMF 2021), and particularly in some developing economies and
44 regions has caused debt distress (Bulow et al. 2021) widening the gap in developing countries’ access to

1 capital (Hourcade et al. 2021b) (Section 15.6.3 in Chapter 15). After decades of global progress in reducing
2 poverty, COVID-19 has pushed hundreds of millions of people below poverty thresholds and raises the
3 spectre of intersecting health and climate crises that are devastating for the most vulnerable (5.1.2 Box 5.1).
4 Like those of climate change, pandemic impacts fall heavily on disadvantaged groups, exacerbate the
5 uneven distribution of future benefits, amplify existing inequities, and introduce new ones. Increased
6 poverty also hinders efforts towards sustainable low-carbon transitions (1.6).

7 **Impacts on profitability and investment.** COVID-19-induced demand reduction in electricity
8 disproportionately affected coal power plants, whilst transport reduction most affected oil (IEA 2020a). This
9 accelerated pre-existing decline in the relative profitability of most fossil fuel industries (Ameli et al. 2021)
10 Renewables were the only energy sector to increase output (IEA 2020a). Within the context of a wider
11 *overall* reduction in energy investment this prompted a substantial *relative* shift towards low carbon
12 investment particularly by the private sector (IEA 2020b; Rosembloom and Markard 2020; 15.2.1, 15.3.1,
13 15.6.1).

14 **Post-pandemic recovery pathways provide an opportunity to attract finance into accelerated and**
15 **transformative low-carbon public investment (15.2, 15.6.3).** In most countries, COVID-19 has increased
16 unemployment and/or state-supported employment. There is a profound difference between short-term
17 ‘bail-outs’ to stem unemployment, and the orientation of new public investment. The public debt is mirrored
18 by large pools of private capital. During deep crises like that of the COVID-19, economic multipliers of
19 stimulus packages can be high (Hepburn et al., 2020), so much so that fiscal injections can then generate
20 multipliers from 1.5 to 2.5, weakening the alleged crowding-out effect of public stimulus (Auerbach and
21 Gorodnichenko 2012; Blanchard and Leigh 2013; Section 15.2.3 in Chapter 15).

22 Recovery packages are motivated by assessments that investing in can boost the macroeconomic
23 effectiveness (‘multipliers’) of public spending, crowd-in and revive private investment (Hepburn et al.
24 2020). There are clear reasons why a low-carbon response can create more enduring jobs, better aligned to
25 future growth sectors: by also crowding-in and reviving private investment (e.g. from capital markets and
26 institutional investors, including the growing profile of Environment and Social Governance (ESG) and
27 green bond markets (15.6)), this can boost the effectiveness of public spending (IMF 2020). Stern and
28 Valero (Stern and Valero 2021) argue that investment in low-carbon innovation and its diffusion,
29 complemented by investments in sustainable infrastructure, are key to shape environmentally sustainable
30 and inclusive growth in the aftermath of the COVID-19 pandemic crisis. This would be the case both for
31 high-income economies on the global innovation frontier, and to promote sustainable development in
32 poorer economies.

33 A study with a global general equilibrium model (Liu et al. 2021) finds that because the COVID-19
34 economic aftermath combines negative impacts on employment and consumption, a shift from employment
35 and consumption taxes to carbon or other resource-related taxes would enhance GDP by 1.7% in 2021
36 relative to ‘no policy’, in addition to reducing CO₂ and other pollutants. A post-Keynesian model of wider
37 ‘green recovery’ policies (Pollitt et al. 2021) finds a short-run benefit of around 3.5% GDP (compared to
38 ‘no policy’), and even c. 1% above a recovery boosted by cuts in consumption taxes, the latter benefit
39 sustained through 2030 - outperforming an equivalent conventional stimulus package while reducing global
40 CO₂ emissions by 12%.

41 **Orientation of recovery packages.** The large public spending on supporting or stimulating economies,
42 exceeding USD12tn by October 2020, dwarfs clean energy investment needs and hence could either help
43 to solve the combined crises, or result in high-carbon lock-in (Andrijevic et al. 2020). The short-term ‘bail-

1 outs' to date do not foster climate resilient long-term investments and have not been much linked to climate
2 action, (Sections 15.2.3 and 15.6.3 in Chapter 15): in the G20 countries, 40% of energy-related support
3 spending went to the fossil fuel industry compared to 37% on low-carbon energy (EPT 2020). Recovery
4 packages are also at risk of being 'colourless' (Hepburn et al., 2020) though some countries and regions
5 have prioritised green stimulus expenditures for example as part of 'Green New Deal' (Rochedo et al. 2021;
6 Section 13.9.6 in Chapter 13 and Section 15.6.3 in Chapter 15).

7 **Integrating analyses.** The response to COVID-19 also reflects the relevance of combining multiple
8 analytic frameworks spanning economic efficiency, ethics and equity, transformation dynamics, and
9 psychological and political analyses (Section 1.7). As with climate impacts, not only has the global burden
10 of disease been distributed unevenly, but capabilities to prevent and treat disease were asymmetrical and
11 those in greatest vulnerability often had the least access to human, physical, and financial resources (Ruger
12 and Horton 2020). 'Green' versus 'brown' recovery has corresponding distributional consequences
13 between these and 'green' producers, suggesting need for differentiated policies with international
14 coordination (Le Billon et al. 2021). This illustrates the role of 'just transition' approaches to global
15 responses including the value of integrated, multi-level governance (Section 1.7 in this Chapter, Section
16 4.5 in Chapter 4 and Section 17.1 in Chapter 17).

17 **Crises and opportunities: the wider context for mitigation and transformation.** The impacts of
18 COVID-19 have been devastating in many ways, in many countries, and may distract political and financial
19 capacity away from efforts to mitigate climate change. Yet, studies of previous post-shock periods suggest
20 that waves of innovation that are ready to emerge can be accelerated by crises, which may prompt new
21 behaviours, weaken incumbent ('meso-level') systems, and prompt rapid reforms (Section 1.6.5; Roberts
22 and Geels 2019a). Lessons from the collective effort to 'flatten the curve' during the pandemic, illustrating
23 aspects of science-society interactions for public health in many countries, may carry over to climate
24 mitigation, and open new opportunities (Section 5.1.2 in Chapter 5). COVID-19 appears to have accelerated
25 the emergence of renewable power, electromobility and digitalisation (Newman 2020; Section 5.1.2 in
26 Chapter 5, Section 6.3 in Chapter 6, Section 10.2 in Chapter 10). Institutional change is often very slow but
27 major economic dislocation can create significant opportunities for new ways of financing and enabling
28 'leapfrogging' investment to happen (Section 10.8 in Chapter 10). Given the unambiguous risks of climate
29 change, and consequent stranded asset risks from new fossil fuel investments (Box 6.11), the most robust
30 recoveries are likely to be those which emerge on lower carbon and resilient pathways (Oberghassel et al.
31 2020). Noting the critical global post-COVID-19 challenge as the double-impact of heightened credit risk
32 in developing countries, along with indebtedness in developed countries, (Hourcade et al. 2021a) estimate
33 that a 'multilateral' sovereign guarantee structure to underwrite low carbon investments could leverage
34 projects up to 15 times its value, contributing to shifting development pathways consistent with the SDGs
35 and Paris goals.

36 COVID-19 can thus be taken as a reminder of the urgency of addressing climate change, a warning of the
37 risk of future stranded assets (Rempel and Gupta 2021; and Chapter 17), but also an opportunity for a
38 cleaner recovery.

39 **END CROSS-CHAPTER BOX 1 HERE**

40
41 In addition to developments in climate science, emissions, the international agreements in 2015, and the
42 recent impact of COVID-19, a few other key developments have strong implications for climate mitigation.

1 ***Cheaper Renewable Energy Technologies:*** Most striking, the cost of solar PV has fallen by a factor of 5-
2 10 in the decade since the IPCC *Special Report on Renewable Energy* (IPCC 2011a) and other data inputting
3 to the AR5 assessments, The SR1.5 reported major cost reductions, the IEA (2020) *World Energy Outlook*
4 described PV as now ‘the cheapest electricity in history’ for projects that ‘tap low cost finance and high
5 quality resources.’ Costs and deployment both vary widely between different countries (chapter 6, 9, 12)
6 but costs are still projected to continue falling (Vartiainen et al. 2020). Rapid technological developments
7 have occurred in many other low-carbon technologies including batteries and electric vehicles (see 1.4.3),
8 IT and related control systems, with progress also where electrification is not possible (Chapters 2, 6, 11)

9 ***Civil society pressures for stronger action.*** Civic engagement increased leading up to the Paris Agreement
10 (Bäckstrand and Lövbrand 2019) and after. Youth movements in several countries show young people’s
11 awareness about climate change, evidenced by the school strikes for the climate (Hagedorn et al. 2019;
12 Buettner 2020; Walker 2020; Thackeray et al. 2020). Senior figures across many religions (Francis 2015;
13 IFEES 2015) stressed the duty of humanity to protect future generations and the natural world, and warned
14 about the inequities of climate change. Growing awareness of local environmental problems such as air
15 pollution in Asia and Africa (Karlsson et al. 2020), and the threat to indigenous people rights and existence
16 has also fuelled climate activism (Etchart 2017). Grass-root movements (Cheon and Urpelainen 2018;
17 Fisher et al. 2019), build political pressure for accelerating climate change mitigation, as does increasing
18 climate litigation (Setzer and Vanhala 2019; Chapters 13 and 14).

19 ***Climate policies also encounter resistance.*** However there are multiple sources of resistance to climate
20 action in practice. Corporations and trade associations often lobby against measures they deem detrimental
21 (Section 1.4.6). The emblematic ‘yellow vest’ movement in France was triggered by higher fuel cost as a
22 result of CO₂ tax hike (Lianos 2019; Driscoll 2021), though it had broader aspect of income inequality and
23 other social issues. There is often mismatch between concerns on climate change and people’s willingness
24 to pay for mitigation. For example, whilst most Americans believe climate change is happening, 68% said
25 in a survey they would oppose climate policies that added just USD10/month to electricity bills (EPIC et
26 al. 2019), and worry about energy costs can eclipse those about climate change elsewhere (Poortinga et al.
27 2018; Chapter 13).

28 ***Global trends contrary to multilateral cooperation.*** State-centred politics and geopolitical/geo-economic
29 tensions seem to have become more prominent across many countries and issues (WEF 2019). In some
30 cases, multilateral cooperation could be threatened by trends such as rising populism, nationalism,
31 authoritarianism and growing protectionism (Abrahamsen et al. 2019), making it more difficult to tackle
32 global challenges including protecting the environment (Schreurs 2016; Parker et al. 2017; WEF 2019).

33 ***Transnational alliances.*** Partly countering this trend, cities, businesses, a wide range of other non-state
34 actors also have emerged with important international networks to foster mitigation. City-based examples
35 include the Cities Alliance in addressing climate change, Carbon Neutral Cities Alliance, the Covenant of
36 Mayors (chapter 8); there are numerous other alliances and networks such as those in finance (chapter 15),
37 technology (chapter 16), amongst many others (chapters 13, 14).

38 Finally, under the Paris Agreement process, during 2020/21, many countries strengthened their Nationally
39 Determined Contributions (NDCs). Including updates until October 2021, these would imply global GHG
40 emissions declining by 2030 to between 1-4% below 2019 levels (unconditional NDCs), or 4-10% (for
41 NDCs conditional on international support), See Table 4.3 in Chapter 4).This is a significant change but
42 would still not be compatible with 1.5°C pathways, and even if delivered in full, to *likely* stay below 2°C,
43 emissions would have to fall very rapidly after 2030 (Section 3.2.5).

1 Thus, developments since AR5 highlight the complexity of the mitigation challenge. There is no far-sighted,
2 globally optimising decision-maker and indeed climate policymaking at all levels is subject to conflicting
3 pressures in multiple ways. The next section overviews the drivers and constraints.

4 5 **1.4 Drivers and Constraints of Climate Mitigation and System** 6 **Transitions/Transformation**

7 This section provides brief assessment of key factors and dynamics that drive, shape and or limit climate
8 mitigation in (i) *Economic factors*: which include sectors and services; trade and leakage; finance and
9 investment; and technological innovation; (ii) *Socio-political issues*; which include political economy;
10 social innovation and equity and fairness; and (iii) *Institutional factors*, which comprise policy, legal
11 frameworks and international co-operation.

12 AR 5 introduced six “enabling conditions” for shifting development pathways which are presented in
13 Chapter 4 of this report and some of which overlap with the drivers reviewed here. However, the
14 terminology of drivers and constraints have been chosen here to reflect the fact that each of these factors
15 can serve as an enabling condition or a constraint to ambitious climate action depending on the context and
16 how they are deployed. Often one sees the factors exerting both push and pull forces at the same time in
17 the same and across different scales. For example, finance and investments can serve as a barrier or an
18 enabler to climate action (Battiston et al. 2021). Similarly, political economy factors can align in favour of
19 ambitious climate action or act in ways that inhibit strong co-operation and low carbon transition. The other
20 key insight from the assessment of the system drivers and constraints undertaken below is that none of the
21 factors or conditions by themselves is more or less important than the others. In addition to being deeply
22 intertwined all the factors matter in different measures with each exacting more or less force depending on
23 prevailing social, economic, cultural and political context. Often achieving accelerated mitigation would
24 require effort to bring several of the factors in alignment in and across multiple levels of political or
25 governance scales.

26 **1.4.1 Services, sectors and urbanisation**

27 Human activities drive emissions primarily through the demand for a wide range of services such as food,
28 shelter, heating/cooling, goods, travel, communication, and entertainment. This demand is fulfilled by
29 various activities often grouped into sectors such as agriculture, industry and commerce. The literature
30 uses a wide range of sectoral definitions to organize data and analysis (Chapter 2). Energy sectors are
31 typically organised into primary energy producers, energy transformation processes (such as power
32 generation, fuel refining), and major energy users such as buildings, industry, transport (Chapters 2, 5).
33 Other research (Chapter 8) organizes data around interacting urban and rural human activities. Land-based
34 activities can be organized into agriculture, forestry, and other land use (AFOLU), or land use, land use
35 change and forestry (LULUCF) (Chapter 7). Each set of sectoral definitions and analysis offers its own
36 insights.

37 Sectoral perspectives help to identify and understand the drivers of emissions, opportunities for emissions
38 mitigation, and interactions with resources, other goals and other sectors, including the co-evolution of
39 systems across scales (Moss et al. 2016; Kyle et al. 2016; Mori et al. 2017; IPBES 2019). Interactions
40 between sectors and agents pursuing multiple goals is a major theme pervading this assessment.

1 The ‘nexus’ between energy, water, and land – all key contributors to human well-being – also helps to
2 provide, regulate and support ecosystem and cultural services (Bazilian et al. 2011; Ringler et al. 2013;
3 Smajgl et al. 2016; Albrecht et al. 2018; D’Odorico et al. 2018; Brouwer et al. 2018; Van Vuuren et al.
4 2019), with important implications for cities in managing new systems of transformation (Chapter 8;
5 Thornbush et al. 2013; Wolfram et al. 2016) . Other important nexus’ shaping our planet’s future (Fajardy
6 et al. 2018) include agriculture, forestry, land use and ecosystem services (Chazdon 2008; Keesstra et al.
7 2018; Nesshöver et al. 2017; Torralba et al. 2016; Settele et al. 2016).

8 Historically, energy-related GHG emissions were considered a by-product of the increasing scale of human
9 activity, driven by population size, economic activity and technology. That simple notion has evolved
10 greatly over time to become much more complex and diverse, with increasing focus on the provision of
11 energy services (Garrett et al. 2020; Bardi et al. 2019; Cullen and Allwood 2010; Brockway et al. 2019))
12 The demand for agricultural products has historically driven conversion of natural lands (land use change).
13 AFOLU along with food processing account for 21-37% of total net anthropogenic GHG emissions
14 (SRCCL SPM A3).⁵

15 Continued growth in population and income are expected to continue driving up demand for goods and
16 services (Chapters 2, 3 & 5), with an important role for urbanisation which is proceeding at an
17 unprecedented speed and scale. In the last decade, the urban population grew by 70 million people each
18 year, or about 1.3 million people per week, with urban area expanding by about 102 km² per day (Chapter
19 8). Urban areas account for most (45-87%) of the global carbon footprint (8.1) and the strong and positive
20 correlation between urbanisation and incomes means higher consumption from urban lifestyles will
21 continue driving direct and indirect GHG emissions. Cities provide conduit to many of the services such as
22 transportation, housing, water, food, medical care, recreation and other services and urban carbon emissions
23 are driven not only by population and income but also by form and structure of urban areas (8.1, 8.3, 8.4,
24 8.5, 8.6). This creates opportunities for decarbonization through urban planning and purposeful
25 “experimentation” (Newman et al. 2017 Chapter 8).

26 Human needs and wants evolve over time making the transition toward climate and sustainable
27 development goals either more or less difficult. For example, changes in the composition of goods
28 consumed, such as, shifting diets toward a more vegetarian balance, can reduce land-use emissions without
29 compromising the quality of life (Stehfest et al. 2009; van Vuuren et al. 2018; van den Berg et al. 2019;
30 Hargreaves et al. 2021; Gough 2017; SRCCL SPM B2.3).

31 Human behavior and choices, including joint achievement of wider social goals, will play an important part
32 in enabling or hindering climate mitigation and sustainable development (Shi et al. 2016), for example
33 shifting passenger transportation preferences in ways that combine climate, health and sustainable
34 development goals (Romanello et al. 2021).

35 **1.4.2 Trade, consumption and leakage**

36 Emissions associated with international trade account for 20-33 % of global emissions, as calculated using
37 multi-regional input-output analysis (Wiedmann and Lenzen 2018). Whether international trade drives
38 increase or decrease in global GHG emissions depends on emissions intensity of traded products as well as
39 the influence of trade on relocation of production, with studies reaching diverse conclusions about the net
40 effect of trade openness on CO₂ emissions (Section 2.4.5). Tariff reduction of low carbon technologies

FOOTNOTE⁵ AFOLU accounted for about 13% of CO₂, 44% of CH₄ and 82% of N₂O global anthropogenic GHG emissions in 2007-2016 (SRCCL SPM A3).

1 could facilitate effective mitigation (de Melo and Vijil 2014; WTO 2016; Ertugrul et al. 2016; Islam et al.
2 2016).

3 The magnitude of carbon leakage (Annex I) caused by unilateral mitigation in a fragmented climate policy
4 world depends on trade and substitution patterns of fossil fuels and the design of policies (see Box 5.4.
5 AR5), but its potential significance in trade-exposed energy-intensive sectors (Naegele and Zaklan 2019;
6 Carbone and Rivers 2017; Bauer et al. 2013) can make it an important constraint on policy. See Section
7 13.6.6.1 in Chapter 13 for channels and evidence. Akimoto et al. (2018) argue that differences in marginal
8 abatement cost of NDCs could cause carbon leakage in energy-intensive, trade-exposed sectors, and could
9 weaken effective global mitigation.

10 Policy responses to cope with carbon leakage include border carbon adjustment (BCAs) and differentiated
11 carbon taxes (Liu et al. 2020). Some BCA options focusing on levelling the cost of carbon paid by
12 consumers on products could be designed in line with WTO (Ismer et al. 2016) while others may not be
13 (Mehling et al. 2019). All proposals could involve difficulty of tracing and verifying the carbon content of
14 inputs (Onder 2012; Denis-Ryan et al. 2016). An international consensus and certification practice on the
15 carbon content would help to overcome WTO compatibility (Holzer 2014). See chapter 13, and (Mehling
16 et al. 2019) on context of trade law and the PA.

17 Official inventories report territorial emissions, which do not consider the impacts embodied in imports of
18 goods. Global supply chains undoubtedly lead to a growth in trade volumes (Federico and Tena-Junguito
19 2017), alternative methods have been suggested to account for emissions associated with international trade,
20 such as shared responsibility (Lenzen et al. 2007), technology adjusted consumption based accounting
21 (Kander et al. 2015), value added-based responsibility (Piñero et al. 2019) and exergy-based responsibility
22 based on thermodynamics (Khajehpour et al. 2019). Consumption-based emissions (i.e. attribution of
23 emissions related to domestic consumption and imports to final destination) are not officially reported in
24 global emissions datasets but data has improved (Afionis et al. 2017; Tukker and Dietzenbacher 2013). This
25 analysis have been used extensively for consumption-based accounting of emissions, and other
26 environmental impacts (Malik et al. 2019; Wiedmann and Lenzen 2018). chapter 2.3).

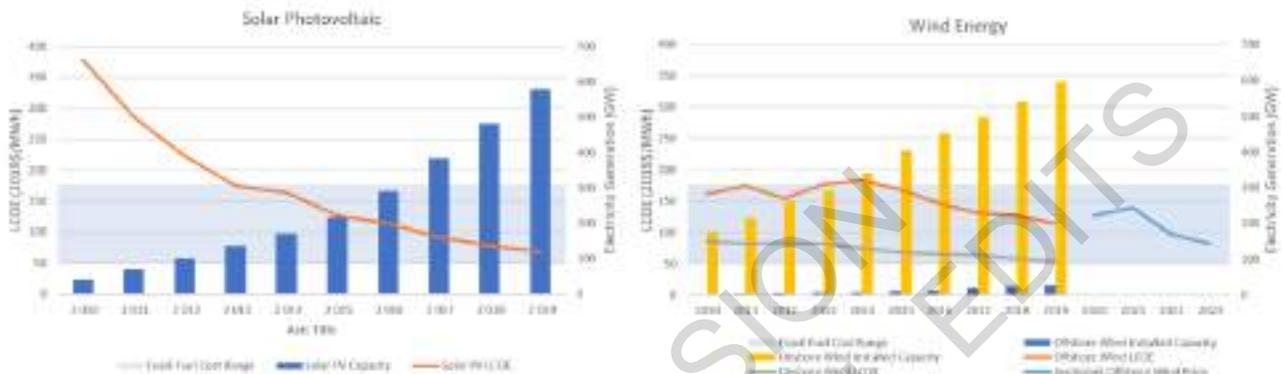

27 Increasing international trade has resulted in a general shifting of fossil-fuel driven emissions-intensive
28 production from developed to developing countries (Arto and Dietzenbacher 2014; Malik and Lan 2016),
29 and between developing countries (Zhang et al. 2019). High-income developed countries thus tend to be
30 net importers of emissions, whereas low/middle income developing countries net-exporters (Peters et al.
31 2011; Figure 1.2c, d). This trend is shifting, with a growth in trade between non-OECD countries (Meng et
32 al. 2018; Zhang et al. 2019), and a decline in emissions intensity of traded goods (Wood et al. 2020b).

33 The Paris Agreement primarily deals with national commitments relating to domestic emissions and
34 removals, hence emissions from international aviation and shipping are not covered. Aviation and shipping
35 accounted for approximately 2.7% of greenhouse gas emissions in 2019 (before COVID-19); see Chapter
36 10.5.2 for discussion. In addition to CO₂ emissions, aircraft-produced contrail cirrus clouds and emissions
37 of black carbon and short-lived aerosols (e.g. sulphates) from shipping are especially harmful for the Arctic
38 (10.8, Box 10.6).

39 **1.4.3 Technology**

40 The rapid developments in technology over the past decade enhance potential for transformative changes,
41 in particular to help deliver climate goals simultaneously with other SDGs.

1 The fall in renewable energy costs alongside rapid growth in capacity (Figure 1.3; Figure X in Chapter 2)
 2 has been accompanied by varied progress in many other technology areas such electric vehicles, fuel cells
 3 for both stationary and mobile applications (Dodds 2019), thermal energy (chapter 6) and battery and other
 4 storage technologies (Chapters 6, 9, 12; Freeman et al. 2017). Nuclear contributions may be enhanced by
 5 new generations of reactors, e.g., Generation III, and small modular reactors (Knapp and Pevec 2018; see
 6 also Chapter 6).
 7

8
 9 **Figure 1.2: Cost reductions and adoption in solar PV and wind energy**

10 Source: (IRENA 2020a,b), with fossil fuel LCOE indicated as shaded blue at USD 50-177/MWh (IRENA 2020b)

11 Large-scale hydrogen developments could provide a complementary energy channel with long-term
 12 storage. Like electricity, hydrogen (H₂) is an energy vector with multiple potential applications, including
 13 in industrial processes such as steel and non-metallic materials production (Chapter 11), for long-range
 14 transportation (Chapter 10), and low-temperature heating in buildings (Chapter 9). Emissions depend on
 15 how it is produced, and deploying H₂ delivery infrastructure economically is a challenge when the future
 16 scale of hydrogen demand is so uncertain (Chapter 6). H₂ from natural gas with CO₂ capture and storage
 17 (CCS) may help to kick-start the H₂ economy (Sunny et al. 2020).

18 CO₂-based fuels and feedstocks such as synthetic methane, methanol, diesel, jet fuel and other
 19 hydrocarbons, potentially from carbon capture and utilisation (CCU), represent drop-in solutions with
 20 limited new infrastructure needs (Artz et al. 2018; Bobeck et al. 2019; Yugo and Soler 2019); Chapter 10.
 21 Deployment and development of CCS technologies (with large-scale storage of captured CO₂) have been
 22 much slower than projected in previous Assessments (Page et al. 2019; IEA 2019b; see also Chapter 11).

23 Potential constraints on new energy technologies may include their material requirements, notably rare
 24 earth materials for electronics or lithium for batteries (Wanger 2011; Flexer et al. 2018), stressing the
 25 importance of recycling (Rosendahl and Rubiano 2019; IPCC 2011b). Innovation is enabling greater
 26 recycling and re-use of energy-intensive materials (Shemi et al. 2018) and introducing radically new and
 27 more environmentally friendly materials, however, still not all materials can be recycled (Allwood 2014).

28 By sequestering carbon in biomass and soils, soil carbon management, and other terrestrial strategies could
 29 offset hard-to-reduce emissions in other sectors. However, large-scale bioenergy deployment could increase
 30 risks of desertification, land degradation, and food insecurity (IPCC 2019a), and higher water withdrawals
 31 (Hasegawa et al. 2018; Fuhrman et al. 2020), though this may be at least partially offset by innovation in
 32 agriculture, diet shifts and plant-based proteins contributing to meeting demand for food, feed, fibre and,
 33 bioenergy (or BECCS with CCS) (Chapters 5, 7; Köberle et al. 2020; Havlik et al. 2014; Popp et al. 2017).

1 A broad class of more speculative technologies propose to counteract effects of climate change by removing
2 CO₂ from the atmosphere (CDR), or directly modify the Earth's energy balance at a large scale (SRM).
3 CDR technologies include ocean iron fertilisation, enhanced weathering and ocean alkalisation (Council
4 2015a), along with Direct Air Capture with Carbon Storage (DACCS). They could potentially draw down
5 atmospheric CO₂ much faster than the Earth's natural carbon cycle, and reduce reliance on biomass-based
6 removal (Realmonte et al. 2019; Köberle 2019), but some present novel risks to the environment and
7 DACCS is currently more expensive than most other forms of mitigation (Fuss et al. 2018; Cross-chapter
8 box 8 in Chapter 12). Solar radiation modification (SRM) could potentially cool the planet rapidly at low
9 estimated direct costs by reflecting incoming sunlight (Council 2015b), but entails uncertain side effects
10 and thorny international equity and governance challenges (Netra et al. 2018; Florin et al. 2020; National
11 Academies of Sciences 2021) (Chapter 14). Understanding the climate response to SRM remains subject
12 to large uncertainties (AR6 WG1). Some literature uses the term “geoengineering” for both CDR or SRM
13 when applied at a planetary scale (Shepherd 2009; GESAMP 2019). In this report, CDR and SRM are
14 discussed separately reflecting their very different geophysical characteristics.

15 Large improvements in information storage, processing, and communication technologies, including
16 artificial intelligence, will affect emissions. They can enhance energy-efficient control, reduce transaction
17 cost for energy production and distribution, improve demand-side management (Raza and Khosravi 2015),
18 and reduce the need for physical transport (Smidfelt Rosqvist and Winslott Hiselius 2016; see Chapters 5,
19 6, 9-11). However, data centres and related IT systems (including blockchain), are electricity-intensive and
20 will raise demand for energy (Avgerinou et al. 2017) - cryptocurrencies may be a major global source of
21 CO₂ if the electricity production is not decarbonised (Mora et al. 2018) – and there is also a concern that
22 information technologies can compound and exacerbate current inequalities (Chapter 16; Box 2). IT may
23 affect broader patterns of work and leisure (Boppart and Krusell 2020), and the emissions intensity of how
24 people spend their leisure time will become more important (see Chapters 5, 9). Because higher efficiency
25 tends to reduce costs, it often involves some ‘rebound’ offsetting at least some of the emission savings
26 (Belkhir and Elmehri 2018; Sudbury and Hutchinson 2016; Cohen and Cavoli 2019).

27 Technology can enable both emissions reductions and/or increased emissions (Chapter 16). Governments
28 play an important role in most major innovations, in both ‘technology-push’ (Mazzucato 2013) and induced
29 by ‘demand-pull’ (Grubb et al. 2021a), so policy is important in determining its pace, direction, and
30 utilisation (Roberts and Geels 2019a; Sections 1.7.1, 1.7.3). Overall, the challenge will be to enhance the
31 synergies and minimise the trade-offs and rebounds, including taking account of ethical and distributional
32 dimensions (Gonella et al. 2019).

33 **1.4.4 Finance and investment**

34 Finance is both an enabler and constraint on mitigation, and since AR5, attention to the financial sector's
35 role in mitigation has grown. This is partly in the context of the Paris Agreement finance articles and Green
36 Climate Fund, the pledge to mobilise USD100bn/yr by 2020, and the Addis Abbaba Action Agenda
37 (Section 1.3.1). However there is a persistent but uncertain gap in mitigation finance (Cui and Huang
38 2018); (Table 15.15.1), even though tracked climate finance overwhelmingly goes toward mitigation
39 compared to adaptation (UNEP 2020; 15.3; Working Group II). Green bond issuance has increased recently
40 in parallel with efforts to reform the international financial system by supporting development of local
41 capital markets (15.6.4).

42 Climate finance is a multi-actor, multi-objective domain that includes central banks, commercial banks,
43 asset managers, underwriters, development banks, and corporate planners. Climate change presents both

1 risks and opportunities for the financial sector. The risks include physical risks related to the impacts of
2 climate change itself; transition risks related to the exposure to policy, technology and behavioural changes
3 in line with a low-carbon transition; and liability risks from litigation for climate-related damages (Box
4 15.2). These could potentially lead to stranded assets (the loss of economic value of existing assets before
5 the end of their useful lifetimes (Bos and Gupta 2019; Section 6.7 in Chapter 6, Section 15.6.3 in Chapter
6 15). Such risks continue to be underestimated by financial institutions (Section 15.6.1 in Chapter 15). The
7 continuing expansion of fossil fuel infrastructure and insufficient transparency on how these are valued
8 raises concerns that systemic risk may be accumulating in the financial sector in relation to a potential low-
9 carbon transition that may already be under way (Battiston et al. 2017; Section 15.6.3 in Chapter 15). The
10 Financial Stability Board’s TCFD recommendations on transparency aim to ensure that investors and
11 companies consider climate change risks in their strategies and capital allocation (TCFD 2018). This is
12 helping “investors to reassess core assumptions” and may lead to “significant” capital reallocation (Fink
13 2020). However, metrics and indicators of assets risk exposure are inadequate (Campiglio et al. 2018;
14 Monasterolo 2017) and transparency alone is insufficient to drive the required asset reallocation in the
15 absence of clear regulatory frameworks (Chenet et al. 2021; Ameli et al. 2020). A coalition of Central Banks
16 have formed the Network for Greening the Financial Sector, to support and advance the transformation of
17 the financial system (Allen et al. 2020; NGFS 2020), with some of them conducting Climate-related
18 institutional stress tests

19 Governments cannot singlehandedly fund the transition (Section 15.6.7 in Chapter 15), least of all in low-
20 income developing countries with large sovereign debt and poor access to global financial markets. Long-
21 term sources of private capital are required to close the financing gap across sectors and geographies
22 (Section 15.6.7 in Chapter 15). Future investment needs are greatest in emerging and developing economies
23 (Section 15.5.2 In Chapter 15) which already face higher cost of capital, hindering capacity to finance a
24 transition (Buhr et al. 2018; Ameli et al. 2020). Requisite North-South financial flows are impeded by both
25 geographic and technological risk premiums (Iyer et al. 2015), and the Covid-19 pandemic has further
26 compromised the ability of developing and emerging economies to finance development activities or attract
27 additional climate finance from developed countries (Cross-Chapter Box 1 in this chapter; Section 15.6.3
28 in Chapter 15). Climate-related investments in developing countries also suffer from structural barriers
29 such as sovereign risk and exchange rate volatility (Farooquee and Shrimali 2016; Guzman et al. 2018)
30 which affect not only climate-related investment but investment in general (Yamahaki et al. 2020) including
31 in needed infrastructure development (Gray and Irwin 2003). A GCF report notes the paradox that USD14
32 trillion of negative-yielding debt in OECD countries might be expected to flow to much larger low-carbon,
33 climate-resilient investment opportunities in developing countries, but “this is not happening” (Hourcade
34 et al. 2021b).

35 There is often a disconnect between stated national climate ambition and finance flows, and overseas direct
36 investment (ODI) from donor countries may be at odds with national climate pledges such as NDCs. One
37 report found funds supported by foreign State-Owned Enterprises into 56 recipient countries in Asia and
38 Africa in 2014-2017 went mostly to fossil fuel-based projects not strongly aligned with low-carbon
39 priorities of recipient countries’ NDCs (Zhou et al. 2018). Similarly, Steffen and Schmidt (2019) found that
40 even within Multilateral Development Banks, ‘public- and private-sector branches differ considerably’,
41 with public-sector lending used mainly in non-renewable and hydropower projects. Political leadership is
42 therefore essential to steer financial flows to support low carbon transition (15.6). Voituriez et al. (2019)
43 identify significant mitigation potential if financing countries simply applied their own environmental
44 standards to their overseas investments.

45

1 1.4.5 Political economy

2 The politics of interest (most especially economic interest) of key actors at subnational, national and global
3 level can be important determinants of climate (in)action (O’Hara 2009; Lo 2010; Tanner and Allouche
4 2011; Sovacool et al. 2015; Clapp et al. 2018; Lohmann 2017; Newell and Taylor 2018; Lohmann 2019).
5 Political economy approaches can be crudely divided into “economic approaches to politics”, and those
6 used by other social scientists (Paterson and P-Laberge 2018). The former shows how electoral concerns
7 lead to weak treaties (Battaglini and Harstad 2016) and when policy negotiations cause status-quo biases
8 and the use of inefficient policy instruments (Austen-Smith et al. 2019) or delays and excessive
9 harmonization (Harstad 2007). The latter emphasises the central role of structures of power, production,
10 and a commitment to economic growth and capital accumulation in relation to climate action, given the
11 historically central role of fossil fuels to economic development and the deep embedding of fossil energy
12 in daily life (Malm 2015; Huber 2012; Di Muzio 2015; Newell and Paterson 2010).

13 The economic centrality of fossil fuels raises obvious questions regarding the possibility of decarbonisation.
14 Economically, this is well understood as a problem of decoupling. But the constraint is also political, in
15 terms of the power of incumbent fossil fuel interests to block initiatives towards decarbonisation (Newell
16 and Paterson 2010; Geels 2014; Jones and Levy 2009). The effects of climate policy are key considerations
17 in deciding the level of policy ambition and direction and strategies of states (Alam et al. 2013; Ibikunle
18 and Okereke 2014; Lo 2010), regions (Goldthau and Sitter 2015); and business actors (Wittneben et al.
19 2012) and there is a widespread cultural assumption that continued fossil fuel use is central to this (Strambo
20 and Espinosa 2020). Decarbonisation strategies are often centred around projects to develop new sources
21 of economic activity: carbon markets creating new commodities to trade profit from (Newell and Paterson
22 2010); the investment generated in new urban infrastructure (Whitehead 2013); innovations in a range of
23 new energy technologies (Fankhauser et al. 2013; Lachapelle et al. 2017; Meckling and Nahm 2018).

24 One factor limiting the ambition of climate policy has been the ability of incumbent industries to shape
25 government action on climate change (Newell and Paterson 1998; Breetz et al. 2018; Jones and Levy 2009;
26 Geels 2014). Incumbent industries are often more concentrated than those benefiting from climate policy
27 and lobby more effectively to prevent losses than those who would gain (Meng and Rode 2019). Drawing
28 upon wider networks (Brulle 2014), campaigns by oil and coal companies against climate action in the US
29 and Australia are perhaps the most well-known and largely successful of these (Brulle et al. 2020; Stokes
30 2020; Mildenerger 2020; Pearse 2017) although similar dynamics have been demonstrated for example in
31 Brazil and South Africa (Hochstetler 2020), Canada (Harrison 2018), Norway, or Germany (Fitzgerald et
32 al. 2019). In other contexts, resistance by incumbent companies is more subtle but nevertheless has
33 weakened policy design on emissions trading systems (Rosebloom and Markard 2020), and limited the
34 development of alternative fuelled automobiles (Wells and Nieuwenhuis 2012; Levy and Egan 2003).

35 The interaction of politics, power and economics is central in explaining why countries with higher per-
36 capita emissions, which logically have more opportunities to reduce emissions, in practice often take the
37 opposite stance, and conversely, why some low-emitting countries may find it easier to pursue climate
38 action because they have fewer vested interests in high-carbon economies. These dynamics can arise from
39 the vested interest of State-owned Enterprises (Polman 2015; Wright and Nyberg 2017; Wittneben et al.
40 2012), the alignment and coalitions of countries in climate negotiations (Gupta 2016; Okereke and Coventry
41 2016), and the patterns of opposition to or support for climate policy among citizens (Swilling et al. 2016;
42 Ransan-Cooper et al. 2018; Turhan et al. 2019; Baker 2015; Heffron and McCauley 2018).

1 **1.4.6 Equity and fairness**

2 Equity and fairness can serve as both driver and barrier to climate mitigation at different scales of
3 governance. Literature regularly highlights equity and justice issues as critical components in local politics
4 and international diplomacy regarding all SDG, such as goals for no poverty, zero hunger, gender equality,
5 affordable clean energy, reducing inequality, but also for climate action (Goal 13) (Marmot and Bell 2018;
6 Spijkers 2018). Equity issues help explain why it has proved hard to reach more substantive global
7 agreements, as it is hard to agree on a level of greenhouse gas mitigation (or emissions) and how to distribute
8 mitigation efforts among countries (Kverndokk 2018) for several reasons. First, an optimal trade-off
9 between mitigation costs and damage costs of climate change depends on ethical considerations, and
10 simulations from integrated assessment models using different ethical parameters producing different
11 optimal mitigation paths, see (IPCC 2018b and Section 3.6.1.2 in Chapter 3). Second, treaties that are
12 considered unfair may be hard to implement (Liu et al. 2017; Klinsky et al. 2017). Lessons from
13 experimental economics show that people may not accept a distribution that is considered unfair, even if
14 there is a cost of not accepting (Gampfer 2014). As equity issues are important for reaching deep
15 decarbonisation, the transition towards a sustainable development (Okereke 2018; Evans and Phelan 2016;
16 Heffron and McCauley 2018) depends on taking equity seriously in climate policies and international
17 negotiations (Martinez et al. 2019; Okereke and Coventry 2016; Klinsky et al. 2017).

18 Climate change and climate policies affect countries and people differently Low-income countries tend to
19 be more dependent on primary industries (agriculture, fisheries, etc.) than richer countries, and their
20 infrastructure may be less robust to tackle more severe weather conditions. Within a country, the burdens
21 may not be equally distributed either, due to policy measures implemented and from differences in
22 vulnerability and adaptive capacity following from e.g. income and wealth distribution, race and gender.
23 For instance, unequal social structures can result in women being more vulnerable to the effects of climate
24 change compared to men, especially in poor countries (Jost et al. 2016; Rao et al. 2019; Arora-Jonsson
25 2011). Costs of mitigation also differ across countries. Studies show there are large disparities of economic
26 impacts of NDCs across regions, and also between relatively similar countries when it comes to the level
27 of development, due to large differences in marginal abatement cost for the emission reduction goal of
28 NDCs (Akimoto et al. 2018; Fujimori et al. 2016; Edmonds et al. 2019; Hof et al. 2017). Equalizing the
29 burdens from climate policies may give more support for mitigation policies (Maestre-Andrés et al. 2019).

30 Taking equity into account in designing an international climate agreement is complicated as there is no
31 single universally accepted equity criterion, and countries may strategically choose a criterion that favours
32 them (Lange et al. 2007, 2010). Still, several studies analyse the consequences of different social
33 preferences in designing climate agreements, such as for instance inequality aversion, sovereignty and
34 altruism (Anthoff et al. 2010; Kverndokk et al. 2014).

35 International transfers from rich to poor countries to support mitigation and adaptation activities may help
36 equalizing burdens, as agreed upon in the UNFCCC (1992; Chapters 14 and 15) such that they may be
37 motivated by strategic as well as equity reasons (Kverndokk 2018; see also 1.4.4).

38 **1.4.7 Social innovation and behaviour change**

39 Social and psychological factors affect both perceptions and behaviour (Whitmarsh et al. 2021; Weber
40 2015). Religion, values, culture, gender, identity, social status and habits strongly influence individual
41 behaviours and choices and therefore, sustainable consumption (Section 1.6.3.1 in this chapter and Section
42 5.2 in Chapter 5). Identities can provide powerful attachments to consumption activities and objects that
43 inhibit shifts away from them (Stoll-Kleemann and Schmidt 2017; Ruby et al. 2020; Brekke et al. 2003;

1 Bénabou and Tirole 2011). Consumption is a habit-driven and social practice rather than simply a set of
2 individual decisions, making shifts in consumption harder to pursue (Evans et al. 2012; Shove and Spurling
3 2013; Kurz et al. 2015; Warde 2017; Verplanken and Whitmarsh 2021). Finally, shifts towards low-carbon
4 behaviour are also inhibited by social-psychological and political dynamics that cause individuals to ignore
5 the connections from daily consumption practices to climate change impacts (Norgaard 2011; Brulle and
6 Norgaard 2019).

7 As a notable example, plant-based alternatives to meat could reduce emissions from diets (Willett et al.
8 2019; Eshel et al. 2019) however, diets are deeply entrenched in cultures and identities and hard to change
9 (Fresco 2015; Mylan 2018). Changing diets also raises cross-cultural ethical issues, in addition to meat's
10 role in providing nutrition (Plumwood 2004). Henceforth, some behaviours that are harder to change will
11 only be transformed by the transition itself: triggered by policies, the transition will bring about
12 technologies that, in turn, will entrench new sustainable behaviours.

13 Behaviour can be influenced through a number of mechanisms besides economic policy and regulation,
14 such as information campaigns, advertising and 'nudging'. Innovations and infrastructure also impact
15 behaviour, as with bicycle lanes to reduce road traffic. Wider social innovations also have indirect impacts.
16 Education is increasing across the world, and higher education will have impacts on fertility, consumption
17 and the attitude towards the environment (Osili and Long 2008; McCrary and Royer 2011; Hamilton 2011).
18 Reducing poverty and improvements in health and reproductive choice will also have implications for
19 fertility, energy use and consumption globally. Finally, social capital and the ability to work collectively
20 may have large consequences for mitigation and the ability to adapt to climate change (Adger 2009; Section
21 4.3.5 in IPCC 2014a).

22 **1.4.8 Policy impacts**

23 Transformation to different systems will hinge on conscious policy to change the direction in which energy,
24 land-use, agriculture and other key sectors develop (Bataille et al. 2016; Chapters 13, 16). Policy plays a
25 central role in in land-related systems (Chapter 7), urban development (Chapter 8), improving energy
26 efficiency in buildings (Chapter 9) and transport / mobility (Chapter 10), and decarbonising industrial
27 systems (Chapter 11).

28 Policy has been and will be central not only because greenhouse gas emissions are almost universally under-
29 priced in market economies (Stern and Stiglitz 2017; World Bank 2019), and because of inadequate
30 economic incentives to innovation (Jaffe et al. 2005) but also due to various delay mechanisms (Karlsson
31 and Gilek 2020) and multiple sources of path-dependence and lock-in to existing systems (Section 1.8.2),
32 including "Infrastructure developments and long-lived products that lock societies into GHG-intensive
33 emissions pathways may be difficult or very costly to change, reinforcing the importance of early action
34 for ambitious mitigation (*robust evidence, high agreement*).” (AR5 p.18).

35 Many hundreds of policies have been introduced explicitly to mitigate GHG emissions, improve energy
36 efficiency or land use, or to foster low carbon industries and innovation, with demonstrable impact. The
37 role of policy to date has been most evident in energy efficiency (Sections 5.4 and 5.6 in Chapter 5) and
38 electricity (Chapter 6). The IPCC Special Report on Renewable Energy already found that "Government
39 policies play a crucial role in accelerating the deployment of RE technologies", (IPCC 2011a, p. 24). Policy
40 packages since then have driven rapid expansion in renewables capacity and cost reductions (eg. through
41 the German *Energiewende*), and emission reductions from electricity (most dramatically with the halving
42 of CO₂ emissions from UK power sector, driven by multiple policy instruments and regulatory changes),
43 as detailed in Chapter 6 (Section 6.7.5).

1 Chapter 13 charts the international evolution of policies and many of the lessons drawn. Attributing the
2 overall impact on emissions is complex, but an emerging literature of several hundred papers indicates
3 impacts on multiple drivers of emissions. Collectively, policies are likely to have curtailed global emissions
4 growth by several GtCO_{2e} annually already by the mid-2010s (see Cross-Chapter Box 10 in Chapter 14).
5 This suggests initial evidence that policy has driven some decoupling (e.g. Figure 1.1d) and started to ‘bend
6 the curve’ of global emissions, but more specific attribution to observed trends is not as yet possible.⁶

7 However, some policies (e.g. subsidies to fossil fuel production or consumption), increase emissions; whilst
8 others (e.g. investment protection) may constrain efforts at mitigation. Also, wider economic and
9 developmental policies have important direct and indirect impacts on emissions. Policy is thus both a driver
10 and a constraint on mitigation.

11 Synergies and trade-offs arise partly because of the nexus of GHG emissions with other adverse impacts
12 (e.g. local air pollution) and critical resources (e.g. water and food) (Conway et al. 2015; Andrews-Speed
13 and Dalin 2017), which also imply interacting policy domains.

14 The literature shows increasing emphasis on policy packages, including those spanning the different levels
15 of niche/behaviour; existing regimes governing markets and public actors; and strategic and landscape
16 levels (Section 1.7.3). Chapters 13, 16, and 17 appraise policies for transformation in the context of
17 sustainable development, indicating the importance of policy as a driver at multiple levels and across many
18 actors, with potential for benefits as well as costs at many levels.

19 National-level legislation may be particularly important to the credibility and long-term stability of policy
20 to reduce the risks, and hence cost, of finance (Chapters 13, 15) and for encouraging private sector
21 innovation at scale (Chapter 16), for example if it offers greater stability and mid-term predictability for
22 carbon prices; Nash and Steurer (2019) find that seven national Climate Change Acts in European countries
23 all act as ‘living policy processes, though to varying extents’.

24 The importance of policy at multiple levels does not lessen the importance of international policy, for
25 reasons including long-term stability, equity, and scope, but examples of effective implementation policy
26 at international levels remain fewer and governance weaker (Chapter 14).

27 **1.4.9 Legal framework and institutions**

28 Institutions are rules and norms held in common by social actors that guide, constrain and shape human
29 interaction (IPCC 2018b). Institutions can be formal, such as laws and policies, or informal, such as norms
30 and conventions. Institutions can both facilitate or constrain climate policy-making and implementation in
31 multiple ways. Institutions set the economic incentives for action or inaction on climate change at national,
32 regional and individual levels (Dorsch and Flachsland 2017; Sullivan 2017).

FOOTNOTE ⁶ Linking estimated policy impacts to trends is complex, and as yet very tentative. An important factor is that many mitigation policies involve investments in low carbon or energy efficient technology, the savings from which persist. As a purely illustrative example: the annual increase in global emissions during 2000-2010 averaged around 1GtCO_{2e} yr⁻¹, but with large fluctuations. If policies by 2010 reduced the *annual increase* in that year by 100MtCO_{2e} (0.1GtCO_{2e}) below what it would otherwise have been, this is hard to discern. But if these savings sustain, and in each subsequent year, policies cut another 100MtCO_{2e} off the annual increase compared to the previous year, global emissions after a decade would be around 5GtCO_{2e} yr⁻¹ below what they would have been without any such policies, and on average close to stabilising. However each step would be difficult to discern in the noise of annual fluctuations.

1 Institutions entrench specific political decision-making processes, often empowering some interests over
2 others, including powerful interest groups who have vested interest in maintaining the current high carbon
3 economic structures (Engau et al. 2017; Okereke and Russel 2010; Wilhite 2016); see also 1.4.6 and Chapter
4 13 on the sub national and national governance challenges including coordination, mediating politics and
5 strategy setting.

6 Some suggest that societal transformation towards low a carbon future requires new politics that involves
7 thinking in intergenerational time horizons, as well as new forms of partnerships between private and public
8 actors (Westman and Broto 2018), and associated institutions and social innovations to increase
9 involvement of non-state actors in climate governance (Fuhr et al. 2018). However literature is divided as
10 to how much democratisation of climate politics, with greater emphasis on equity and community
11 participation, would advance societal transformation in the face of climate change (Stehr 2005), or may
12 actually hinder radical climate action in some circumstances (Povitkina 2018).

13 Since 2016, the number of climate litigation cases has increased rapidly. UN Environment’s “Global
14 Climate Litigation Report: 2020 Status Review” (UNEP 2020) noted that between March 2017 and 1 July
15 2020, the number of cases nearly doubled with at least 1,550 climate cases filed in 8 countries. Several
16 important cases such as Urgenda Foundation v. The State of the Netherlands (“Urgenda”) and Juliana et al
17 v. United States (“Juliana”) have had ripple effects, inspiring other similar cases (Lin and Kysar 2020).

18 Numerous international climate governance initiatives engage national and subnational governments,
19 NGOs and private corporations, constituting a “regime complex” (Keohane and Victor 2011; Raustiala and
20 Victor 2004). They may have longer-run and second-order effects if commitments are more precise and
21 binding (Kahler 2017). However, without targets, incentives, defined baseline or monitoring, reporting, and
22 verification, they are not likely to fill the “mitigation gap” (Michaelowa and Michaelowa 2017).

23 **1.4.10 International cooperation**

24 Tackling climate change is often mentioned as an important reason for strong international co-operation in
25 the 21st century (Bodansky et al. 2017; Cramton et al. 2017b; Keohane and Victor 2016; Falkner 2016).
26 Mitigation costs are borne by countries taking action, while the benefits of reduced climate change are not
27 limited to them, being in economic terms “global and non-excludable”. Hence anthropogenic climate
28 change is typically seen as a global commons problem (Wapner and Elver 2017; Falkner 2016). Moreover,
29 the belief that mitigation will raise energy cost and may adversely affect competitiveness creates incentives
30 for free riding, where states avoid taking their fair share of action (Barrett 2005; Keohane and Victor 2016).
31 International cooperation has the potential to address these challenges through collective action (Tulkens,
32 2019) and international institutions offer opportunity for actors to engage in meaningful communication,
33 and exchange of ideas about potential solutions (Cole 2015). International cooperation is also vital for the
34 creation and diffusion of norms and the framework for stabilising expectations among actors (Pettenger
35 2016).

36 Some key roles of the UNFCCC have been detailed by its former heads (Kinley et al. 2021). In addition to
37 specific agreements (most recently the PA) it has enhanced transparency through reporting and data, and
38 generated or reinforced several important norms for global climate action including the principles of equity,
39 common but differentiated responsibility and respective capabilities, and the precautionary principles for
40 maintaining global cooperation among states with unevenly distributed emissions sources, climate impacts,
41 and varying mitigation cost across countries (Keohane and Victor, 2016). In addition to formal negotiations,
42 the annual Conference of Parties have increased awareness, and motivated more ambitious actions,
43 sometimes through for example the formation of ‘coalitions of the willing’. It provides a structure for

1 measuring and monitoring action towards a global goal (Milkoreit and Haapala 2019). International
2 cooperation (including the UNFCCC) can also promote technology development and transfer and capacity
3 building; mobilise finance for mitigation and adaptation, and help address concerns on climate justice (Chan
4 et al. 2018; Okereke and Coventry 2016; see Chapters 14-16).

5 A common criticism of international institutions is their limited (if any) powers to enforce compliance
6 (Zahar 2017). As a global legal institution, the PA has little enforcement mechanism (Sindico 2015), but
7 enforcement is not a necessary condition for an instrument to be legally binding (Bodansky 2016; Rajamani
8 2016). In reality implementation of specific commitments tends to be high once countries have ratified and
9 a Treaty or an Agreement is in force (Bodansky 2016; Rajamani 2016). Often, the problem is not so much
10 of 'power to enforce compliance or sanction non-compliance', but the level of ambition (Chapter 14).

11 However, whilst in most respects a driver, international cooperation has also been characterised as
12 'organised hypocrisy' where proclamations are not matched with corresponding action (Egnell 2010).
13 Various reasons for inadequate progress after 30 years of climate negotiations, have been identified
14 (Stoddard et al. 2021). International cooperation can also seem to be a barrier to ambitious action when
15 negotiation is trapped in 'relative-gains' calculus, seek to game the regime or gain leverage over one
16 another (Purdon 2017), or where states lower ambition to the 'least common denominator' to accommodate
17 participation of the least ambitious states (Falkner 2016). Geden (2016) and Dubash (2020) offer more
18 nuanced assessments.

19 International collaboration works best if an agreement can be made self-reinforcing with incentives for
20 mutual gains and joint action (Keohane and Victor 2016; Barrett 2016), but the structure of the climate
21 challenge makes this hard to achieve. The evidence from the Montreal Protocol on ozone depleting
22 substances and from the Kyoto Protocol on GHGs, is that legally binding targets have been *effective* in that
23 participating Parties complied with them (Albrecht and Parker 2019; Shishlov et al. 2016), and (for Kyoto)
24 these account for most of the countries that have sustained emission reductions for at least the past 10-15
25 years (Section 1.3.2; Section 2.2 in Chapter 2). However, such binding commitments may deter
26 *participation* if there are no clear incentives to sustain participation and especially if other growing emitters
27 are omitted by design, as with the Kyoto Protocol. Consequently the US refused to ratify (and Canada
28 withdrew), particularly on the grounds that developing countries had no targets; with participation in
29 Kyoto's second period commitments declining further, the net result was limited global progress in
30 emissions under Kyoto (Scavenius and Rayner 2018; Bodansky 2016; Okereke and Coventry 2016) despite
31 full legal compliance in both commitment periods (chapter 14).

32 The negotiation of the Paris Agreement was thus done in the context of serious questions about how best
33 to structure international climate cooperation to achieve better results. This new agreement is designed to
34 side-step the fractious bargaining which characterised international climate cooperation (Marcu 2017). It
35 contains a mix of hard, soft and non-obligations, the boundaries between which are blurred, but each of
36 which plays a distinct and valuable role (Rajamani 2016). The provisions of the PA could encourage flexible
37 responses to changing conditions, but limit assurances of ambitious national commitments and their
38 fulfilment (Pickering et al. 2018). The extent to which this new arrangement will drive ambitious climate
39 policy in the long run remains to be seen (Chapter 14).

40 Whilst the PA abandoned common accounting systems and timeframes, outside the UNFCCC many other
41 platforms and metrics for comparing mitigation efforts have emerged (Aldy 2015). Countries may assess
42 others' efforts in determining their actions through multiple platforms including Climate Change
43 Cooperation Index (C3-I), Climate Change Performance Index (CCPI) 'Climate Laws, Institutions and

1 Measures Index' (CLIMI) (Bernauer and Böhmelt 2013) and Energy Transition Index (Singh et al. 2019).
2 International cooperative initiatives between and among non-state (e.g., business, investors, civil society)
3 and subnational (e.g., city, state) actors have also been emerging, taking the forms of public-private
4 partnerships, private sector governance initiatives, NGO transnational initiatives, and subnational
5 transnational initiatives (Bulkeley and Schroeder 2012; Hsu et al. 2018). Literature is mostly positive about
6 the role of these transnational initiatives in facilitating climate action across scales although criticism and
7 caution about their accountability and effectiveness remain (Chan et al. 2016; Roger et al. 2017; Widerberg
8 and Pattberg 2017; Michaelowa and Michaelowa 2017; Chapter 14).

10 **1.5 Emissions Scenarios and Illustrative Mitigation Pathways (IMPs)**

11 Scenarios are a powerful tool for exploring an uncertain future world against the background of alternative
12 choices and development. Scenarios can be constructed using both narrative and quantitative methods.
13 When these two methods are combined they provide complementary information and insights. Quantitative
14 and narrative models are frequently used to represent scenarios to explore choices and challenges. The
15 IPCC has a long history of assessing scenarios (Nakicenovic et al. 2000; van Vuuren et al. 2011, 2014; see
16 also section 1.6 of AR6 WGI for a history of scenarios within the IPCC). This WGIII assessment employs
17 a wide range of qualitative and quantitative scenarios including quantitative scenarios developed through a
18 wide and heterogeneous set of tools ranging from spreadsheets to complex computational models (Annex
19 III provides further discussion and examples of computational models).

20 The concept of an **illustrative pathway (IP)** was introduced in IPCC Special Report on 1.5 (IPCC 2018b)
21 to highlight a subset of the quantitative scenarios, drawn from a larger pool of published literature, with
22 specific characteristics that would help represent some of the key findings emerging from the assessment
23 in terms of different strategies, ambitions and options available to achieve the Paris goals.

24 **Integrated Assessment Models (IAMs)** are the primary tools for quantitatively evaluating the technological
25 and macro-economic implications of decarbonisation, particularly for global long-term pathways. They
26 broadly divide into 'stylized aggregate benefit-cost models', and more complex, 'detailed process' IAMs
27 (Weyant 2017), often mirroring the benefit-cost and cost-effective approaches outlined in 1.7.1, with more
28 detailed classification in eg. Nikas et al. (2019). IAMs embody a number of structural and socio-
29 demographic assumptions and include multiple modelling approaches, ranging from economic optimising
30 behaviour to simulation (See Annex III). Detailed process models can include energy system models used
31 to analyse decarbonisation and 'net zero' scenarios by international agencies (eg. IEA 2020a).

32 Calculating cost-effective trajectories towards given goals typically involves detailed process IAMs. Often
33 these calculate the dynamic portfolio of technologies consistent with a given climate target. Some track
34 records of technology forecasting in IAMs are outlined in Chapters 2.5.4, and Box 16.1. Climate targets
35 may be imposed in models in a variety of ways that include, but are not limited to, constraints on emissions
36 or cumulated emissions (carbon budgets), and the pricing of emissions. The time-path of mitigation costs
37 calculated through these models may be translated into 'shadow prices' that (like the social-cost-of-carbon)
38 offer a benchmark to assess the cost-effectiveness of investments, as used by some governments and
39 companies (1.8.2).

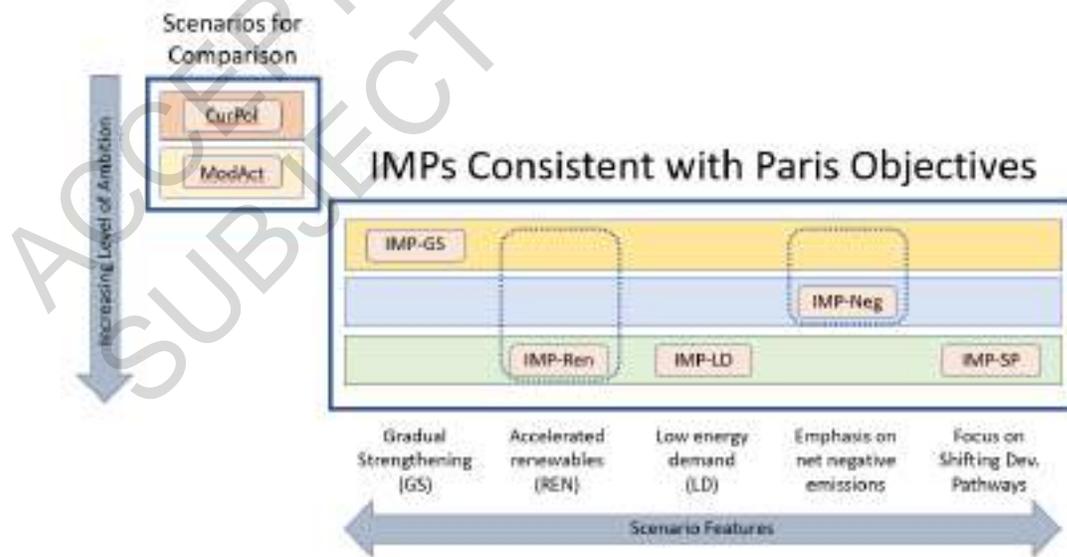

40 **Scenarios in the IPCC and AR6.** For AR6, WG III received submissions of more than 2500 model-based
41 scenarios published in the scientific literature. Such scenarios, which explore different possible evolutions
42 of future energy and land use (with or without climate policy) and associated emissions, are made available

1 through an interactive AR6 scenario database. The main characteristics of pathways in relation to ‘net zero’
 2 emissions and remaining ‘carbon budgets’ are summarised in Box 3.5 in Chapter 3. The warming
 3 contribution of CO₂ is very closely related to cumulative CO₂ emissions, but the remaining ‘carbon budget’
 4 for a given warming depends strongly *inter alia* on emissions of other GHGs; for targets below 2°C this
 5 may affect the corresponding ‘carbon budget’ by c. +/- 220GtCO₂, compared to central estimates of around
 6 500GtCO₂ (for 1.5°C) and 1350GtCO₂ (for 2°C) (AR6 WGI, Table SPM.2; Cross-Working Group Box 1
 7 in Chapter 3).

8 **Pathways and ‘net zero’.** The date at which the world needs aggregate emissions to reach net zero for Paris-
 9 consistent temperature goals depends both on progress in reducing non-CO₂ GHG emissions and near-term
 10 progress in reducing CO₂ emissions. Faster progress in the near term extends the date at which net zero
 11 must be reached, while conversely, slower near-term progress brings the date even closer to the present.
 12 Some of the modelled 1.5°C pathways with limited overshoot cut global CO₂ emissions in half until 2030,
 13 which allows for a more gradual decline thereafter, reaching net zero CO₂ after 2050; also, net zero GHGs
 14 occurs later, with remaining emissions of some non-CO₂ GHGs compensated by ‘net negative’ CO₂ (see
 15 Annex I and FAQ 1.3, and Cross-Chapter Box 3 in Chapter 3).

16 Drawing from the scenarios database, five **Illustrative Mitigation Pathways’ (IMPs)** were defined for this
 17 report (Figure 3.5 in Chapter 3 and Table 1.1). These are introduced here, with a more complete description
 18 and discussion provided in Section 3.2.5 of Chapter 3. These IMPs were chosen to illustrate key themes
 19 with respect to mitigation strategies across the entire WG III assessment. The IMPs embody both a storyline,
 20 which describes in narrative form the key socio-economic characteristics of that scenario, and a quantitative
 21 illustration providing numerical values that are internally consistent and comparable across chapters of this
 22 report. Quantitative IMPs can be associated directly with specific human activities and provide a
 23 quantitative point of reference that links activities in different parts of socioeconomic systems. Some parts
 24 of the report draw on these quantitative scenarios, whilst others use only the narratives. No assessment of
 25 the likelihood of each IMP has been made (as they reflect both human choice and deep uncertainty).

26

27

1 **Figure 1.3 Illustrative Mitigation Pathways (IMPs) used in AR6 – illustration of key features and levels of**
2 **ambition**

3
4 The IMPs are organized around two dimensions: the *level of ambition* consistent with meeting Paris goals
5 and the scenario features (Figure 1.4). The IMPs explore different pathways potentially consistent with
6 meeting the long-term temperature goals of the Paris Agreement. As detailed in Section 3.2.5 of Chapter 3
7 and Chapter 4, a pathway of Gradual Strengthening of current policies (**IMP-GS**) to 2030, if followed by
8 very fast reductions, may stay below 2C. The **IMP-NEG** pathway, with somewhat deeper emission
9 cutbacks to 2030, might enable 1.5C to be reached but only after significant overshoot, through the
10 subsequent extensive use of CDR in the energy and the industry sectors to achieve net negative global
11 emissions, as discussed in Chapters 3, 12, 7, 6, and 10.

12 Three other IMPs illustrate different features of technology scenarios with more short term rapid emission
13 reductions, which could deliver outcomes compatible with the temperature range in the Paris agreement
14 without large overshoot. Based on the assessment in Section 5.3.3 of Chapter 5, one key mitigation strategy
15 would be to rely on the opportunities for reducing demand (**IMP-LD**). Chapter 6 and the Chapter 7-11 show
16 how energy systems based on accelerated deep renewable energy penetration and electrification can also
17 provide a pathway to deep mitigation (**IMP-REN**). Chapter 4, 17 and 3 provide insights how shifting
18 development pathways can lead to deep emission reductions and achieve sustainable development goals
19 (**IMP-SP**).

20 These pathways can be implemented with different levels of ambition, that can be measured through the
21 classes (C) of temperature levels from the scenarios database, see Chapter 3 (Table 3.2). In the IMP
22 framework, Section 3.2.5 in Chapter 3 presents and explores quantitative scenarios that can limit warming
23 to 1.5 °C (with a probability of 50% or greater, i.e., C1 for the illustrated quantification of LD, SP and REN,
24 and C2 for NEG scenario), along with others GS pathway which keeps warming below 2°C with a
25 probability of 67% or greater (C3). In addition to these primary IMPs, the full scenario database contains
26 sensitivity cases that explore alternative warming levels.

27 In addition to the IMPs two additional scenarios were selected, which illustrate the consequences of current
28 policies and pledges. Current Policies (**CurPol**) explores the consequences of continuing along the path of
29 implemented climate policies in 2020 and only a gradual strengthening after that, drawing on numerous
30 such scenarios in the literature. Moderate Action (**ModAct**) explores the impact of implementing NDCs to
31 2030, but without further strengthening; both results in global mean temperature above 2°C. They provide
32 benchmarks against which to compare the IMPs.

33 Table 1.1 summarises the main storyline elements of the reference scenarios and each IMP.
34

Table 1.1 Illustrative Mitigation Pathways used in AR6

Scenarios		Full Name	Main Policy Characteristics	
CurPol		Current Policies	Implementation of current climate <i>policies</i> (mostly as reported in NDCs), neglecting stated subsequent goals and objectives (e.g. for 2030); only gradual strengthening after 2030; Grey Covid recovery.	
ModAct		Moderate Action	Implementation of current policies <i>and</i> achievement of 2030 NDCs, with further strengthening post-2030. Similarly to the situation implied by the diversity of NDCs (both policies and pledge), a fragmented policy landscape remains; mixed Covid recovery.	
IMPs	1.5/<2	GS	Gradual Strengthening	Until 2030, primarily current NDCs are implemented; after that a strong, universal regime leads to coordinated and rapid decarbonisation actions.
		Neg	Net Negative Emissions	Successful international climate policy regime reduces emissions below ModAct or GS to 2030, but with a focus on the long-term temperature goal, negative emissions kick in at growing scales thereafter, so that mitigation in all sectors also includes a growing and ultimately large reliance on negative emissions, with large ‘net global negative’ after 2050 to meet 1.5C after significant overshoot
		Ren	Renewables	Successful international climate policy regime with immediate action particularly policies and incentives (including international finance) favouring renewable energy; Less emphasis on negative-emission technologies. Rapid deployment and innovation of renewables and systems; electrification of all end-use.
		LD	Low Demand	Successful international climate policy regime with immediate action on the demand side; policies and financial incentives favouring reduced demand that in turn leads to early emission reductions; this reduces the decarbonisation effort on the supply side.
		SP	Shifting Pathways	Successful international climate policy regime with a focus on additional SDG policies aiming, for example, at poverty reduction and broader environmental protection. Major transformations shift development towards sustainability and reduced inequality, including deep GHG emissions reduction.

1 ***What the IMPs do and don't do.*** The IMPs are, as their name implies, a set of scenarios meant to
2 illustrate some important themes that run through the entire WGIII assessment. They illustrate that the
3 climate outcomes that the individuals and society will face in the century ahead depend on individual
4 and societal choices. In addition, they illustrate that there are multiple ways to successful achievement
5 of Paris long-term temperature goals.

6 IMPs are not intended to be comprehensive. They are not intended to illustrate all possible themes in
7 this report. They do not, for example attempt to illustrate the range of alternative socioeconomic
8 pathways against which efforts to implement Paris goals may be set, or to reflect variations in potential
9 regional development pathways. They do not explore issues around income distribution or
10 environmental justice, but assume implicitly that *where* and *how* action occurs can be separated from
11 who pays, in ways to adequately address such issues. They are essentially pathways of technological
12 evolution and demand shifts reflecting broad global trends in social choice. The IMPs do not directly
13 assess issues of realization linked to the “drivers and constraints” summarized in our previous section,
14 and the quantifications use, for the most part, models that are grounded mainly in the Aggregate
15 Economics Frameworks (section 7.1). As such they reflect primarily the geophysical, economic and
16 technological Dimensions of Assessment, but can be assessed in relation to the full set of Feasibility
17 criteria (section 1.8.1).

18 Together the IMPs provide illustrations of potential future developments that can be shaped by human
19 choices, including: Where are current policies and pledges leading? What is needed to reach specific
20 temperature goals under varying assumptions? What are the consequences of different strategies to meet
21 climate targets (i.e. demand-side strategy, a renewable energy strategy or a strategy with a role for net
22 negative emissions)? What are the consequences of delay? What are the implications for other SDGs of
23 various climate mitigation pathways?

25 **1.6 Achieving mitigation in the context of sustainable development**

26 This chapter now sets out approaches to understanding the mitigation challenge, working from its broad
27 location in the context of wider aspirations for sustainable development, then identifying specific
28 analytic approaches, before summarising the corresponding main dimensions used for assessment of
29 options and pathways in much of the report.

30 **1.6.1 The Climate Change and Development Connection**

31 Climate change mitigation is one of many goals that societies pursue in the context of sustainable
32 development, as evidenced by the wide range of the Sustainable Development Goals (SDGs). Climate
33 change and sustainable development as well as development more broadly, are interwoven along
34 multiple and complex lines of relationship (Fankhauser 2016; Gomez-Echeverri 2018a; Okereke and
35 Massaquoi 2017; Okereke et al. 2009), as highlighted in several previous IPCC reports (IPCC 2007,
36 2019a, 2018b, 2011a, 2014a). With its significant negative impact on natural systems, food security and
37 infrastructure, loss of lives and territories, species extinction, conflict health, among several other risks,
38 climate change poses a serious threat to development and wellbeing in both rich and poor countries
39 (IPCC 2019b, 2018b, 2007, 2011a, 2014a). Without serious efforts at mitigation and adaptation, climate
40 change could push millions further into poverty and limit the opportunities for economic development
41 (Chapter 4 and 17). It follows that ambitious climate mitigation is necessary to secure a safe climate
42 within which development and wellbeing can be pursued and sustained.

43 At the same time, rapid and largescale economic development (which has in the past driven climate
44 change through land use change and dependence on fossil fuels), is widely seen as needed to improve
45 global wellbeing and lift millions especially in low- and middle-income countries out of poverty
46 (Baarsch et al. 2020; Lu et al. 2019; Mugambiwa and Tirivangasi 2017; Chen et al. 2017; See Figure

1 1.6). This strand of literature emphasises the importance of economic growth including for tackling
2 climate change itself, pointing to the relationship between economic development and climate resilience
3 as well as the role of industry-powered technologies such as electric vehicles in reducing GHG levels
4 and promoting wellbeing (Heinrichs et al. 2014; Kasztelan 2017). Yet, others argue that the character
5 of social and economic development produced by the nature of capitalist society (Pelling and Manuel-
6 Navarrete 2011; Koch 2012; Malm 2016) is ultimately unsustainable.

7 There are at least two major implications of the very close link between climate change and
8 development as outlined above. The first is that the choice of development paths made by countries and
9 regions have significant consequences for GHG emissions and efforts to combat climate change (see
10 Chapters 2, 3, 4, 5, and 14). The second is that climate mitigation at local, national and global level
11 cannot be effectively achieved by a narrow focus on ‘climate-specific’ sectors, actors and policies; but
12 rather through a much broader attention to the mix of development choices and the resulting
13 development paths and trajectories (see Chapter 4, 6, 10; O’Neill et al. 2014).

14 As a key staple of IPCC reports and global climate policy landscape (Gidden et al. 2019; Quilcaille et
15 al. 2019; van Vuuren et al. 2017; IPCC 2014b, 2007; see also Chapter 2), integrated assessment models
16 and global scenarios (such as the “Shared Socio-Economic Pathways” – SSPs) highlight the interaction
17 between development paths, climate change and emission stabilisation (see Section 3.6 in Chapter 3).
18 The close links are also recognised in the PA (section 1.3.1).

19 The impact of climate change in limiting wellbeing is most acutely felt by the world’s poorest people,
20 communities, and nations, who have the smallest carbon footprint, constrained capacity to respond and
21 limited voice in important decision-making circles (Okereke and Ehresman 2015; Tosam and Mbih
22 2015; Mugambiwa and Tirivangasi 2017). The wide variation in the contribution to, and impact of
23 climate change within and across countries makes equity, inequality, justice, and poverty eradication,
24 inescapable aspects of the relationship between sustainable development and climate change (Reckien
25 et al. 2017; Okereke and Coventry 2016; Bos and Gupta 2019; Klinsky et al. 2017; Baarsch et al. 2020;
26 Kayal et al. 2019; Diffenbaugh and Burke 2019). This underpins the conclusion as commonly expressed
27 that climate action needs to be pursued in the context of sustainable development, equity and poverty
28 eradication (Burton et al. 2001; Smit et al. 2001; Klinsky and Winkler 2014; Tschakert and Olsson
29 2005; IPCC 2014a, 2018b).

30 **1.6.2 Concepts and frameworks for integrating climate mitigation and development:**

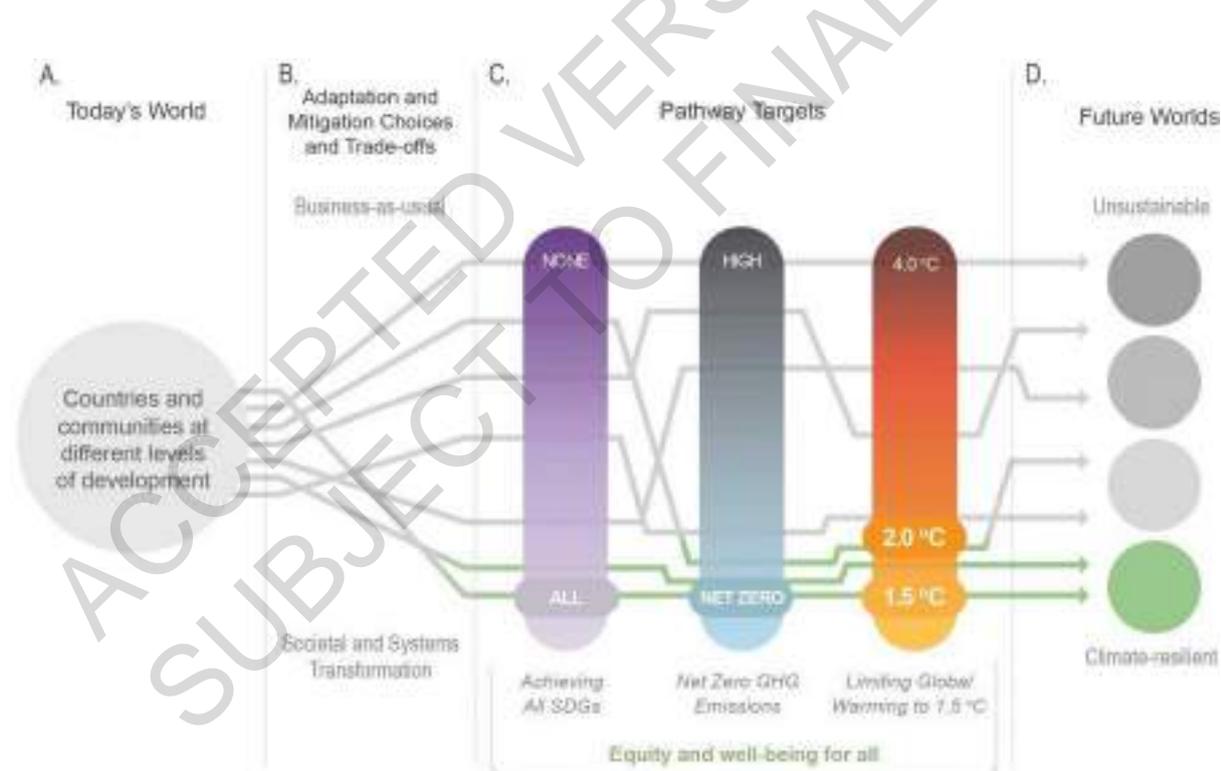

31 At one level, sustainable development can be seen as a meta framework for integrating climate action
32 with other global sustainability goals (Antal and Van Den Bergh 2016; Casadio Tarabusi and Guarini
33 2013). Fundamentally, the concept of sustainable development underscores the interlinkages and
34 interdependence of human and natural systems and the need to balance economic, social, and
35 environmental (including climate pollution) aspects in development planning and processes (Nunan
36 2017; Gomez-Echeverri 2018b; Zhenmin and Espinosa 2019).

37 Despite the appeal of the concept, tensions remain over the interpretation and practical application, with
38 acute disagreements regarding what the balancing entails in real life, how to measure wellbeing, which
39 goals to set, and the means through which such goals might be pursued (Michelsen et al. 2016; Shang
40 et al. 2019; Okereke and Massaquoi 2017; UNEP 2018b; Arrow et al. 2011; Dasgupta et al. 2015;
41 Sugiawan et al. 2019; Haberl et al. 2019).

42 Moreover, countries differ enormously in their respective situation regarding their development path –
43 a condition which affects their capability, goals, priorities and approach to the pursuit of sustainability
44 (Ramos-Mejía et al. 2018; Okereke et al. 2019; Shi et al. 2016). Most of the literature recognises that
45 despite its limitations, sustainable development with its emphasis on integrating social, economic and
46 environmental goals, provides a more comprehensive approach to the pursuit of planetary health and

1 human wellbeing. Sustainable development is then not a static objective but a dynamic framework for
 2 measuring human progress (Costanza et al. 2016; Fotis and Polemis 2018), relevant for all countries
 3 even if different groups of nations experience the challenge of sustainability in different ways.

4 Much like sustainable development, concepts like low-carbon development (Mulugetta and Urban
 5 2010; Yuan et al. 2011; Wang et al. 2017; Tian et al. 2019), climate-compatible development (CCD)
 6 (Mitchell and Maxwell 2010; Tompkins et al. 2013; Stringer et al. 2014; Bickersteth et al. 2017) and
 7 more recently climate-resilient development (CRD) (Fankhauser and McDermott 2015; Henly-Shepard
 8 et al. 2018) (see IPCC SR 1.5 2018b) have all emerged as ideas, tools and frameworks, intended to
 9 bring together the goals of climate mitigation and the SDGs, as well as development more broadly.
 10 Figure 1.5 suggests that the prospects for realizing a climate-resilient and equitable world is enhanced
 11 by a process of transformation and development trajectories that seek to limit global warming while
 12 also achieving the SDGs. The SDGs represent medium-term goals, and long-term sustainability
 13 requires continued effort to keep the world along a climate resilient development path. A key feature of
 14 development or transformation pathways that achieve a climate resilient world is that they maximise
 15 the synergies and minimise the trade-offs between climate mitigation and other sustainable development
 16 goals (Dagnachew et al. 2018; Fuso Nerini et al. 2018; Thornton and Comberti 2017; Wüstemann et al.
 17 2017; Mainali et al. 2018; Klausbruckner et al. 2016). Crucially, the nature of trade-offs and timing of
 18 related decisions will vary across countries depending on circumstances including the level of
 19 development, capability and access to resources (see Cross-chapter Box 5, Shifting Development Paths
 20 to increase Sustainability, in Chapter 4).

22
 23 **Figure 1.4: A climate-resilient and equitable world requires limiting global warming while achieving the**
 24 **SDGs.**

25 Source: IPCC 2018b

26
 27 Other concepts such as “Doughnut Economics” (Raworth 2018), ecological modernisation, and
 28 mainstreaming are also used to convey ideals of development pathways that take sustainability, climate
 29 mitigation, and environmental limits seriously (Dale et al. 2015a). Mainstreaming focuses on

1 incorporating climate change into national development activities, such as the building of infrastructure
2 (Wamsler and Pauleit 2016; Runhaar et al. 2018). The ‘green economy’ and green growth – growth
3 without undermining ecological systems, partly by gaining economic value from cleaner technologies
4 and systems and is inclusive and equitable in its outcomes - has gained popularity in both developed
5 and developing countries as an approach for harnessing economic growth to address environmental
6 issues (Bina 2013; Georgeson et al. 2017; Capasso et al. 2019; Song et al. 2020; Hao et al. 2021). Critics
7 however argue that green economy ultimately emphasises economic growth to the detriment of other
8 important aspects of human welfare such as social justice (Adelman 2015; Death 2014; Kamuti 2015),
9 and challenge the central idea that it is possible to decouple economic activity and growth (measured
10 as GDP increment) from increasing use of biophysical resources (raw materials, energy) (Jackson and
11 Victor 2019; Parrique et al. 2019; Hickel and Kallis 2020; Haberl et al. 2020; Vadén et al. 2020).

12 Literature on degrowth, post growth, and post development questions the sustainability and imperative
13 of more growth especially in already industrialised countries and argues that prosperity and the ‘Good
14 Life’ are not immutably tied to economic growth (Escobar 2015; Asara et al. 2015; Kallis 2019;
15 Latouche 2018; see also Section 5.2.1 in Chapter 5). The concept of ‘just transition’ also stresses the
16 need to integrate justice concerns so as to not impose hardship on already marginalised populations
17 within and between countries (Goddard and Farrelly 2018; Smith, Jackie and Patterson 2018;
18 McCauley and Heffron 2018; Evans and Phelan 2016; Heffron and McCauley 2018; see section 1.7.2).
19 The key insight is that pursuing climate goals in the context of sustainable development requires holistic
20 thinking including on how to measure well-being, serious consideration of the notion of ecological
21 limits, at least some level of decoupling and certainly choices and decision-making approaches that
22 exploit and maximise the synergy and minimises the trade-off between climate mitigation and other
23 sustainable development goals. It also requires consideration of equity and justice within and between
24 countries. However, ideas of a synergistic relationship between development and climate mitigation
25 can sometimes offer limited practical guidelines for reconciling the tensions that are often present in
26 practical policy making (Dale et al. 2015b; Ferguson et al. 2014; Kasztelan 2017; Kotzé 2018).

27 **1.6.3 Climate Mitigation, Equity and the Sustainable Development Goals (SDGs)**

28 Climate action can be conceptualised as both a stand-alone and cross-cutting issue in the 2030 SDGs
29 (Makomere and Liti Mbeva 2018), given that several of the other goals such as ending poverty (Goal
30 1), zero hunger (Goal 2), good health and wellbeing (Goal 3), affordable and clean energy (Goal 7)
31 among many others are related to climate change (see Figure 3.39 in Chapter 3).

32 In addition to galvanising global collective action, the SDGs provide concrete themes, targets and
33 indicators for measuring human progress to sustainability (Kanie and Biermann 2017). The SDGs also
34 provide a basis for exploring the synergies and trade-offs between sustainable development and climate
35 change mitigation (Makomere and Liti Mbeva 2018; Mainali et al. 2018; Fuso Nerini et al. 2018;
36 Pradhan et al. 2017). Progress to date (Sachs et al. 2016) shows fulfilling SDGs is a challenge for all
37 groups of countries – developed and developing – even though the challenge differs between countries
38 and regions (Pradhan et al. 2017).

39 Historically, the industrialisation associated with economic development has involved a strong
40 relationship with GHG emissions (see Section 5.2.1 in Chapter 5). Figure 1.6 shows per capita GHG
41 emissions on the vertical axis and Historical Index of Human Development (HIHD) levels (Prados de
42 la Escosura 2015) on the horizontal axis.⁷ The grey line shows historic global average GHG emissions

FOOTNOTE⁷ The Historical Index of Human Development (HIHD) emulates the widely used Human Development Index (HDI) as they both summarise in indexes, key human development dimensions consisting of a healthy life, knowledge and a decent standard of living. HDI is based on: life expectancy, expected years of

1 per capita and levels of human development over time, from 1870 to 2014. The current position of
2 different regions are shown by bubbles, with sizes representing total GHG emissions. Figure 1.6 also
3 shows the estimated position of the SDGs zone for the year 2030, and a “sustainable development
4 corridor” as countries reach towards higher HDI and lower emissions. To fulfil the SDGs, including
5 SDG 13 climate action, the historic relationship needs to change.

6 The top of the SDG zone is situated around the global per capita GHG emissions level of 5 tonnes
7 CO₂eq required for the world to be path towards fulfilling the Paris Agreement.⁸ The horizontal position
8 of the SDG zone is estimated based on the HIHD levels (Prados de la Escosura 2015) of countries that
9 have been shown to either have achieved, or have some challenges, when it comes to SDG 3, SDG 4
10 and SDG 8 (Sachs et al. 2016); as these SDGs are related to the constituent parts of the HIHD. Beyond
11 2030, the sustainable development corridor allows for increasing levels of human development while
12 lowering per capita GHG emissions.

13 Figure 1.6 shows that at present, regions with HIHD levels of around 0.5 all have emissions at or above
14 about 5tCO₂eq per-capita (even more so on a consumption footprint basis, see Figure 1.1c,d), but there
15 are wide variations within this. Indeed, there are regions with HIHD levels above 0.8 which have GHG
16 per-capita emissions lower than several with HIHD levels of around 0.5. The mitigation challenge
17 involves countries at many different stages of development seeking paths towards higher welfare with
18 low emissions.

19 From Figure 1.6, there are two distinct dimensions to sustainable development pathways for fulfilling
20 the SDGs. In terms of per-capita GHG emissions (the vertical), some regions have such low levels that
21 they could increase and still be below the global average required in 2030 for the world to be on path
22 to fulfil the Paris Agreement. Meanwhile other regions with high per capita GHG emissions would
23 require a rapid transformation in technologies and practices. It is against this background that Dubash
24 (2019) emphasises placing the need for urgent action on climate change in the context of domestic
25 political priorities and the institutions within which national frameworks are crystallised.

26 Concerns over equity in the context of growing global inequality and very tight remaining global carbon
27 budgets have motivated an emphasis on equitable access to sustainable development (Peters et al. 2015;
28 Kartha et al. 2018b; Matthews et al. 2019; van den Berg et al. 2019). This literature emphasises the
29 need for less developed countries to have sufficient room for development while addressing climate
30 change (Pan et al. 2014; Winkler et al. 2013; Gajevic Sayegh 2017; Warlenius 2018; Robinson and
31 Shine 2018). Meanwhile, many countries reliant on fossil fuels, related technologies and economic
32 activities are eager to ensure tax revenues are maintained, workers and industries have income and
33 justice is embedded in the economic transformations required to limit GHG emissions (Cronin et al.
34 2021).

schooling of children, the mean years of schooling of the adult population, and GNI per capita adjusted for purchasing power; the HIHD is based on: life expectancy at birth, adult literacy rates, educational enrolment rates, and GDP per capita, and is used in Figure 1.6 because it is available for a longer time series (Prados de la Escosura 2015).

FOOTNOTE⁸ Based on global population projections of between 8 and 8.5 billion people in 2030, and GHG emissions levels from the C1, C2 and C3 categories of scenarios in Table 3.2 and Box 3.7 in Chapter 3.

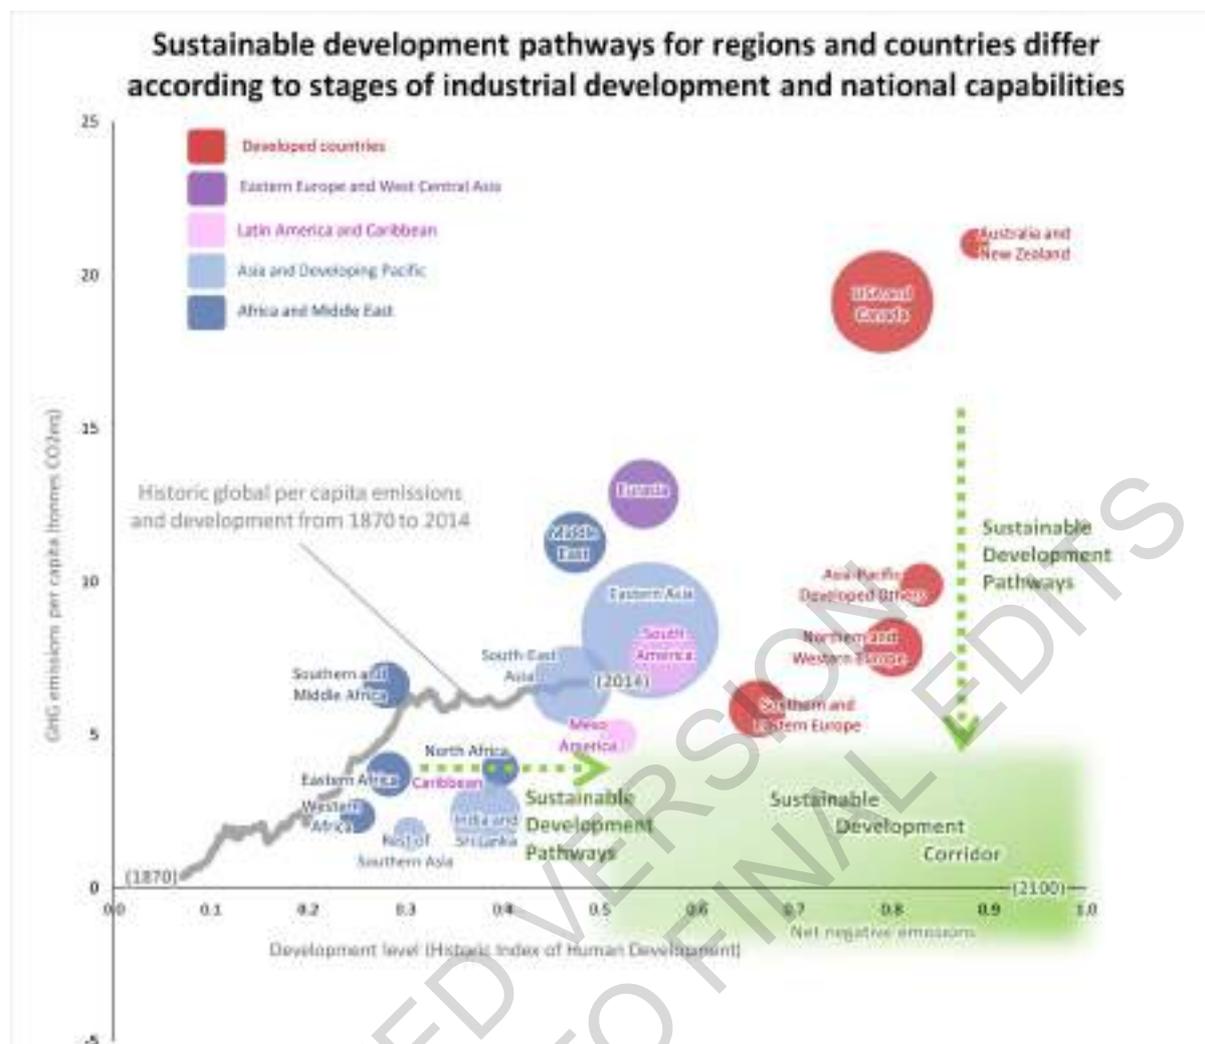

Figure 1.5: Sustainable development pathways towards fulfilling the SDGs.

The graph shows global average per capita GHG emissions (vertical axis) and relative "Historic Index of Human Development" (HIHD) levels (horizontal) have increased globally since the industrial revolution (grey line). The bubbles on the graph show regional per capita GHG emissions and human development levels in the year 2015, illustrating large disparities. Pathways towards fulfilling the Paris Agreement (and SDG 13) involve global average per capita GHG emissions below about 5 tCO₂e by 2030. Likewise, to fulfil SDGs 3, 4 and 8, HIHD levels (see footnote 7) need to be at least 0.5 or greater. This suggests a 'sustainable development zone' for year 2030 (in green); the in-figure text also suggests a sustainable development corridor, where countries limit per capita GHG emissions while improving levels of human development over time. The emphasis of pathways into the sustainable development zone differ (green arrows) but in each case transformations are needed in how human development is attained while limiting GHG emissions.

1 Correlation between CO₂ emission intensity, or absolute emission and gross domestic product growth,
2 is not rigid, unambiguous and deterministic (Ojekunle et al. 2015), but the extent to which SDGs and
3 economic growth expectations can be fulfilled while decoupling GHG emissions remains a concern
4 (Hickel and Kallis 2020; Haberl et al. 2020). Below some thresholds of absolute poverty, more
5 consumption is necessary for development to lead to well-being (see Section 5.2.1.1 in Chapter 5),
6 which may not be the case at higher levels of consumption (Steinberger et al. 2020; Lamb and
7 Steinberger 2017; Section 1.7.2).

8 In conclusion, achieving climate stabilisation in the context of sustainable development and efforts to
9 eradicate poverty requires collective action and exploiting synergies between climate action and
10 sustainable development, while minimising the impact of trade-offs (Najam 2005; Makomere and Liti
11 Mbeva 2018; Okereke and Massaquoi 2017; Dooley et al. 2021). It also requires a focus on equity
12 considerations to avoid climate induced harm, as well as unfairness that can result from urgent actions
13 to cut emissions (Kartha et al. 2018a; Robiou du Pont et al. 2017; Pan et al. 2014). This is ever more
14 important as the diminishing carbon budget has intensified debates on which countries should have the
15 greatest claim to the ‘remaining space’ for emissions (Raupach et al. 2014) or production (McGlade
16 and Ekins 2015), amplified by persistent concerns over the insufficiency of support for means of
17 implementation, to support ambitious mitigation efforts (Pickering et al. 2015; Weikmans and Roberts
18 2019).

19 20 **1.7 Four Analytic Frameworks for understanding mitigation response** 21 **strategies**

22 Climate change is unprecedented in its scope (sectors, actors and countries), depth (major
23 transformations) and timescales (over generations). As such, it creates unique challenges for analysis.
24 It has been called “the greatest market failure in history” (Stern 2007); the Perfect Moral Storm
25 (Gardiner 2006) and a “super wicked problem” (Lazarus 2009; Levin et al. 2012) - one which appears
26 difficult to solve through the traditional tools and assumptions of social organisation and analysis.

27 To complement the extensive literature on risks and decision-making under uncertainty reviewed in
28 AR6-WGII (notably, Chapter 19), this section summarises insights and developments in key analytic
29 frameworks and tools particularly relevant to understanding specific mitigation strategies, policies and
30 other actions, including explaining the observed if limited progress to date. Organised partly as reflected
31 in the quotes above, these include *aggregated* (principally, economic) frameworks to evaluate system-
32 level choices; *ethical* perspectives on values and equity including stages of development and
33 distributional concerns; and *transition* frameworks which focus on the processes and actors involved in
34 major technological and social transitions. These need to be complemented by a fourth set of approaches
35 which shine more light on *psychological/behavioural and political* factors. All these frameworks are
36 relevant, and together they point to the multiple perspectives and actions required if the positive drivers
37 of emission reduction summarised in section 4 are to outweigh the barriers and overcome the
38 constraints.

39 **1.7.1 Aggregated approaches: economic efficiency and global dynamics of mitigation**

40 Some of the most established and influential approaches to understand *aggregate* causes and
41 consequences of climate change and mitigation across societies, draw upon economic theories and
42 modelling to generate global emission pathways in the absence of climate policies (a reference) and to
43 study alternative mitigation pathways (described in detail in Section 3.2.5 in Chapter 3). The underlying
44 economic concepts aggregate wealth or other measures of welfare based on utilitarian ethical

1 foundations, and in most applications, a number of additional assumptions detailed in AR5 (Chapters 2
2 and 3).

3 **1.7.1.1 Cost-benefit and cost-effectiveness analysis**

4 Such global aggregate economic studies coalesce around two main questions. One, as pioneered by
5 Nordhaus (1992; 2008) attempts to monetize overall climate damages and mitigation costs so as to
6 strike a ‘cost-benefit optimum’ pathway. More detailed and empirically-grounded ‘cost-effectiveness
7 analysis’ explores pathways that would minimise mitigation costs (IPCC 2014a section 2.5; Ekholm
8 2014; Weyant 2017) for given targets (e.g. as agreed in international negotiations, see Section 3.2 in
9 Chapter 3). Both approaches recognise that resources are limited, and climate change competes with
10 other priorities in government policymaking, and are generally examined with some form of Integrated
11 Assessment Model (IAMs: see 1.5, and Appendix C). Depending on the regional disaggregation of the
12 modelling tools used and on the scope of the analyses, these studies may or may not address
13 distributional aspects within and across nations associated with climate policies (Bauer et al. 2020).

14 For at least 10-15 years after the first computed global cost-benefit estimate (Nordhaus 1992), the
15 dominant conclusions from these different approaches seemed to yield very different recommendations,
16 with cost-benefit studies suggesting lenient mitigation compared to the climate targets typically
17 recommended from scientific risk assessments (Weyant 2017). Over the past 10-15 years, literature has
18 made important strides towards reconciling these two approaches, both in the analytic methods and the
19 conclusions arising.

20 **Damages and risks** Incorporating impacts which may be extremely severe but are uncertain (known as
21 “fat tails” (Weitzman 2009, 2011), strengthens the economic case for ambitious action to avoid risks of
22 extreme climate impacts (Ackerman et al. 2010; Dietz and Stern 2015; Fankhauser et al. 2013). The
23 salience of risks has also been amplified by improved understanding of climate ‘tipping points’
24 (Lontzek et al. 2015; Lenton et al. 2019); valuations should reflect that cutting emissions reduces not
25 only average expected damages, but also the risk of catastrophic events (IWG 2021).

26 **Discounting.** The role of time-discounting, in weighting future climate change impacts against today’s
27 costs of mitigating emissions, has been long recognised (Weitzman 1994, 2001; Nordhaus 2007;
28 Dasgupta 2008; Stern 2007). Its importance is underlined in analytical Integrated Assessment Models
29 (IAMs) (Golosov et al. 2014; van der Ploeg and Rezai 2019; van den Bijgaart et al. 2016); also Annex
30 III. Economic literature suggests applying risk-free, public, and long-term interest rates when evaluating
31 overall climate strategy (Arrow et al. 2013; Groom and Hepburn 2017; Weitzman 2001; Dasgupta
32 2008). Expert elicitations indicate values around 2% (majority) to 3% (Drupp et al. 2018). This is lower
33 than in many of the studies reviewed in earlier IPCC Assessments, and many IAM studies since, and
34 by increasing the weight accorded to the future would increase current ‘optimal effort’. The U.S.
35 Interagency Working Group on the Social Cost of Carbon used 3% as its central value (IAWG 2016;
36 Li and Pizer 2018; Adler et al. 2017). Individual projects may require specific risk adjustments.

37 **Distribution of impacts.** The economic damages from climate change at the nationally aggregated and
38 subnational level are very diverse (Moore et al. 2017; Ricke et al. 2018; Carleton et al. 2020). A ‘global
39 damage function’ necessarily implies aggregating impacts across people and countries with different
40 levels of income, and over generations, a process which obscures the strategic considerations that drive
41 climate policy making (Keohane and Oppenheimer 2016). Economics acknowledges there is no single,
42 objectively-defined such ‘social welfare function’ (IPCC 1995, 2014a). This applies also to distribution
43 of responses; both underline the relevance of equity (next section) and global negotiations to determine
44 national and collective objectives.

1 Obvious limitations arise from these multiple difficulties in assessing an objective, globally-acceptable
2 single estimate of climate change damages (e.g. Pindyck 2013; Arrow et al. 2013; Auffhammer 2018;
3 Stern et al. 2021), with some arguing that agreement on a specific value can never be expected (Rosen
4 and Guenther 2015; Pezzey 2018). A new generation of cost-benefits analysis, based on projections of
5 actual observed damages, result in stronger mitigation efforts as optimal (Glanemann et al. 2020; Hänsel
6 et al. 2020). Overall the combination of improved damage functions with the wider consensus on low
7 discount rates (as well as lower mitigation costs due to innovation) has increasingly yielded ‘optimal’
8 results from benefit-cost studies in line with the range established in the Paris Agreement (see Cross-
9 Working-Group Box 1 in Chapter 3).

10 **Hybrid cost-benefit approaches** that extend the objective of the optimisation beyond traditional
11 welfare, adding some form of temperature targets as in (Llavador et al. 2015; Held 2019) also represent
12 a step in bridging the gap between the two approaches and result in proposed strategies much more in
13 line with those coming from the cost-effectiveness literature. Approaching from the opposite side, cost-
14 effectiveness studies have looked into incorporating benefits from avoided climate damages, to improve
15 the assessment of net costs (Drouet et al. 2021).

16 Cost-benefit IAMs utilise damage functions to derive a social cost of CO₂ emissions’ (SCC - the
17 additional cost to society of a pulse of CO₂ emissions). One review considered “the best estimate” of
18 the optimal [near-term] level “still ranges from a few tens to a few hundreds of dollars per ton of carbon
19 (Tol 2018)”, with various recent studies in the hundreds, taking account of risks (Taconet et al. 2019),
20 learning (Ekholm 2018) and distribution (Ricke et al. 2018). In addition to the importance of
21 uncertainty/risk, aggregation, and realistic damage functions as noted, on which some progress has been
22 made, some reviews additionally critique how IAMs represent abatement costs in terms of energy
23 efficiency and innovation (e.g. Rosen and Guenther 2015; Farmer et al. 2015; Keen 2021); see also
24 1.7.3 and 1.7.4. IAMs may better reflect associated ‘rebound’ at system level (Saunders et al. 2021),
25 and *inefficient implementation* would raise mitigation costs (Homma et al. 2019); conversely, *co-*
26 *benefits* – most extensively estimated for air-quality, valued at a few tens of USD/tCO₂ across sixteen
27 studies (Karlsson et al. 2020) - complement global with additional local benefits (see also Table 1.2).

28 Whereas many of these factors affect primarily cost-benefit evaluation, discounting also determines the
29 cost-effective trajectory: Emmerling et al. (2019) find that, for a remaining budget of 1000GtCO₂,
30 reducing the discount rate from 5% to 2% would more than double current efforts, limit ‘overshoot’,
31 greatly reduce a late rush to negative emissions, and improve intergenerational justice by more evenly
32 distributing policy costs across the 21st century.

33 **1.7.1.2 Dynamic efficiency and uncertainty**

34 Care is required to clarify what is optimised (Dietz and Venmans 2019). Optimising a path towards a
35 given temperature goal *by a fixed date* (e.g. 2100) gives time-inconsistent results backloaded to large,
36 last-minute investment in carbon dioxide removal. ‘Cost-effective’ optimisations generate less initial
37 effort than *equivalent* cost-benefit models (Gollier 2021; Dietz and Venmans 2019) as they do not
38 incorporate benefits of reducing impacts earlier.

39 ‘Efficient pathways’ are affected by inertia and innovation. Inertia implies amplifying action on long-
40 lived investments and infrastructure that could otherwise lock in emissions for many decades (Vogt-
41 Schilb et al. 2018; Baldwin et al. 2020). Chapter 3 (section 3.5) discusses interactions between near,
42 medium and long-term actions in global pathways, particularly *vis-à-vis* inertia. Also, to the extent that
43 early action induces low carbon innovation, it ‘multiplies’ the optimal effort (for given damage
44 assumptions), because it facilitates subsequent cheaper abatement. For example, a ‘learning-by-doing’

1 analysis concludes that early deployment of expensive PV was of net global economic benefit, due to
2 induced innovation (Newbery 2018).

3 Research thus increasingly emphasises the need to understand climate transformation in terms of
4 dynamic, rather than static, efficiency (Gillingham and Stock 2018). This means taking account of
5 inertia, learning and various additional sources of ‘path-dependence’. Including induced innovation in
6 stylised IAMs can radically change the outlook (Acemoglu et al. 2012, 2016), albeit with limitations
7 (Pottier et al. 2014); many more detailed-process IAMs now do include endogenous technical change
8 (as reviewed in Yang et al. (2018) and Grubb et al. (2021b); also Annex III).

9 These dynamic and uncertainty effects typically justify greater up-front effort (Kalkuhl et al. 2012;
10 Bertram et al. 2015), including accelerated international diffusion (Schultes et al. 2018), and strengthen
11 optimal initial effort in cost-benefit models (Grubb et al. 2021b; Baldwin et al. 2020). Approaches to
12 risk premia common in finance would similarly amplify the initial mitigation effort, declining as
13 uncertainties reduce (Daniel et al. 2019).

14 **1.7.1.3 Disequilibrium, complex systems and evolutionary approaches**

15 Other approaches to aggregate evaluation draw on various branches of intrinsically non-equilibrium
16 theories (e.g. Chang 2014). These including long-standing theories from the 1930s (e.g. Schumpeter
17 1934a; Keynes 1936) to understand situations of structurally under-employed resources, potential
18 financial instabilities (Minsky 1986), and related economic approaches which emphasise time
19 dimensions (e.g. recent reviews in Legrand and Hagemann 2017; Stern 2018). More recently
20 developing have been formal economic theories of endogenous growth building on eg. Romer (1986),
21 and developments of Schumpeterian creative destruction (Aghion et al. 2021) and evolutionary
22 economic theories which abandon any notion of full or stable resource utilisation even as a reference
23 concept (Nelson and Winter 1982; Freeman and Perez 1988; Carlsson and Stankiewicz 1991; Perez
24 2001; Freeman and Louçã 2001).

25 The latter especially are technically grounded in complex system theories (e.g. Arthur 1989, 1999;
26 Beinhocker 2007; Hidalgo and Hausmann 2009). These take inherently dynamic views of economies
27 as continually evolving systems with continuously unfolding and path-dependent properties, and
28 emphasise uncertainty in contrast to any predictable or default optimality. Such approaches have been
29 variously applied in policy evaluation (Walton 2014; Moore et al. 2018), and specifically for global
30 decarbonisation (e.g. Barker and Crawford-Brown 2014) using global simulation models. Because these
31 have no natural reference ‘least lost’ trajectory, they illustrate varied and divergent pathways and tend
32 to emphasise the diversity of possibilities and relevant policies, particularly linked to innovation and
33 potentially ‘sensitive intervention points’ (Farmer et al. 2019; see also section 1.7.3). They also illustrate
34 that different representations of innovation and financial markets together can explain why estimated
35 impacts of mitigation on GDP can differ very widely (potentially even in sign), between different model
36 types (Chapter 15, Section 15.6.3 and Box 15.7).

37 **1.7.2 Ethical approaches**

38 Gardiner's (2011) description of climate change as “The Perfect Moral Storm” identified three
39 ‘tempests’. Its *global* dimension, in a world of sovereign states which have only fragmentary
40 responsibility and control, makes it ‘difficult to generate the moral consideration and necessary political
41 will’. Its impacts are *intergenerational* but future generations have no voice in contemporary affairs,
42 the usual mechanism for addressing distributional injustices, amplified by the intrinsic inequity of
43 wealthy big emitters impacting particularly poorer victims. He argues that these are exacerbated by a
44 third, *theoretical* failure to acknowledge a central need for ‘moral sensitivity, compassion, transnational
45 and transgenerational care, and other forms of ethical concern to rise to the surface’ to help guide

1 effective climate action. As noted in section 1.4.6, however, equity and ethics are both a driver of and
2 constraint on mitigation.

3 *1.7.2.1 Ethics and values*

4 A large body of literature examines the critical role of values, ethics, attitudes, and behaviours as
5 foundational frames for understanding and assessing climate action, sustainable development and
6 societal transformation (IPCC WGIII IPCC 2014a chapter 3). Most of this work is offered as a counter
7 point or critique to mainstream literature's focus on safe-guarding of economic growth of nations,
8 corporations and individuals (Castree 2017; Gunster 2017). These perspectives highlight the dominance
9 of economic utilitarianism in western philosophical thought as a key driver for unsustainable
10 consumption and global environmental change (Hoeing et al. 2015; Popescu 2016).

11 Entrenching alternative values that promote deep decarbonisation, environmental conservation and
12 protection across all levels of society is then viewed as foundational component of climate resilient and
13 sustainable development and for achieving human rights, and a safe climate world (Jolly et al. 2015;
14 Evensen 2015; Popescu 2016; Tàbara et al. 2019). The UN Human Rights Office of the High
15 Commissioner has highlighted the potentially crucial role of human rights in relation to climate change
16 (UNHCR 2018). While acknowledging the role of policy, technology, and finance, the 'managerialist'
17 approaches that emphasise 'technical governance' and fail to challenge the deeper values that underpin
18 societies may not secure the deep change required to avert dangerous climate change and other
19 environmental challenges (Hartzell-Nichols 2014; Steinberger et al. 2020).

20 Social justice perspectives emphasise the distribution of responsibilities, rights, and mutual obligations
21 between nations in navigating societal transformations (Patterson et al. 2018; Gawel and Kuhlicke 2017;
22 Leach et al. 2018). Current approaches to climate action may fail to match what is required by science
23 because they tend to circumvent constraints on human behaviour, especially constraints on economic
24 interest and activity. Related literature explores governance models that are centred on environmental
25 limits, planetary boundaries and the moral imperative to prioritise the poor in earth systems governance
26 (Carley and Konisky 2020; Kashwan et al. 2020), with emphasis on trust and solidarity as foundations
27 for global co-operation on climate change (Jolly et al. 2015). A key obstacle is that the economic
28 interests of states tend to be stronger than the drivers for urgent climate action (Bain 2017).

29 Short-term interests of stakeholders is acknowledged to impede the reflection and deliberation needed
30 for climate mitigation and adaptation planning (Hackmann 2016; Herrick 2018; Sussman et al. 2016;
31 Schlosberg et al. 2017). Situationally appropriate mitigation and adaptation policies at both national
32 and international level may require more ethical self-reflection (Herrick 2018), including self-
33 transcendent values such as universalism and benevolence, and moderation which are positively related
34 to pro-environmental behaviours (Howell and Allen 2017; Jonsson and Nilsson 2014; Katz-Gerro et al.
35 2015; Braitto et al. 2017).

36 Another strong theme in the literature concerns recognition of interdependence including the intimate
37 relationship between humans and the non-human world (Hannis 2016; Gupta and Racherla 2018;
38 Howell and Allen 2017), with such ecological interdependence offered as an organising principle for
39 enduring transformation to sustainability. A key policy implication of this is moving away from valuing
40 nature only in market and monetary terms to strongly incorporating existential and non-material value
41 of nature in natural resource accounting (Neuteleers and Engelen 2015; Himes-Cornell et al. 2018;
42 Shackleton et al. 2017). There has been increasing attention on ways to design climate policy
43 frameworks to help reconcile ecological virtue (with its emphasis on the collective) with and individual
44 freedoms and personal autonomy (Kasperbauer 2016; Nash et al. 2017; Xiang et al. 2019). In such a
45 framework, moderation, fairness, and stewardship are all understood and promoted as directly

1 contributing to the ‘Good Life’. Such approaches are deemed vital to counteract tendencies to ‘free
2 ride’, and to achieve behavioural changes often associated with tackling climate change (Section 5.2.1
3 in Chapter 5).

4 Some literature suggests that attention to emotions, especially with regards to climate communication,
5 could help societies and individuals act in ways that focus less on monetary gain and more on climate
6 and environmental sustainability (Bryck and Ellis 2016; Chapman et al. 2017; Nabi et al. 2018; Zummo
7 et al. 2020).

8 **1.7.2.2 Equity and representation: international public choice across time and space**

9 Equity perspectives highlight three asymmetries relevant for climate change (Okereke 2017; Okereke
10 and Coventry 2016; 1.4.6). *Asymmetry in contribution* highlights different contributions to climate
11 change both in historical and current terms, and apply both within and between states as well as between
12 generations (Caney 2016; Heyward and Roser 2016). *Asymmetry in impacts* highlight the fact that the
13 damages will be borne disproportionately across countries, regions, communities, individuals and
14 gender; moreover, it is often those that have contributed the least that stand to bear the greatest impact
15 of climate change (Shi et al. 2016; IPCC 2014a). *Asymmetry in capacity* highlights differences of power
16 between groups and nations to participate in climate decision and governance, including capacity to
17 implement mitigation and adaptation measures.

18 If attention is not paid to equity, efforts designed to tackle climate change may end up exacerbating
19 inequities among communities and between countries (Heffron and McCauley 2018). The implication
20 is that to be sustainable in the long run, mitigation involves a central place for consideration of justice,
21 both within and between countries (Chapters 4, 14). Arguments that the injustices following from
22 climate change are symptomatic of a more fundamental structural injustice in social relations, are taken
23 to imply a need to address the deeper inequities within societies (Routledge et al. 2018).

24 Climate change and climate policies affect countries and people differently, with the poor likely to be
25 more affected (1.6.1). Ideas of ‘just transition’ (outlined in 1.8.2.) often have a national focus in the
26 literature, but also imply that mitigation should not increase the asymmetries between rich and poor
27 countries, implying a desire for transitions which seek reduce (or at least avoid adverse) distributional
28 affects. Thus, it comes into play in the timing of zero emissions (chapter 3 and 14). International climate
29 finance in which rich countries finance mitigation and adaptation in poor countries is also essential for
30 reducing the asymmetries between rich and poor countries (1.6.3 and chapter 15).

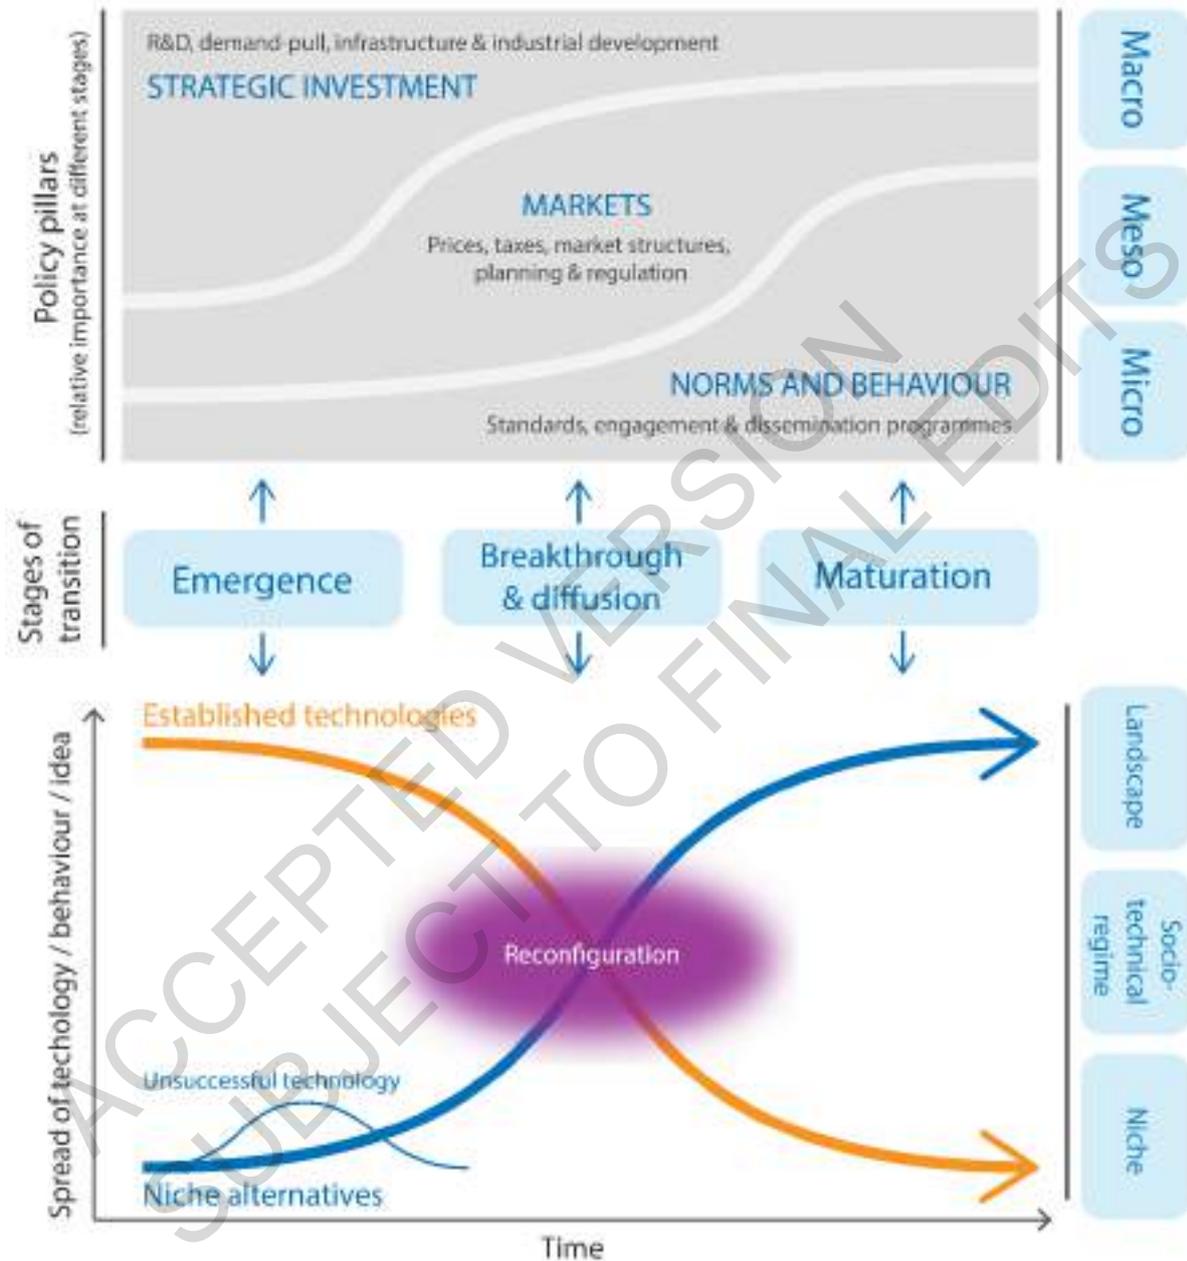

31 Equity across generations also matters, i.e., the distribution between the present and future generations.
32 One aspect is discounting (1.7.1). Another approach has been to study the burdens on each generation
33 following from the transition to low-carbon economies (IPCC 2014a chapter 3, Cross Working Group
34 Box 3 in Chapter 12). Suggestions include shifting more investments into ‘natural capital’, so that future
35 generations will inherit less physical capital but a better environment, or financing mitigation efforts
36 today using governmental debt redeemed by future generations (Broome 2012; Heijdra et al. 2006; Karp
37 and Rezai 2014; Hoel et al. 2019).

38 **1.7.3 Transition and transformation processes**

39 This report uses the term *transition* as the process, and *transformation* as the overall change or outcome,
40 of large-scale shifts in technological, economic and social systems, called socio-technical systems in
41 the innovation literature. Typically, new technologies, ideas and associated systems initially grow
42 slowly in absolute terms, but may then ‘take-off’ in a phase of exponential growth as they emerge from
43 a position of niche into mainstream diffusion, as indicated by the ‘S-curve’ growth in Figure 1.7 (lower
44 panel). These dynamics arise from interactions between innovation (in technologies, companies and

1 other organisations), markets, infrastructure and institutions, at multiple levels (Geels et al. 2017;
 2 Kramer 2018). Consequently, interdisciplinary perspectives are needed (Turnheim et al. 2015; Geels et
 3 al. 2016; Hof et al. 2020). Beyond aggregated economic perspectives on dynamics (1.7.1.2), these
 4 emphasise the multiple actors and processes involved.

5

6

7

Figure 1.6: Transition dynamics: levels, policies and processes

8

Note: The lower panel illustrates growth of innovative technologies or practices, which if successful emerge from niches into an S-shape dynamic of exponential growth. The diffusion stage often involves new infrastructure and reconfiguration of existing market and regulatory structures (known in the literature as the “socio-technical regime”). During the phase of more widespread diffusion; growth levels off to linear, then slows as the industry and market matures. The processes displace incumbent technologies/practices which decline, initially slowly but then at an accelerating pace. Many related

12

13

1 **literatures identify three main levels with different characteristics, most generally termed micro, meso**
2 **and macro. Transitions can be accelerated by policies appropriately targeted, which may be similarly**
3 **grouped and sequenced (upper panel) in terms of corresponding three pillars of policy (Section 1.7.3);**
4 **generally all are relevant, but their relative importance differs according to stage of the transition.**

5
6 *Technological Innovation Systems (TIS)* frameworks (chapter 16.4) focus on processes and policies of
7 early innovation and ‘emergence’, which combine experimentation and commercialisation, involving
8 *Strategic Niche Management* (Rip and Kemp 1998; Geels and Raven 2006). Literatures on the wider
9 processes of transition highlight different stages (eg. Cross-Chapter box 12 in Chapter 16) and scales
10 across three main levels, most generally termed *micro, meso and macro* (Rotmans et al. 2001).

11 The widely-used ‘*Multi-Level Perspective*’ or MLP (Geels 2002) identifies the meso-level as the
12 established ‘socio-technical (ST) regime’, an set of interrelated sub-systems which define rules and
13 regulatory structures around existing technologies and practices. The micro level is an ecosystem of
14 varied niche alternatives, and overlaying the ST regime is a macro ‘landscape’ level. Transitions often
15 start with niche alternatives (Köhler et al. 2019; Grin et al. 2010), which may break through to wider
16 diffusion (second stage in Figure 1.8), especially if external landscape developments ‘create pressures
17 on the regime that lead to cracks, tensions and windows of opportunity’ (Geels 2010; Rotmans et al.
18 2001); an example is climate change putting sustained pressure on current regimes of energy production
19 and consumption (Kuzemko et al. 2016). There are continual interactions between landscape, regime
20 and niches, with varied implications for *Transition Management* (Loorbach 2010; Rotmans et al. 2001).

21 In contrast to standard economic metrics of marginal or smooth change (e.g. elasticities), transition
22 theories emphasise interdisciplinary approaches and the non-linear dynamics, social, economic and
23 environmental aspects of transitions to sustainability (Köhler et al. 2018; Cherp et al. 2018). This may
24 explain persistent tendencies to underestimate the exponential pace of change now being observed in
25 renewable electricity (Chapters 2, 6) and emerging in mobility (Chapter 10).

26 Recent decades have seen parallel broadening of economic perspectives and theories. Building also on
27 the New Institutional Economics literatures (Williamson 2000), Grubb et al. (2015) classify these into
28 three ‘domains of economic decision-making’ associated with different branches of economic theory,
29 respectively (1) *behavioural and organisational*; (2) *neoclassical and welfare*, and (3) *evolutionary and*
30 *institutional*. Like MLP, these are related to different social and temporal scales, as applied also in
31 studying the ‘adaptive finance’ in UK electricity transition (Hall et al. 2017). There are significant
32 differences but these approaches all point to understanding the characteristics of different actors,
33 notably, individuals/local actors; larger corporate organisations (public or private); and (mainly) public
34 authorities, each with different decision-making characteristics.

35 Sustainability may require purposeful actions at the different levels to foster the growth of sustainable
36 technologies and practices, including support for niche alternatives (Grin et al. 2010). The middle level
37 (established ‘socio-technical regime’) tends to resist major change, reforms generally involve pressures
38 from the other two levels. Thus, transitions can be accelerated by policies appropriately targeting
39 relevant actors at the different levels (Köhler et al. 2019), the foundations for “three pillars of policy”
40 (Grubb et al. 2014), which logically evolve in the course of transition (Figure 2.6a). Incumbent
41 industries have to adapt if they are to thrive within the growth of new systems. Policy may need to
42 balance existing socio-technical systems with strategic investment and institutional development of the
43 emerging niches (e.g. the maintenance of energy provision and energy security with the development
44 of renewables), and help manage declining industries (Koasidis et al. 2020).

1 There is usually a social dimension to such transitions. Key elements include capacity to transform
2 (Folke et al. 2010), planning, and interdisciplinarity (Woiwode 2013). The Second World War
3 demonstrated the extent to which crises can motivate (sometimes positive) change across complex
4 social and technical systems, including industry, and agriculture which then doubled its productivity
5 over 15 years (Roberts and Geels 2019b). In practice, climate change may involve a combination of
6 (reactive) transformational adaptation, and (proactive) societal transformation (Feola 2015), the latter
7 seen as reorientation (including values and norms) in a sustainable direction (Section 5.4 in Chapter 5),
8 including eg. ‘democratisation’ in energy systems (Sorman et al. 2020). Business change management
9 principles could be relevant to support positive social change (Stephan et al. 2016). Overall, effective
10 transitions rest on appropriate enabling conditions, which can also link socio-technical transitions to
11 broader development pathways (Cross-Chapter Box 12 in Chapter 16).

12 Transition theories tend to come from very different disciplines and approaches compared to either
13 economics or other social sciences, with less quantification, notwithstanding evolutionary and complex
14 system models (1.7.1.3). However, a few distinct types of quantitative models of ‘socio-technical
15 energy transition’ (Li et al. 2015) have emerged. For policy evaluation, transitions can be viewed as
16 processes in which dynamic efficiency (1.7.2) dominates over static allocative efficiency, with potential
17 ‘positive intervention points’ (Farmer et al. 2019). Given inherent uncertainties, there are obvious risks
18 (e.g. Alic and Sarewitz 2016). All this may make an evaluation framework of *risks and opportunities*
19 more appropriate than traditional cost-benefit (Mercure et al. 2021), and (drawing on lessons from
20 renewables and electric vehicles), create foundations for sector-based international ‘positive sum
21 cooperation’ in climate mitigation (Sharpe and Lenton 2021).

22 **1.7.4 Approaches from psychology and politics of changing course**

23 The continued increase in global emissions to 2019, despite three decades of scientific warnings of ever-
24 greater clarity and urgency, motivates growing attention in the literature to the psychological ‘faults of
25 our rationality’ (Bryck and Ellis 2016), and the political nature of climate mitigation.

26 **1.7.4.1 Psychological and behavioural dimensions**

27 AR5 emphasised that decision processes often include both deliberate (‘calculate the costs and
28 benefits’) and intuitive thinking, the latter utilising emotion- and rule-based responses that are
29 conditioned by personal past experience, social context, and cultural factors (e.g. Kahneman 2003), and
30 that laypersons tend to judge risks differently than experts - for example, ‘intuitive’ reactions are often
31 characterised by biases to status quo and aversion to perceived risks and ambiguity (Kahneman and
32 Tversky 1979). Many of these features of human reasoning create ‘psychological distance’ from climate
33 change (Spence et al. 2012; Marshall 2014). These can impede adequate personal responses, in addition
34 to the collective nature of the problem, where such problems can take the form of ‘uncomfortable
35 knowledge’, neglected and so becoming ‘Unknown knowns’ (Sarewitz 2020). These decision processes,
36 and the perceptions that shape them, have been studied through different lenses from psychology
37 (Weber 2016) to sociology (Guilbeault et al. 2018), and media studies (Boykoff 2011). Karlsson and
38 Gilek (2020) identify science denialism and ‘decision thresholds’ as key mechanisms of delay.

39 Experimental economics (Allcott 2011) also helps explain why cost-effective energy efficiency
40 measures or other mitigation technologies are not taken up as fast or as widely as the benefits might
41 suggest, including procrastination and inattention, as “we often resist actions with clear long-term
42 benefits if they are unpleasant in the short run.” (Allcott and Mullainathan 2010). Incorporating
43 behavioural and social dynamics in models is required particularly to better represent the demand side
44 (Nikas et al. 2020), eg. Safarzyńska (2018) demonstrates how behavioural factors change responses to
45 carbon pricing relative to other instruments. A key perspective is to eschew ‘either/or’ between

1 economic and behavioural frameworks, as the greatest effects often involve combining behavioural
2 dimensions (e.g. norms, social influence networks, convenience and quality assurance) with financial
3 incentives and information (Stern et al. 2010). Randomised, controlled field trials can help predict the
4 effects of behavioural interventions (Levitt and List 2009; McRae and Meeks 2016; Gillan 2017).
5 Chapter 5 explores both positive and negative dimensions of behaviour in more depth, including the
6 development of norms and interactions with the wider social context, with emphasis upon the services
7 associated with human wellbeing, rather than the economic activities per se.

8 **1.7.4.2 Socio-political and institutional approaches**

9 Political and institutional dynamics shape climate change responses in important ways, not least because
10 incumbent actors have frequently blocked climate policy (1.4.5). Institutional perspectives probe
11 networks of opposition (Brulle 2019) and emphasise that their ability to block - as well as the ability
12 of others to foster low carbon transitions - are structured by specific institutional forms across countries
13 (Lamb and Minx 2020). National institutions have widely been developed to promote traditionally
14 fossil-fuel based sectors like electricity and transport as key to economic development, contributing to
15 carbon lock-in (Seto et al. 2016) and inertia (Rosenschöld et al. 2014).

16 The influence of interest groups on policy-making varies across countries. Comparative political
17 economy approaches tend to find that countries where interests are closely coordinated by governments
18 ('coordinated market economies') have been able to generate transformative change more than those
19 with a more arms-length, even combative relationship between interest groups and governments
20 ('liberal market economies') (Lachapelle and Paterson 2013; Meckling 2018; Četković and Buzogány
21 2016; Zou et al. 2016). 'Developmental states' often have the capacity for strong intervention but any
22 low-carbon interventions may be overwhelmed by other pressures and very rapid economic growth
23 (Wood et al. 2020a).

24 Institutional features affecting climate policy include levels and types of democracy (Povitkina 2018),
25 electoral systems, or levels of institutional centralisation (federal vs unitary states, presidential vs
26 parliamentary systems) (Steurer and Clar 2018; Clulow 2019; Lachapelle and Paterson 2013). Countries
27 that have constructed an overarching architecture of climate governance institutions (e.g. cross-
28 department and multilevel coordination, and semi-autonomous climate agencies), are more able to
29 develop strategic approaches to climate governance needed to foster transformative change (Dubash
30 2021).

31 Access of non-governmental organisations (NGOs) to policy processes enables new ideas to be adopted,
32 but too close an NGO-government relation may stifle innovation and transformative action (Dryzek et
33 al. 2003). NGO campaigns on fracking (Neville et al. 2019) or divestment (Mangat et al. 2018) have
34 raised attention to ideas such as 'stranded assets' in policy arenas (Piggot 2018; Newell et al. 2020;
35 Paterson 2021; Green 2018). Attempts to depoliticise climate change may narrow the space for
36 democratic participation and contestation, thus impacting policy responses (Swyngedouw 2010, 2011;
37 Kenis and Lievens 2014). Some institutional innovations have more directly targeted enhanced public
38 deliberation and participation, notably in citizens' climate assemblies (Howarth et al. 2020) and in the
39 use of legal institutions to litigate against those opposing climate action (Peel and Osofsky 2020). This
40 literature shows that transformative pathways are possible within a variety of institutional settings,
41 although institutional innovation will be necessary everywhere to pursue zero carbon transitions; see
42 also Chapters 4 (Section 4) and 13.

43 Balancing the forces outlined in Section 4.6 in Chapter 4 typically involves building coalitions of actors
44 who benefit economically from climate policy (Levin et al. 2012). Policy stability is critical to enabling
45 long-term investments in decarbonisation (Rietig and Laing 2017; Rosenbloom et al. 2018). Policy

1 design can encourage coalitions to form, that sustain momentum by supporting further policy
2 development to accelerate decarbonisation (Roberts et al. 2018), for example by generating
3 concentrated benefits to coalition members (Millar et al. 2020; Bernstein and Hoffmann 2018; Meckling
4 2019), as with renewable feed-in-tariffs (FiTs) in Germany (Michaelowa et al. 2018). Coalitions may
5 also be sustained by overarching framings, especially to involve actors (e.g. NGOs) for whom the
6 benefits of climate policy are not narrowly economic. However policy design can also provoke
7 coalitions to oppose climate policy, as in the FiT programme in Ontario (Stokes 2013; Raymond 2020)
8 or the yellow vest protests against carbon taxation in France (Berry and Laurent 2019). The ‘just
9 transitions’ frame can thus also be understood in terms of coalition-building, as well as ethics, as the
10 pursuit of low carbon transitions which spread the economic benefits broadly, through ‘green jobs’, and
11 the redistributive policies embedded in them both nationally and globally (Healy and Barry 2017;
12 Winkler 2020). Appropriate policy design will be different at different stages of the transition process
13 (Meckling et al. 2017; Breetz et al. 2018).

14 *Integration.* Politics is ultimately the way in which societies make decisions – which in turn, reflect
15 diverse forces and assumed frameworks. Effective policy requires understandings which combine
16 economic efficiency, ethics and equity, the dynamics and processes of large-scale transitions, and the
17 role of psychology and politics. No one framework is adequate to such a broad-ranging goal, nor are
18 single tools. Chapter 13 (Figure 13.6) presents a ‘framing’ table for policy instruments depending on
19 the extent to which they focus on mitigation *per se* or wider socio-economic development, and whether
20 they aim to shift marginal incentives or drive larger transitions. Holistic analysis needs to bridge
21 modelling, qualitative transition theories illuminated by case studies, and practice-based action research
22 (Geels et al. 2016).

23 These analytic frameworks also point to arenas of potential synergies and trade-offs (when broadly
24 known), and opportunities and risks (when uncertainties are greater), associated with mitigation. This
25 offers theoretical foundations for mitigation strategies which can also generate co-benefits. Climate
26 policy may help to motivate policies with beneficial synergies (such as the consumer cost savings from
27 energy efficiency, better forest management, transitions to cleaner vehicles) and opportunities (such as
28 stimulating innovation), by focusing on options for which the positives outweigh the negatives, or can
29 be made to through smart policy (e.g. Karlsson et al. 2020). More broadly, climate concerns may help
30 to attract international investment, and help overcoming bureaucratic or political obstacles to better
31 policy, to support synergies between mitigation, adaptation, and other SDGs, a foundation for shifting
32 development pathways towards sustainability (Section 1.6.1; Chapter 17)

Table 1.2: Potential for net co-benefits arising from synergies and trade-offs, opportunities and risks

	Positives	Negatives
Broadly known (e.g. air pollution, distributional)	Synergies	Trade-offs
Deep uncertainties (e.g. radical innovations)	Opportunities	Risks
	Select options with maximum synergies, and foster and exploit opportunities	Ameliorate trade-offs (e.g. revenue redistribution), and minimize or allocate risks appropriately
	↑ ↑ ↑ ↑ ↑ ↑ ↑ ↑ ↑ ↑ Net co-benefits from appropriate mitigation choices	

1.8 Feasibility and multi-dimensional assessment of mitigation

1.8.1 Building on the SR1.5 assessment framework: feasibility and enabling conditions

While previous ARs dealt with the definition of alternative mitigation pathways mostly exploring the technological potentials, latest research focused on what kind of mitigation pathways are feasible in a broader sense, underlining the multi-dimensional nature of the mitigation challenge. Building on frameworks introduced by Majone (1975) and Gilabert and Lawford-Smith (2012), SR1.5 introduced multi-dimensional approaches to analysing ‘feasibility’ and ‘enabling conditions’, which AR6 develops and applies broadly in relation to six ‘dimensions of feasibility assessment’ (Figure 1.7). Two reflect the physical environment:

- *Geophysical*, not only the global risks from climate change but also, for technology assessment, the global availability of critical resources;
- *Environmental & ecological*, including local environmental constraints and co-benefits of different technologies and pathways

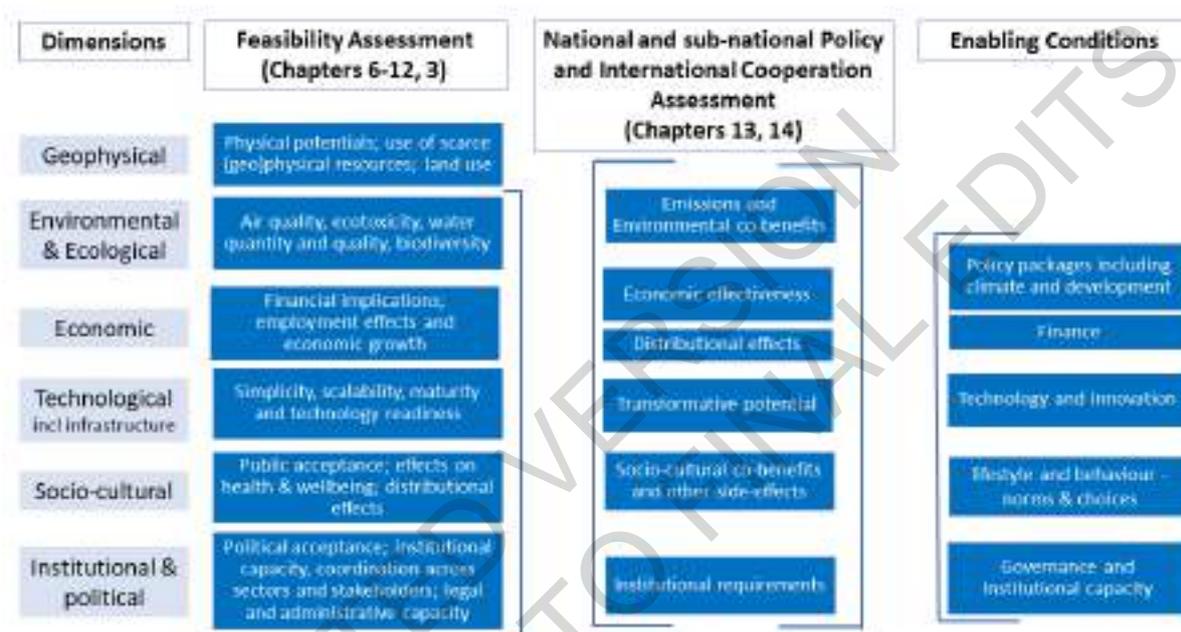

The other four dimensions correspond broadly to the four Analytic Frameworks outlined in Section 1.7:

- *Economic*, particularly aggregate economic and financial indicators, and SDGs reflecting different stages and goals of economic development;
- *Socio-cultural*, including particularly ethical and justice dimensions, and social and cultural norms;
- *Technological*, including innovation needs and transitional dynamics associated with new and emergent technologies and associated systems; and
- *Institutional & political*, including political acceptability, legal and administrative feasibility, and the capacity and governance requirements at different levels to deliver sustained mitigation in the wider context of sustainable development.

1 AR6 emphasises that all pathways involve different challenges and require choices to be made.
 2 Continuing ‘business as usual’ is still a choice, which in addition to the obvious geophysical risks,
 3 involves not making best use of new technologies, risks of future stranded assets, greater local pollution,
 4 and multiple other environmental threats.

5 The dimensions as listed provide a basis for this assessment both in the sectoral chapters (6-11),
 6 providing a common framework for cross-sectoral assessment detailed further in chapter 12, and in the
 7 evaluation of global pathways (Section 3.2 in Chapter 3). More specific indicators under each of these
 8 dimensions offer consistency in assessing the challenges, choices, and enabling requirements facing
 9 different aspects of mitigating climate change.

10

11

12

Figure 1.7: Feasibility and related dimensions of assessment

13

14 Figure 1.7 also illustrates variants on these dimensions appropriate for evaluating domestic and
 15 international policies (Chapters 13 and 14). The SR1.5 (Section 4.4 in Chapter 4) also introduced a
 16 framework of ‘*Enabling Conditions for systemic change*’, which as illustrated also has key dimensions
 17 in common with those of our feasibility assessment. In AR6 these enabling conditions are applied
 18 particularly in the context of shifting developments pathways (Chapter 4.4).

19 Some fundamental criteria may span across several dimensions. Most obviously, issues of ethics and
 20 equity are intrinsic to the economic, socio-cultural (values, including intergenerational justice) and
 21 institutional (e.g., procedural justice) dimensions. Geopolitical issues could also clearly involve several
 22 dimensions, e.g., concerning the politics of international trade, finance and resource distribution
 23 (economic dimension); international vs nationalistic identity (socio-cultural); and multilateral
 24 governance (institutional).

25 In this report, chapters with a strong demand-side dimension also suggest a simple policy hierarchy,
 26 reflecting that avoiding wastage – demands superfluous to human needs and wants – can carry benefits
 27 across multiple indicators. Consequently, chapters 5 and 10 organise key actions in a hierarchy of **Avoid**

1 (unnecessary demand) – **Shift** (to less resource-intensive modes) - **Improve** (technologies for existing
2 modes), with a closely-related policy hierarchy in Chapter 9 (buildings).

3 **1.8.2 Illustrations of multi-dimensional assessment: lock-in, policies and ‘just** 4 **transition’**

5 The rest of this section illustrates briefly how such multi-dimensional assessment, utilising the
6 associated analytic frameworks, can shed light on a few key issues which arise across many chapters of
7 this assessment.

8 **‘Carbon Lock-in’.** The continued rise of global emissions reflects in part the strongly *path-dependent*
9 nature of socio-economic systems, which implies a historic tendency to ‘carbon lock-in’ (Unruh 2000).
10 An interdisciplinary review (Seto et al. 2016) identifies a dozen main components organised into four
11 types, across the relevant Dimensions of Assessment as summarised in Table 1.3.

12 **Table 1.3: Carbon lock-in – types and key characteristics**

13 Source: Adapted from (Seto et al. 2016)

Lock-in type	Key characteristics
Economic	<ul style="list-style-type: none"> - Large investments with long lead-times and sunk costs, made on basis of anticipated use of resources, capital, and equipment to pay back the investment and generate profits - Initial choices account for private but not social costs and benefits
Socio-cultural, equity and behaviour	<ul style="list-style-type: none"> - Lock-in through social structure (e.g., norms and social processes) - Lock-in through individual decision making (e.g., psychological processes) - Single, calculated choices become a long string of non-calculated and self-reinforcing habits which are- Interrupting habits is difficult but possible (e.g., family size, thermostat setting) to change - Individuals and communities become dependent on fossil-fuel economy, meaning that change may have adverse distributional impacts
Technology and infrastructure	<ul style="list-style-type: none"> - Learning-by-doing and scale effects, including cumulative nature of innovation, reinforces established technologies - Interaction of technologies and networks (physical, organisational, financial) on which they depend - Random, unintentional events including network and learning effect final outcomes (e.g., Lock-in to the QWERTY keyboard)
Institutional & political	<ul style="list-style-type: none"> - Powerful economic, social, and political actors seek to reinforce status quo that favours their interests - Laws and Institutions, including regulatory structures, are designed to stabilise and lock -in also to provide long-term predictability (socio-technical regimes in transition theories) - Beneficial and intended outcomes for some actors - Not random chance but intentional choice (e.g., support for renewable electricity in Germany) can develop political consistencies that reinforce a direction of travel

14
15 Along with the long lifetime of various physical assets detailed in AR5, AR6 underlines the exceptional
16 degree of path-dependence in urban systems (Chapter 8) and associated buildings (9) and transport (10)
17 sectors, but it is a feature across almost all the major emitting sectors. The (typically -expected)
18 operating lifetimes of existing carbon-emitting assets would involve anticipated emissions (often but
19 inaccurately called ‘committed’ emissions in the literature), substantially exceeding the remaining

1 carbon budgets associated with 1.5C pathways (Chapter 2.7). Ongoing GHG-intensive investments,
2 including those from basic industrialisation in poorer countries, are adding to this.

3 The fact that investors anticipate a level of fossil fuel use that is not compatible with severe climate
4 constraints creates a clear risk of ‘*stranded assets*’ facing these investors (Box 6.2), and others who
5 depend on them, which itself raises issues of equity. A multi-dimensional / multi-framework assessment
6 helps to explain why such investments have continued, even in rich countries, and the consequent risks,
7 and the complexity of shifting such investments in all countries. It may also inform approaches that
8 could exploit path-dependence in clean energy systems, if there is sufficient investment in building up
9 the low-GHG industries, infrastructures and networks required.

10 **Carbon pricing.** Appraisal of policy instruments also requires such multi-dimensional assessment.
11 Stern’s (2007) reference to climate change as “the greatest market failure in history” highlights that
12 damages inflicted by climate change are not properly costed in most economic decision-making.
13 Economic perspectives emphasise the value of removing fossil-fuel subsidies, and pricing emissions to
14 ‘internalise’ in economic decision-making the ‘external’ damages imposed by GHG emissions, and/or
15 to meet agreed goals. Aggregate economic frameworks generally indicate carbon pricing (on principles
16 which extend to other gases) as the most cost-effective way to reduce emissions, notwithstanding
17 various market failures which complicate this logic.⁹ The High Level Commission on carbon pricing
18 (Stern and Stiglitz 2017) estimated an appropriate range as USD40-80/tCO₂ in 2020, rising steadily
19 thereafter. In practice the extent and level of carbon pricing implemented to date is far lower than this
20 or than most economic analyses now recommend (Section 3.6.1 in Chapter 3), and nowhere is carbon
21 pricing the only instrument deployed.

22 A socio-cultural and equity perspective emphasises that the faith in and role of markets varies widely
23 between countries – many energy systems do not in fact operate on a basis of competitive markets – and
24 that because market-based carbon pricing involves large revenues transfers, it must also contend with
25 major distributional effects and political viability (Klenert et al. 2018; Prinn et al. 2017), both domestic
26 (Chapter 13) and international (Chapter 14). A major review (Maestre-Andrés et al. 2019) finds
27 persistent distributional concerns (rich incumbents have also been vocal in using arguments about
28 impacts on the poor (Rennkamp 2019), but suggests these may be addressed by combining
29 redistribution of revenues with support for low carbon innovation. Measures could include
30 redistributing the tax revenue to favour of low-income groups or differentiated carbon taxes (Metcalf
31 2009; Klenert and Mattauch 2016; Stiglitz 2019), including ‘dual track’ approaches (van den Bergh et
32 al. 2020). To an extent though, all these depend on levels of trust, and institutional capacity.

33 Technological and transitions perspectives in turn find carbon pricing incentives may only stimulate
34 incremental improvements, but other instruments may be much more effective for driving deeper
35 innovation and transitions (Chapters 14, 15, 16), whilst psychological and behavioural studies
36 emphasise many factors beyond only pricing (Sections 5.4.1 and 5.4.2 in Chapter 5). In practice, a wide
37 range of policy instruments are used (Chapter 13).

38 Finally, in economic theory, negotiations on a common carbon price (or other common policies) may
39 have large benefits (less subject to ‘free riding’) compared to a focus on negotiating national targets
40 (Cramton et al. 2017a). The fact that this has never even been seriously considered (outside some efforts
41 in the EU) may reflect the exceptional sovereignty sensitivities around taxation and cultural differences
42 around the role of markets. However, carbon pricing concepts can be important outside of the traditional

FOOTNOTE⁹ Beyond GHG externalities, Stern (2015) lists such market failures as; inadequate R&D; failures in risk/capital markets; network effects creating coordination failures; wider information failures; and co-benefits.

1 market ('tax or trading') applications. A 'social cost of carbon' can be used to evaluate government and
2 regulatory decisions, to compensate for inadequate carbon prices in actual markets, and by companies
3 to reflect the external damage of their emissions and strategic risks of future carbon controls (Zhou and
4 Wen 2020). An agreed 'social value of mitigation activities' could form a basic index for underwriting
5 risks in low carbon investments internationally (Hourcade et al. 2021a).

6 Thus, practical assessment of carbon pricing inherently needs multi-dimensional analysis. The realities
7 of political economy and lobbying have to date severely limited the implementation of carbon pricing
8 (Mildenberger 2020), leading some social scientists to ask 'Can we price carbon?' (Rabe 2018). Slowly
9 growing adoption (World Bank 2019) suggests "yes", but only through complex evolution of efforts: a
10 study of 66 implemented carbon pricing policies show important effects of regional clustering,
11 international processes, and seizing political windows of opportunity (Skovgaard et al. 2019).

12 **Just Transitions.** Finally, whilst 'transition' frameworks may explain potential dynamics that could
13 transform systems, a multi-dimensional/multi-framework assessment underlines the motivation for 'just
14 transitions' (see subsection 1.6.2.3 in this chapter and section 4.5 in Chapter 4). This can be defined as
15 a transition from a high-carbon to a low-carbon economy which is considered sufficiently equitable for
16 the affected individuals, workers, communities, sectors, regions and countries (Jasanoff 2018; Newell
17 and Mulvaney 2013). As noted, sufficient equity is not only an ethical issue but an enabler of deeper
18 ambition for accelerated mitigation (Hoegh-Guldberg et al. 2019; Klinsky and Winkler 2018;
19 Urpelainen and Van de Graaf 2018). Perception of fairness influences the effectiveness of cooperative
20 action (Winkler et al. 2018), and this can apply to affected individuals, workers, communities, sectors,
21 regions and countries (Newell and Mulvaney 2013; Jasanoff 2018).

22 A 'just transitions' framing can also enable coalitions which integrate low carbon transformations with
23 concerns for climate adaptation (Patterson et al. 2018). All this explains the emergence of 'just transition
24 Commissions' in several of the more ambitious developed countries and complex social packages for
25 coal phase-out in Europe (Section 4.5 in Chapter 4; Sovacool et al. 2019; Green and Gambhir 2020), as
26 well as reference to the concept in the PA and its emphasis in the Talanoa dialogue and Silesia
27 declaration (1.2.2).

28 Whilst the broad concepts of 'just transition' have roots going back decades, its specific realisation in
29 relation to climate change is of course complex: Section 5 in Chapter 4 identifies at least eight distinct
30 elements proposed in the literature, even before considering the international dimensions.

32 1.9 Governing climate change

33 Previous sections have highlighted the multiple factors that drive and constrain climate action, the
34 complex interconnection between climate mitigation and other societal objectives, and the diversity of
35 analytical frames for interpreting these connections. Despite the complexities, there are signs of
36 progress including increased societal awareness, change in social attitudes, policy commitments by a
37 broad range of actors and sustained emission reductions in some jurisdictions. Nevertheless, emission
38 trends at the global level remains incompatible with the goals agreed in the Paris Agreement.
39 Fundamentally, the challenge of how best to urgently scale up and speed-up the climate mitigation effort
40 at all scales –from local to global – to the pace needed to address the climate challenge is that of
41 governance understood as 'modes and mechanisms to steer society' (Jordan et al. 2015). The concept
42 of governance encompasses the ability to plan and create the organisations needed to achieve a desired
43 goal (Güney 2017) and the process of interaction among actors involved in a common problem for
44 making and implementing decisions (Hufty 2012; Kooiman 2003).

1 Climate change governance has been projected as conscious transformation at unprecedented scale and
2 speed involving a contest of ideas and experimentation across scales of authority and jurisdiction
3 (Hildén et al. 2017; Laakso et al. 2017; Gordon 2018; van der Heijden 2018; Kivimaa et al. 2017). Yet,
4 there remains a sense that achieving the urgent transition to a low carbon, climate resilient and
5 sustainable world requires significant innovation in governance (Hoffmann 2011; Stevenson and
6 Dryzek 2013; Aykut 2016).

7 Starting from an initial focus on multilateral agreements, climate change governance has long evolved
8 into a complex polycentric structure that spans from the global to national and sub-national levels, with
9 “multiple parallel initiatives involving a range of actors at different levels of governance” (Okereke et
10 al. 2009) and relying on both formal and informal networks and policy channels channels (Bulkeley et
11 al. 2014; Jordan et al. 2015). At the international level, implementation of the Paris Agreement and the
12 UNFCCC more broadly is proceeding in parallel with other activities in an increasingly diverse
13 landscape of loosely coordinated institutions, constituting ‘regime complex’ (Keohane and Victor
14 2011), and new cooperative efforts demonstrate an evolution in the shifting authority given to actors at
15 different level of governance (Chan et al. 2018).

16 Multi-level governance has been used to highlight the notion that the processes involved in making and
17 implementing decisions on climate change is no longer the exclusive preserve of government actors but
18 rather involve a range of non-nation state actors such as cities, businesses, and civil society
19 organisations (Bäckstrand et al. 2017; Jordan et al. 2018; IPCC 2014a Chapter 13, 13.3.1 and 13.5.2).
20 Increased multi-level participation of subnational actors, along with a diversity of other transnational
21 and non-state actors have helped to facilitate increased awareness, experimentation, innovation,
22 learning and achieving benefits at multiple scales. Multi-level participation in governance systems can
23 help to build coalitions to support climate change mitigation policies (Roberts et al. 2018) and
24 fragmentation has the potential to take cooperative and even synergistic forms (Biermann et al. 2009)

25 However, there is no guarantee that multilevel governance can successfully deal with complex human-
26 ecological systems (Biermann et al. 2017; York et al. 2005; Di Gregorio et al. 2019). Multi-level
27 governance can contribute to an extremely polarised discussion and policy blockage rather than
28 enabling policy innovation (Fisher and Leifeld 2019). Fragmented governance landscape may lead to
29 coordination and legitimacy gaps undermining the regime (Nasiritousi and Bäckstrand 2019).
30 Nevertheless, the realities of the ‘drivers and constraints’ detailed in Section 4 the “glocal” nature of
31 climate change, the divided authority in world politics, diverse preferences of public and private entities
32 across the spectrum, and pervasive suspicions of free riding, implying the challenge as how to
33 incrementally deepen cooperation in a polycentric global system, rather than seeking a single, integrated
34 governance (Keohane and Victor 2016).

35 Crucially, climate governance takes place in the context of embedded power relations, operating at
36 global, national and local context. Effective rules and institutions to govern climate change are more
37 likely to emerge when where power structures and interests favour action. However widespread and
38 enduring co-operation can only be expected to when the benefits outweigh the cost of cooperation and
39 when the interest of key actors are sufficiently aligned (Barrett 1994; Victor 2011; Finus and Rübhelke
40 2008; Tulkens 2019; Mainali et al. 2018). Investigating the distribution and role of hard and soft power
41 resources, capacities and power relations within and across different jurisdictional levels is therefore
42 important to uncover hindrances to effective climate governance (Marquardt 2017). Institutions at
43 international and national levels as also critical as they have the ability to mediate power and interest of
44 actors and sustain cooperation based on equity and fair rules and outcomes. Governance, in fact, helps
45 to align and moderate the interests of actors as well as to shift perceptions, including the negative,
46 burden-sharing narratives that often accompany discussion about climate action especially in

1 international negotiations. It is also useful for engaging the wider public and international networks in
2 imagining low carbon societies (e.g. Levy and Spicer 2013; Milkoreit 2017; Nikoleris et al. 2017;
3 Wapner and Elver 2017; Bengtsson Sonesson et al. 2019; Fatemi et al. 2020). Experimentation also
4 represents an important source of governance innovation and capability-formation, linked to global
5 knowledge and technology flows, which could reshape emergent socio-technical regimes and so
6 contribute to alternative development pathways (Berkhout et al. 2010; Roberts et al. 2018; Turnheim et
7 al. 2018; Lo and Castán Broto 2019).

9 **1.10 Conclusions**

10 Global conditions have changed substantially since the IPCCs Fifth Assessment in 2014. The Paris
11 Agreement and the SDGs provided a new international context, but global intergovernmental
12 cooperation has been under intense stress. Growing direct impacts of climate change are unambiguous
13 and movements of protest and activism – in countries and transnational organisations at many levels –
14 have grown. Global emissions growth had slowed but not stopped up to 2018/19, albeit with more
15 diverse national trends. Growing numbers of countries have adopted ‘net zero’ CO₂ and/or GHG
16 emission goals and decarbonisation or low carbon growth strategies, but the current NDCs to 2030
17 collectively would barely reduce global emissions below present levels (1.3.3).. An unfolding
18 technology revolution is making significant contributions in some countries, but as yet its global impact
19 is limited. Global climate change can only be tackled within, and if integrated with, the wider context
20 of sustainable development, and related social goals including equity concerns. Countries and their
21 populations have many conflicting priorities. Developing countries in particular have multiple urgent
22 needs associated with earlier stages of sustainable development as reflected in the non-climate SDGs.
23 Developed countries are amongst the most unsustainable in terms of overall consumption, but also face
24 social constraints particularly arising from distributional impacts of climate policies.

25 The assessment of the key drivers for, and barriers against mitigation undertaken in this chapter
26 underscore the complexity and multidimensional nature of climate mitigation. Historically, much of the
27 academic analysis of mitigating climate change, particularly global approaches, has focused on
28 modelling costs and pathways, and discussion about ‘optimal’ policy instruments. Developments since
29 AR5 have continued to highlight the role of a wide range of factors intersecting the political, economic,
30 social and institutional domains. Yet despite such complexities, there are signs of progress emerging
31 from years of policy effort in terms of technology, social attitudes, emission reductions in some
32 countries, with tentative signs of impact on the trajectory of global emissions. The challenge remains
33 how best to urgently scale up and speed-up the climate mitigation effort at all scales –from local to
34 global – to achieve the level of mitigation needed to address the problem as indicated by climate science.
35 A related challenge is how to ensure that mitigation effort and any associated benefits of action are
36 distributed fairly within and between countries and aligned to the overarching objective of global
37 sustainable development. Lastly, globally effective and efficient mitigation will require international
38 co-operation especially in the realms of finance, and technology.

39 Multiple frameworks of analytic assessment, adapted to the realities of climate change mitigation, are
40 therefore required. We identified four main groups. *Aggregate economic* frameworks – including
41 environmental costs or goals, and with due attention to implied behavioural, distributional and dynamic
42 assumptions - can provide insights about trade-offs, cost-effectiveness and policies for delivering
43 agreed goals. *Ethical frameworks* are equally essential to inform both international and domestic
44 discourse and decisions, including the relationship with international (and intergenerational)
45 responsibilities, related financial systems, and domestic policy design in all countries. Explicit

1 frameworks for analysing *transition and transformation* across multiple sectors need to draw on both
2 socio-technical transition literatures, and those on social transformation. Finally, literatures on
3 *psychology, behaviour and political sciences* can illuminate obstacles that have impeded progress to
4 date, and suggest ways to overcome them.

5 No single analytical framework, or single discipline, on its own can offer a comprehensive assessment
6 of climate change mitigation. Together they point to the relevance of growing literatures and discourses
7 on ‘just transitions’, and the role of governance at multiple levels. Ultimately all these frameworks are
8 needed to inform the decisions required to deepen and connect the scattered elements of progress to
9 date, and hence accelerate progress towards agreed goals and multiple dimensions of climate change
10 mitigation in the context of sustainable development.

12 **1.11 Knowledge gaps**

13 Despite huge expansion in the literature (Callaghan et al. 2020), knowledge gaps remain. Modeling still
14 struggles to bring together detailed physical and economic climate impacts and mitigation, with limited
15 representation of financial and distributional dynamics. There are few interdisciplinary tools which
16 apply theories of transition and transformation to questions of economic and social impacts,
17 compounded by remaining uncertainties concerning the role of new technological sets, international
18 instruments, policy and political evaluation.

19 One scan of future research needs suggests three priority areas (Roberts et al. 2020); 1. Human welfare
20 focused development (e.g. reducing inequality), 2. How the historic position of states within
21 international power relations conditions their ability to respond to climate change, 3. Transition
22 dynamics and the flexibility of institutions to drive towards low carbon development pathways. There
23 remain gaps in understanding how international dynamics and agreements filter down to affect
24 constituencies and local implementation. Literature on the potential for supply side agreements, in
25 which producers agree to restrict the supply of fossil fuels (e.g. Asheim et al. 2019) is limited but gaining
26 increasing academic attention.

27 Nature is under pressure both at land and at sea as demonstrated by declining biodiversity (IPBES
28 2019). Climate policies could increase the pressure on land and oceans (see IPCC 2019c,b), with
29 insufficient attention to relationships between biodiversity and climate agreements and associated
30 policies. IPBES aims to coordinate with the IPCC more directly, but literature will be required to
31 support these reports.

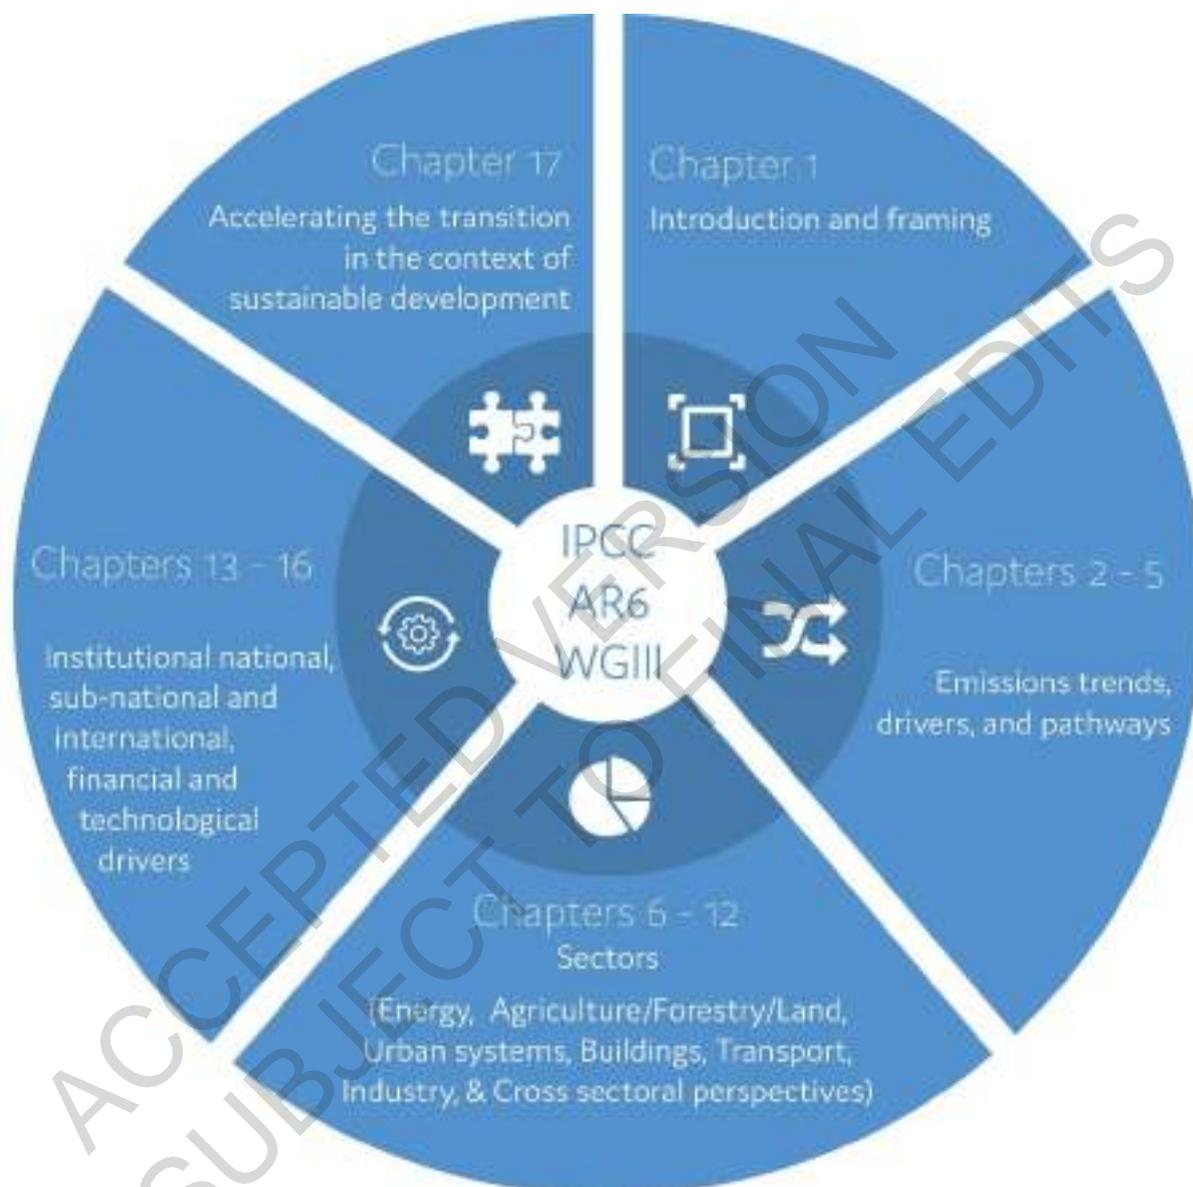

32 Compounding these gaps is the fact that socially oriented, agriculture-related options, where human and
33 non-human systems intersect most obviously, remain under-researched (e.g. Balasubramanya and Stifel
34 2020). Efforts to engage with policies here, especially framed around ecosystem services, have often
35 neglected their “practical fitness” in favor of focusing on their “institutional fitness”, which needs to be
36 addressed in future research (Stevenson et al. 2021).

37 The relative roles of short-term mitigation policies and long-term investments, including government
38 and financial decision-making tools, remains inadequately explored. Strategic investments may include
39 city planning, public transport, EV charging networks, and CCU/CCS. Understanding how international
40 treaties can increase incentives to make such investments is all the more salient in the aftermath of
41 COVID-19, on which research is necessarily young but rapidly growing. Finally, the economic,
42 institutional and political strategies to close the gap between NDCs, actual implementation, and
43 mitigation goals– informed by the PA and the UNFCCC Global Stocktake – require much further
44 research.

1 1.12 Roadmap to the Report

2 This Sixth Assessment Report covers Mitigation in five main parts (**Figure 1.8**), namely: introduction
3 and frameworks; emission trends, scenarios and pathways; sectors; institutional dimensions including
4 national and international policy, financial and technological mitigation drivers; and conclusions.

5

6

7

Figure 1.8: The Structure of AR6 Mitigation Report

8 Chapters 2-5 cover the big picture trends, drivers and projections at national and global levels. (2)
9 analyses emission trends and drivers to date. (3) presents long-term global scenarios, including the
10 projected economic and other characteristics of mitigation through to balancing of sources and sinks
11 through the second half this century, and the implications for global temperature change and risks. (4)
12 explores the shorter-term prospects including NDCs, and the possibilities for accelerating mitigation
13 out to 2050 in the context of sustainable development at the national, regional and international scales.

(5), a new chapter for IPCC Assessments, focuses upon the role of services and derived demand for energy and land use, and the social dimensions.

Chapters 6-12 examine sectoral contributions and possibilities for mitigation. (6) summarises characteristics and trends in the energy sector, specifically supply, including the remarkable changes in the cost of some key technologies since AR5; (7) examines the roles of AFOLU, drawing upon and updating the recent Special Report, including the potential tensions between the multiple uses of land; (8) presents a holistic view of the trends and pressures of urban systems, as both a challenge and an opportunity for mitigation; Chapters 9 and 10 then examine two sectors which entwine with, but go well beyond, urban systems: buildings (9) including construction materials and zero carbon buildings; and transport (10), including shipping and aviation and a wider look at mobility as a general service; (11) explores the contribution of industry, including supply chain developments, resource efficiency/circular economy, and the cross-system implications of decarbonisation for industrial systems; finally (12) takes a cross-sectoral perspective and explores cross-cutting issues like the interactions of biomass energy, food and land, and carbon dioxide removal.

Four chapters then review thematic issues in implementation and governance of mitigation. (13) explores national and sub-national policies and institutions, bringing together lessons of policies examined in the sectoral chapters, as well as insights from service and demand-side perspectives (5), along with governance approaches and capacity-building, and the role and relationships of sub-national actors. (14) then considers the roles and status of international cooperation, including the UNFCCC agreements and international institutions, sectoral agreements and multiple forms of international partnerships, and the ethics and governance challenges of Solar Radiation Modification. (15) explores investment and finance, including current trends, the investment needs for deep decarbonisation, and the complementary roles of public and private finance. This includes climate-related investment opportunities and risks (e.g. 'stranded assets'), linkages between finance and investments in adaptation and mitigation; and the impact of COVID-19. A new chapter on innovation (16) looks at technology development, accelerated deployment and global diffusion as systemic issues that hold potential for transformative changes, and the challenges of managing such changes at multiple levels including the role of international cooperation.

Finally, (17) considers Accelerating the transition in the context of sustainable development, including practical pathways for joint responses to climate change and sustainable development challenges. This includes major regional perspectives, mitigation-adaptation interlinkages, and enabling conditions including the roles of technology, finance and cooperation for sustainable development.

Frequently Asked Questions (FAQs)

FAQ 1.1 What is climate change mitigation?

Climate change mitigation refers to actions or activities that limit emissions of GHGs from entering the atmosphere and/or reduce their levels in the atmosphere. Mitigation includes reducing the GHGs emitted from energy production and use (eg. that reduces use of fossil fuels) and land use, and methods to mitigate warming eg. by carbon sinks which remove emissions from the atmosphere through land use or other (including artificial) mechanisms (See section 12.3, 14.4.5; see WGI for physical science, and Chapter 7 for AFOLU mitigation).

The ultimate goal of mitigation is to preserve a biosphere which can sustain human civilisation and the complex of ecosystem services which surround and support it. This means reducing anthropogenic GHGs emissions towards net zero to limit the warming, with global goals agreed in the Paris

1 Agreement. Effective mitigation strategies require an understanding of mechanisms that underpin
2 release of emissions, and the technical, policy and societal options for influencing these

3 **FAQ 1.2 Which Greenhouse Gasses (GHGs) are relevant to which sectors?**

4 Anthropogenic GHGs such as carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O), and
5 fluorinated gases (e.g. hydrofluorocarbons, perfluorocarbons, Sulphur hexafluoride) are released from
6 various sources. CO₂ makes the largest contribution to global GHG emissions; but some have extremely
7 long atmospheric lifetimes extending to tens of thousands of years, such as F gases (Chapter 2).

8 Different combinations of gases are emitted from different activities. The largest source of CO₂ is
9 combustion of fossil fuels in energy conversion systems like boilers in electric power plants, engines in
10 aircraft and automobiles, and in cooking and heating within homes and businesses (approximately 64%
11 of emissions, Figure SPM.2). Fossil fuels are also a major source of methane (CH₄), the second biggest
12 contributor to global warming. While most GHGs come from fossil fuel combustion, about one quarter
13 comes from land-related activities like agriculture (mainly CH₄ and N₂O) and deforestation (mainly
14 CO₂), with additional emissions from industrial processes (mainly CO₂, N₂O and F-gases), and
15 municipal waste and wastewater (mainly CH₄) (2). In addition to these emissions, black carbon – an
16 aerosol that is, for example, emitted during incomplete combustion of fossil fuels – contributes to
17 warming of the Earth’s atmosphere, whilst some other short-lived pollutants temporarily cool the
18 surface (IPCC WG1 Chapter 6.5.4.3).

19 **FAQ 1.3 What is the difference between “net zero emissions” and “carbon neutrality”?**

20 Annex I states that “carbon neutrality and net zero CO₂ emissions are overlapping concepts” which
21 “can be applied at the global or sub-global scales (e.g., regional, national and sub-national)”. At the
22 global scale the terms are equivalent. At sub-global scales, net-zero CO₂ typically applies to emissions
23 under direct control or territorial responsibility of the entity reporting them (e.g. a country, district or
24 sector); while carbon neutrality is also applied to firms, commodities and activities (e.g. a service or an
25 event) and generally includes emissions and removals beyond the entity’s direct control or territorial
26 responsibility, termed ‘Scope 3’ or ‘value chain emissions’ (Bhatia et al. 2011).

27 This means the emissions and removals that should be included are wider for ‘neutrality’ than for net-
28 zero goals, but also that offset mechanisms could be employed to help achieve neutrality through
29 abatement beyond what is possible under the direct control of the entity. Rules and environmental
30 integrity criteria are intended to ensure additionality and avoid double counting of offsets consistent
31 with “neutrality” claims (see Annex I definitions of “Carbon neutrality” and “Offset” for detail and a
32 list of criteria).

33 While the term ‘carbon’ neutrality in this report is defined as referring specifically to CO₂ neutrality,
34 use of this term in practice can be ambiguous, as some users apply it to neutrality of all GHG emissions.
35 GHG neutrality means an entity’s gross emissions of all GHG must be balanced by the removal of an
36 equivalent amount of CO₂ from the atmosphere. This requires the selection of a suitable metric that
37 aggregates emissions from non-CO₂ gases, such as the commonly used GWP100 metric (for a
38 discussion of GHG metrics, see AR6 WG1 Box 1.3 and Cross-Chapter Box 2 in Chapter 2 of this
39 report).

1 Executive Summary

2 **Global net anthropogenic Greenhouse Gas (GHG) emissions during the last decade (2010-2019)**
3 **were higher than at any previous time in human history** (*high confidence*). Since 2010, GHG
4 emissions have continued to grow reaching 59 ± 6.6 GtCO₂eq in 2019¹, but the average annual growth
5 in the last decade (1.3%, 2010-2019) was lower than in the previous decade (2.1%, 2000-2009) (*high*
6 *confidence*). Average annual GHG emissions were 56 GtCO₂eqyr⁻¹ for the decade 2010-2019 growing
7 by about 9.1 GtCO₂eqyr⁻¹ from the previous decade (2000-2009) – the highest decadal average on record
8 (*high confidence*). {2.2.2, Table 2.1, Figure 2.5}

9 **Emissions growth has varied, but persisted across all groups of greenhouse gases** (*high*
10 *confidence*). The average annual emission levels of the last decade (2010-2019) were higher than in any
11 previous decade for each group of greenhouse gases (*high confidence*). In 2019, CO₂ emissions were
12 45 ± 5.5 GtCO₂,² CH₄ 11 ± 3.2 GtCO₂eq, N₂O 2.7 ± 1.6 GtCO₂eq and fluorinated gases (F-gases: HFCs,
13 PFCs, SF₆, NF₃) 1.4 ± 0.41 GtCO₂eq. Compared to 1990, the magnitude and speed of these increases
14 differed across gases: CO₂ from fossil fuel and industry (FFI) grew by 15 GtCO₂eqyr⁻¹ (67%), CH₄ by
15 2.4 GtCO₂eqyr⁻¹ (29%), F-gases by 0.97 GtCO₂eqyr⁻¹ (250%), N₂O by 0.65 GtCO₂eqyr⁻¹ (33%). CO₂
16 emissions from net land use, land-use change and forestry (LULUCF) have shown little long-term
17 change, with large uncertainties preventing the detection of statistically significant trends. F-gases
18 excluded from GHG emissions inventories such as *chlorofluorocarbons* and *hydrochlorofluorocarbons*
19 are about the same size as those included (*high confidence*). {2.2.1, 2.2.2, Table 2.1, Figure 2.2, Figure
20 2.3, Figure 2.5}

21 **Globally, GDP per capita and population growth remained the strongest drivers of CO₂ emissions**
22 **from fossil fuel combustion in the last decade** (*robust evidence, high agreement*). Trends since 1990
23 continued in the years 2010 to 2019 with GDP per capita and population growth increasing emissions
24 by 2.3% and 1.2% yr⁻¹, respectively. This growth outpaced the reduction in the use of energy per unit
25 of GDP (-2% yr⁻¹, globally) as well as improvements in the carbon intensity of energy (-0.3%yr⁻¹).
26 {2.4.1, Figure 2.19}

27 **The global COVID-19 pandemic led to a steep drop in CO₂ emissions from fossil fuel and industry**
28 (*high confidence*). Global CO₂-FFI emissions dropped in 2020 by about 5.8% (5.1% – 6.3%) or about
29 2.2 (1.9-2.4) GtCO₂ compared to 2019. Emissions, however, have rebounded globally by the end of
30 December 2020 (*medium confidence*). {2.2.2, Figure 2.6}

31 **Cumulative net CO₂ emissions of the last decade (2010-2019) are about the same size as the**
32 **remaining carbon budget for keeping warming to 1.5°C** (*medium confidence*). Cumulative net CO₂
33 emissions since 1850 are increasing at an accelerating rate. 62% of total cumulative CO₂ emissions
34 from 1850 to 2019 occurred since 1970 (1500 ± 140 GtCO₂), about 43% since 1990 (1000 ± 90 GtCO₂),
35 and about 17% since 2010 (410 ± 30 GtCO₂). For comparison, the remaining carbon budget for keeping
36 warming to 1.5°C with a 67% (50%) probability is about $400(500)\pm 220$ GtCO₂. {2.2.2, Figure 2.7;
37 WG1 5.5; WG1 Table 5.8}

38 **A growing number of countries have achieved GHG emission reductions longer than 10 years –**
39 **a few at rates that are broadly consistent with climate change mitigation scenarios that limit**

FOOTNOTE ¹ Emissions of GHGs are weighed by Global Warming Potentials with a 100-year time horizon (GWP100) from the Sixth Assessment Report (Forster et al., 2021). GWP-100 is commonly used in wide parts of the literature on climate change mitigation and is required for reporting emissions under the United Nations Framework Convention on Climate Change (UNFCCC). All metrics have limitations and uncertainties. (Cross-Chapter Box 2, Annex II, Part II, Section 8)

FOOTNOTE ² In 2019, CO₂ from fossil fuel and industry (FFI) were 38 ± 3.0 Gt, CO₂ from net land use, land-use change and forestry (LULUCF) 6.6 ± 4.6 Gt

1 **warming to well below 2°C** (*high confidence*). There are about 24 countries that have reduced CO₂
2 and GHG emissions for longer than 10 years. Reduction rates in a few countries have reached 4% in
3 some years, in line with rates observed in pathways that *likely* limit warming to 2°C. However, the total
4 reduction in annual GHG emissions of these countries is small (about 3.2 GtCO₂eqyr⁻¹) compared to
5 global emissions growth observed over the last decades. Complementary evidence suggests that
6 countries have decoupled territorial CO₂ emissions from Gross Domestic Product (GDP), but fewer
7 have decoupled consumption-based emissions from GDP. This decoupling has mostly occurred in
8 countries with high per capita GDP and high per capita CO₂ emissions. {2.2.3, 2.3.3, Figure 2.11, Table
9 2.3, Table 2.4}

10 **Consumption-based CO₂ emissions in developed countries and the Asia and Developing Pacific**
11 **region are higher than in other regions** (*high confidence*). In developed countries, consumption-based
12 CO₂ emissions peaked at 15 GtCO₂ in 2007, declining to about 13 GtCO₂ in 2018. The Asia and
13 Developing Pacific region, with 52% of current global population, has become a major contributor to
14 consumption-based CO₂ emission growth since 2000 (5.5% yr⁻¹ for 2000-2018); it exceeded the
15 developed countries region, which accounts for 16% of current global population, as the largest emitter
16 of consumption-based CO₂. {2.3.2, Figure 2.14}

17 **Carbon intensity improvements in the production of traded products have led to a net reduction**
18 **in CO₂ emissions embodied in international trade** (*robust evidence, high agreement*). A decrease in
19 the carbon intensity of traded products has offset increased trade volumes between 2006 and 2016.
20 Emissions embodied in internationally traded products depend on the composition of the global supply
21 chain across sectors and countries and the respective carbon intensity of production processes
22 (emissions per unit of economic output). {2.3, 2.4}

23 **Developed countries tend to be net CO₂ emission importers, whereas developing countries tend**
24 **to be net emission exporters** (*robust evidence, high agreement*). Net CO₂ emission transfers from
25 developing to developed countries via global supply chains have decreased between 2006 and 2016.
26 Between 2004 and 2011, CO₂ emission embodied in trade between developing countries have more
27 than doubled (from 0.47 to 1.1 Gt) with the centre of trade activities shifting from Europe to Asia.
28 {2.3.4, Figure 2.15}

29 **Emissions from developing countries have continued to grow, starting from a low base of per**
30 **capita emissions and with a lower contribution to cumulative emissions than developed countries**
31 (*robust evidence, high agreement*). Average 2019 per capita CO₂-FFI emissions in three developing
32 regions - Africa (1.2 tCO₂/cap), Asia and developing Pacific (4.4 tCO₂/cap), and Latin America and
33 Caribbean (2.7 tCO₂/cap) - remained less than half that of developed countries (9.5 tCO₂/cap) in 2019.
34 CO₂-FFI emissions in the three developing regions together grew by 26% between 2010 and 2019,
35 compared to 260% between 1990 and 2010, while in Developed Countries emissions contracted by
36 9.9% between 2010-2019 and by 9.6% between 1990-2010. Historically, the three developing regions
37 together contributed 28% to cumulative CO₂-FFI emissions between 1850 and 2019, whereas
38 Developed Countries contributed 57% and least developed countries contributed 0.4%. {2.2.3, Figure
39 2.9, Figure 2.10}

40 **Globally, GHG emissions continued to rise across all sectors and subsectors; most rapidly in**
41 **transport and industry** (*high confidence*). In 2019, 34% (20 GtCO₂eq) of global GHG emissions came
42 from the energy sector, 24% (14 GtCO₂eq) from industry, 22% (13 GtCO₂eq) from AFOLU, 15% (8.7
43 GtCO₂eq) from transport and 5.6% (3.3 GtCO₂eq) from buildings. Once indirect emissions from energy
44 use are considered, the relative shares of industry and buildings emissions rise to 34% and 17%,
45 respectively. Average annual GHG emissions growth during 2010-2019 slowed compared to the
46 previous decade in energy supply (from 2.3% to 1.0%) and industry (from 3.4% to 1.4%, direct
47 emissions only), but remained roughly constant at about 2% per year in the transport sector (*high*

1 *confidence*). Emission growth in AFOLU is more uncertain due to the high share of CO₂-LULUCF
2 emissions. {2.4.2, Figure 2.13, Figures 2.16 to 2.21}.

3 **Average annual growth in GHG emissions from energy supply decreased from 2.3% for 2000–**
4 **2009 to 1.0% for 2010–2019 (*high confidence*).** This slowing of growth is attributable to further
5 improvements in energy efficiency (annually, 1.9% less energy per unit of GDP was used globally
6 between 2010 and 2019). Reductions in global carbon intensity by -0.2% yr⁻¹ contributed further -
7 reversing the trend during 2000-2009 (+0.2% yr⁻¹) (*medium confidence*). These carbon intensity
8 improvement were driven by fuel switching from coal to gas, reduced expansion of coal capacity
9 particularly in Eastern Asia, and the increased use of renewables. {2.2.4, 2.4.2.1, Figure 2.17}

10 **GHG emissions in the industry, buildings and transport sectors continue to grow, driven by an**
11 **increase in the global demand for products and services (*high confidence*).** These final demand
12 sectors make up 44% of global GHG emissions, or 66% when the emissions from electricity and heat
13 production are reallocated as indirect emissions to related sectors, mainly to industry and buildings.
14 Emissions are driven by the large rise in demand for basic materials and manufactured products, a global
15 trend of increasing floor space per capita, building energy service use, travel distances, and vehicle size
16 and weight. Between 2010-2019, domestic and international aviation were particularly fast growing at
17 average annual rates of +3.3% and +3.4%. Global energy efficiencies have improved in all three demand
18 sectors, but carbon intensities have not. {2.2.4; Figure 2.18; Figure 2.19; Figure 2.20}.

19 **Providing access to modern energy services universally would increase global GHG emissions by**
20 **at most a few percent (*high confidence*).** The additional energy demand needed to support decent
21 living standards³ for all is estimated to be well below current average energy consumption (*medium*
22 *evidence, high agreement*). More equitable income distributions can reduce carbon emissions, but the
23 nature of this relationship can vary by level of income and development (*limited evidence, medium*
24 *agreement*). {2.4.3}

25 **Evidence of rapid energy transitions exists, but only at sub-global scales (*medium evidence, medium***
26 ***agreement*).** Emerging evidence since AR5 on past energy transitions identifies a growing number of
27 cases of accelerated technology diffusion at sub-global scales and describes mechanisms by which
28 future energy transitions may occur more quickly than those in the past. Important drivers include
29 technology transfer and cooperation, intentional policy and financial support, and harnessing synergies
30 among technologies within a sustainable energy system perspective (*medium evidence, medium*
31 *agreement*). A fast global low-carbon energy transition enabled by finance to facilitate low-carbon
32 technology adoption in developing and particularly in least developed countries can facilitate achieving
33 climate stabilisation targets (*robust evidence, high agreement*). {2.5.2, Table 2.5}

34 **Multiple low-carbon technologies have shown rapid progress since AR5 – in cost, performance,**
35 **and adoption – enhancing the feasibility of rapid energy transitions (*robust evidence, high***
36 ***agreement*).** The rapid deployment and cost decrease of modular technologies like solar, wind, and
37 batteries have occurred much faster than anticipated by experts and modelled in previous mitigation
38 scenarios (*robust evidence, high agreement*). The political, economic, social, and technical feasibility
39 of solar energy, wind energy and electricity storage technologies has improved dramatically over the
40 past few years. In contrast, the adoption of nuclear energy and CO₂ capture and storage in the electricity
41 sector has been slower than the growth rates anticipated in stabilisation scenarios. Emerging evidence
42 since AR5 indicates that small-scale technologies (e.g. solar, batteries) tend to improve faster and be
43 adopted more quickly than large-scale technologies (nuclear, CCS) (*medium evidence, medium*
44 *agreement*). {2.5.3, 2.5.4, Figures 2.22 and 2.23}

FOOTNOTE ³ Decent Living Standards (DLS) – a benchmark of material conditions for human well-being – overlaps with many Sustainable Development Goals (SDGs). Minimum requirements of energy use consistent with enabling well-being for all is between 20 and 50 GJ cap-1 yr-1 depending on the context. {5.2.2, 5.2.2, Box 5.3, Figure 5.6}

1 **Robust incentives for investment in innovation, especially incentives reinforced by national policy**
2 **and international agreements, are central to accelerating low-carbon technological change** (*robust*
3 *evidence, medium agreement*). Policies have driven innovation, including instruments for technology
4 push (e.g., scientific training, R&D) and demand pull (e.g., carbon pricing, adoption subsidies), as well
5 as those promoting knowledge flows and especially technology transfer. The magnitude of the scale-up
6 challenge elevates the importance of rapid technology development and adoption. This includes
7 ensuring participation of developing countries in an enhanced global flow of knowledge, skills,
8 experience, equipment, and technology itself requires strong financial, institutional, and capacity
9 building support (*robust evidence, high agreement*). {2.5.4, 2.5, 2.8}

10 **The global wealthiest 10% contribute about 36-45% of global GHG emissions** (*robust evidence,*
11 *high agreement*). The global 10% wealthiest consumers live in all continents, with two thirds in high-
12 income regions and one third in emerging economies (*robust evidence, medium agreement*). The
13 lifestyle consumption emissions of the middle income and poorest citizens in emerging economies are
14 between 5-50 times below their counterparts in high-income countries (*medium evidence, medium*
15 *agreement*). Increasing inequality within a country can exacerbate dilemmas of redistribution and social
16 cohesion, and affect the willingness of rich and poor to accept lifestyle changes for mitigation and
17 policies to protect the environment (*medium evidence, medium agreement*) {2.6.1, 2.6.2, Figure 2.25}

18 **Estimates of future CO₂ emissions from existing fossil fuel infrastructures already exceed**
19 **remaining cumulative net CO₂ emissions in pathways limiting warming to 1.5°C with no or**
20 **limited overshoot** (*high confidence*). Assuming variations in historic patterns of use and
21 decommissioning, estimated future CO₂ emissions from existing fossil fuel infrastructure alone are 660
22 (460-890) GtCO₂ and from existing and currently planned infrastructure 850 (600-1100) GtCO₂. This
23 compares to overall cumulative net CO₂ emissions until reaching net zero CO₂ of 510 (330-710) Gt in
24 pathways that limit warming to 1.5°C with no or limited overshoot, and 880 (640-1160) Gt in pathways
25 that limit *likely* warming to 2°C (*high confidence*). While most future CO₂ emissions from existing and
26 currently planned fossil fuel infrastructure are situated in the power sector, most remaining fossil fuel
27 CO₂ emissions in pathways that limit likely warming to 2°C and below are from non-electric energy –
28 most importantly from the industry and transportation sectors (*high confidence*). Decommissioning and
29 reduced utilization of existing fossil fuel installations in the power sector as well as cancellation of new
30 installations are required to align future CO₂ emissions from the power sector with projections in these
31 pathways (*high confidence*). {2.7.2, 2.7.3, Figure 2.26, Table 2.6, Table 2.7}

32 **A broad range of climate policies, including instruments like carbon pricing, play an increasing**
33 **role in GHG emissions reductions**. The literature is in broad agreement, but the magnitude of the
34 reduction rate varies by the data and methodology used, country, and sector (*robust evidence, high*
35 *agreement*). Countries with a lower carbon pricing gap (higher carbon price) tend to be less carbon
36 intensive (*medium confidence*). {2.8.2, 2.8.3}

37 **Climate-related policies have also contributed to decreasing GHG emissions**. Policies such as taxes
38 and subsidies for clean and public transportation, and renewable policies have reduced GHG emissions
39 in some contexts (*robust evidence, high agreement*). Pollution control policies and legislations that go
40 beyond end-of-pipe controls have also had climate co-benefits, particularly if complementarities with
41 GHG emissions are considered in policy design (*medium evidence, medium agreement*). Policies on
42 agriculture, forestry and other land use (AFOLU) and AFOLU sector-related policies such as
43 afforestation policies can have important impacts on GHG emissions (*medium evidence, medium*
44 *agreement*). {2.8.4}

45

1 **2.1 Introduction**

2 As demonstrated by the contribution of Working Group I to the Sixth Assessment Report (IPCC,
3 2021a), greenhouse gas⁴ (GHG) concentrations in the atmosphere and annual anthropogenic GHG
4 emissions continue to grow and have reached a historic high driven mainly by continued fossil fuels
5 use (Peters et al., 2020; Jackson et al., 2019; Friedlingstein et al., 2020). Unsurprisingly, a large volume
6 of new literature has emerged since the AR5 on the trends and underlying drivers of anthropogenic
7 GHG emissions. This chapter provides a structured assessment of this new literature and establishes the
8 most important thematic links to other chapters in this report.

9 While AR5 has mostly assessed GHG emissions trends and drivers between 1970 and 2010, this
10 assessment focusses on the period 1990–2019 with the main emphasis on changes since 2010.
11 Compared to Chapter 5 in the contribution of WG III to the AR5 (Blanco et al., 2014), the scope of the
12 present chapter is broader. It presents the historical background of global progress in climate change
13 mitigation for the rest of the report and serves as a starting point for the assessment of long-term as well
14 as near- and medium-term mitigation pathways in Chapters 3 and 4, respectively. It also provides a
15 systemic perspective on past emission trends in different sectors of the economy (Chapters 6–12), and
16 relates GHG emissions trends to past policies (Chapter 13) and observed technological development
17 (Chapter 16). There is also a greater thrust into the analysis of consumption-based sectoral emissions
18 trends, empirical evidence of emissions consequences of behavioural choices and lifestyles, and the
19 social aspects of mitigation (Chapter 5). Finally, a completely new section discusses the mitigation
20 implications of existing and planned long-lived infrastructure and carbon lock-in.

21 Figure 2.1 presents the road map of this chapter. It is a simplified illustration of the causal chain driving
22 emissions along the black arrows. It also highlights the most important linkages to other chapters in this
23 volume (blue lines). The logic of the figure is the following: the main topic of this chapter is trends of
24 GHG emissions (discussed only in this chapter at such level of detail), hence they are at the top of the
25 figure in yellow-shaded boxes. The secondary theme is the drivers behind these trends, depicted in the
26 second line of yellow-shaded boxes. Four categories of drivers highlight key issues and guide readers
27 to chapters in which more details are presented. Finally, in addition to their own motivations and
28 objectives, climate and non-climate policies and measures shape the aspirations and activities of actors
29 in the main driver categories, hence shown in the yellow-shaded box below.

FOOTNOTE⁴ Greenhouse gases are gaseous constituents of the atmosphere that absorb and emit radiation at specific wavelengths within the spectrum of radiation emitted by the Earth's surface, by the atmosphere itself, and by clouds. This property causes the greenhouse effect. Water vapour (H₂O), carbon dioxide (CO₂), nitrous oxide (N₂O), methane (CH₄), and ozone (O₃) are the primary GHGs in the Earth's atmosphere. Human-made GHGs include sulphur hexafluoride (SF₆), hydrofluorocarbons (HFCs), chlorofluorocarbons (CFCs), and perfluorocarbons (PFCs); see Annex I.

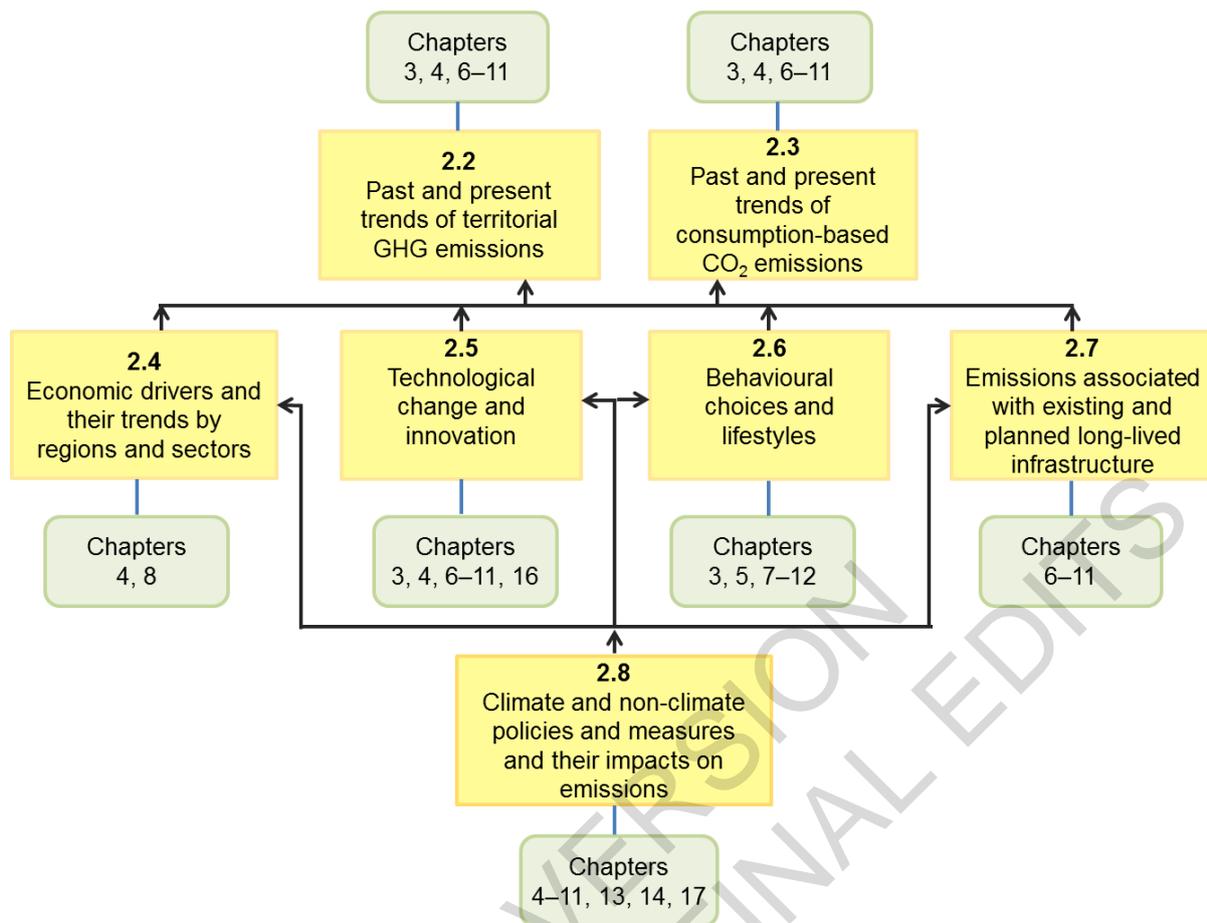

Figure 2.1 Chapter 2 road map and linkages to other chapters

Black arrows show the causal chain driving emissions, blue lines indicate key linkages to other chapters in this report.

Accordingly, the yellow-shaded boxes at the top of Figure 2.1 show that the first part of the chapter presents GHG emissions from two main perspectives: their geographical locations and the places where goods are consumed and services are utilised. A complicated chain of factors called drivers underlie these emissions. They are linked across time, space, and various segments of the economy and society in complex non-linear relationships. Sections shown in the second row of yellow-shaded boxes assess the latest literature and improve the understanding of the relative importance of these drivers in mitigating GHG emissions. A huge mass of physical capital embodying immense financial assets and potentially operating over a long lifetime produces vast GHG emissions. This long-lived infrastructure can be a significant hindrance to fast and deep reductions of emissions, it is therefore also shown as an important driver. A large range of economic, social, environmental, and other policies has been shaping these drivers of GHG emissions in the past and are anticipated to influence them in the future, as indicated by the yellow-shaded policies box and its manifold linkages. As noted, blue lines show linkages of sections to other chapters discussing these drivers and their operating mechanisms in detail.

2.2 Past and present trends of territorial GHG emissions

Total anthropogenic greenhouse gas (GHG) emissions as discussed in this chapter comprise CO₂ emissions from fossil fuel combustion and industrial processes⁵ (FFI), net CO₂ emissions from land use,

⁵ FOOTNOTE⁵ Industrial processes relate to CO₂ releases from fossil fuel oxidation and carbonate decomposition.

1 land-use change, and forestry (CO₂-LULUCF) (in previous IPCC reports often named FOLU: forestry
2 and other land-use), methane (CH₄), nitrous oxide (N₂O) and fluorinated gases (F-gases) comprising
3 hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulphur hexafluoride (SF₆) as well as nitrogen
4 trifluoride (NF₃). There are other major sources of F-gas emissions that are regulated under the Montreal
5 Protocol such as chlorofluorocarbons (CFCs) and hydrochlorofluorocarbons (HCFCs) that also have
6 considerable warming impacts (see Figure 2.4), however they are not considered here. Other substances
7 including ozone and aerosols that further contribute climate forcing are only treated very briefly, but a
8 full chapter is devoted to it in the Working Group I contribution to AR6 (Naik et al., 2021a; b).

9 A growing number of global GHG emissions inventories have become available since AR5 (Minx et
10 al., 2021). However, only a few are comprehensive in their coverage of sectors, countries and gases –
11 namely EDGAR (Emissions Database for Global Atmospheric Research) (Crippa et al., 2021),
12 PRIMAP (Potsdam Real-time Integrated Model for probabilistic Assessment of emissions Paths)
13 (Gütschow et al., 2021a), CAIT (Climate Analysis Indicators Tool) (WRI, 2019) and CEDS (A
14 Community *Emissions* Data System for Historical *Emissions*) (Hoesly et al., 2018). None of these
15 inventories presently cover CO₂-LULUCF, while CEDS excludes F-gases. For individual gases and
16 sectors, additional GHG inventories are available, as shown in Figure 2.2, but each has varying system
17 boundaries leading to important differences between their respective estimates (Section 2.2.1). Some
18 inventories are compiled bottom-up, while others are produced synthetically and are dependent on other
19 inventories. A more comprehensive list and discussion of different datasets is provided in the Chapter
20 2 Supplementary Material (SM2.1) and in Minx et al. (2021).

21 Across this report version 6 of EDGAR (Crippa et al., 2021) provided by the Joint Research Centre of
22 the European Commission is used for a consistent assessment of GHG emission trends and drivers. It
23 covers anthropogenic releases of CO₂-FFI, CH₄, N₂O, and F-gas (HFCs, PFCs, SF₆, NF₃) emissions by
24 228 countries and territories and across 5 sectors and 27 subsectors. EDGAR is chosen, because it
25 provides the most comprehensive global dataset in its coverage of sources, sectors and gases. For
26 transparency and as part of the uncertainty assessment EDGAR is compared to other global datasets in
27 Section 2.2.1 as well as in the Chapter 2 Supplementary Material (SM2.1). For individual country
28 estimates of GHG emissions, it may be more appropriate to use inventory data submitted to the
29 UNFCCC under the common reporting format (CRF) (UNFCCC, 2021). However, these inventories
30 are only up to date for Annex I countries and cannot be used to estimate global or regional totals. As
31 part of the regional analysis, a comparison of EDGAR and CRF estimates at the country-level is
32 provided, where the latter is available (Figure 2.9).

33 Net CO₂-LULUCF estimates are added to the dataset as the average of estimates from three
34 bookkeeping models of land-use emissions (Houghton and Nassikas, 2017; Hansis et al., 2015; Gasser
35 et al., 2020) following the Global Carbon Project (Friedlingstein et al., 2020). This is different to AR5,
36 where land-based CO₂ emissions from forest fires, peat fires, and peat decay, were used as an
37 approximation of the net-flux of CO₂-LULUCF (Blanco et al., 2014). Note that the definition of CO₂-
38 LULUCF emissions by global carbon cycle models, as used here, differs from IPCC definitions (IPCC,
39 2006) applied in national greenhouse gas inventories (NGHGI) for reporting under the climate
40 convention (Grassi et al., 2018, 2021) and, similarly, from FAO estimates of carbon fluxes on forest
41 land (Tubiello et al., 2021). The conceptual difference in approaches reflects different scopes. We use
42 the global carbon cycle models' approach for consistency with Working Group I (Canadell et al., 2021)
43 and to comprehensively distinguish natural from anthropogenic drivers, while NGHGI generally report
44 as anthropogenic all CO₂ fluxes from lands considered managed (see Section 7.2.2 in Chapter 7).
45 Finally, note that the CO₂-LULUCF estimate from bookkeeping models as provided in this chapter is
46 indistinguishable to the CO₂ from Agriculture, Forestry and other Land Use (AFOLU) as reported in
47 Chapter 7, because the CO₂ emissions component from agriculture is negligible.

1 The resulting synthetic dataset used here has undergone additional peer-review and is publicly available
2 (<https://doi.org/10.5281/zenodo.5566761>). Comprehensive information about the dataset as well as
3 underlying uncertainties (including a comparison with other datasets) can be found in the
4 Supplementary Material to this chapter and in Minx et al. (2021).

5 In this chapter and the report as a whole, different greenhouse gases are frequently converted into
6 common units of CO₂ equivalent (CO₂eq) emissions using 100-year Global Warming Potentials
7 (GWP100) from WGI of IPCC's Sixth Assessment Report (AR6) (Forster et al., 2021a). This reflects
8 the dominant use in the scientific literature and is consistent with decisions made by Parties to the Paris
9 Agreement for reporting and accounting of emissions and removals (UNFCCC, 2019). Other GHG
10 emissions metrics exist, all of which, like GWP100, are designed for specific purposes and have
11 limitations and uncertainties. The appropriate choice of GHG emissions metrics depends on policy
12 objective and context (Myhre et al., 2013; Kolstad et al., 2015). A discussion of GHG metrics is
13 provided in a Cross-Chapter Box later in the chapter (see Cross-Chapter Box 2) and, at length, in the
14 Chapter 2 Supplementary Material. Throughout the chapter GHG emissions are reported (in GtCO₂eq)
15 at two significant digits to reflect prevailing uncertainties in emissions estimates. Estimates are subject
16 to uncertainty, which we report for a 90% confidence interval.

17

18 **2.2.1 Uncertainties in GHG emissions**

19 Estimates of historical GHG emissions – CO₂, CH₄, N₂O and F-gases – are uncertain to different
20 degrees. Assessing and reporting uncertainties is crucial in order to understand whether available
21 estimates are sufficiently robust to answer policy questions; for example, if GHG emissions are still
22 rising, or if a country has achieved an emission reduction goal (Marland, 2008). These uncertainties can
23 be of scientific nature, such as when a process is not sufficiently understood. They also arise from
24 incomplete or unknown parameter information (e.g. activity data, or emission factors), as well as
25 estimation uncertainties from imperfect modelling techniques. There are at least three major ways to
26 examine uncertainties in emission estimates (Marland et al., 2009): 1) by comparing estimates made by
27 independent methods and observations (e.g. comparing atmospheric measurements with bottom-up
28 emissions inventory estimates) (Saunio et al., 2020; Petrescu et al., 2020b; a; Tian et al., 2020); 2) by
29 comparing estimates from multiple sources and understanding sources of variation (Andrew, 2020;
30 Macknick, 2011; Ciais et al., 2021; Andres et al., 2012); 3) by evaluating estimates from a single source
31 (Hoesly and Smith, 2018), for instance via statistical sampling across parameter values (e.g. Robert J.
32 Andres et al., 2014; Monni et al., 2007; Solazzo et al., 2021; Tian et al., 2019).

33 Uncertainty estimates can be rather different depending on the method chosen. For example, the range
34 of estimates from multiple sources is bounded by their interdependency; they can be lower than true
35 structural plus parameter uncertainty or than estimates made by independent methods. In particular, it
36 is important to account for potential bias in estimates, which can result from using common
37 methodological or parameter assumptions, or from missing sources (systemic bias). It is further crucial
38 to account for differences in system boundaries, i.e. which emissions sources are included in a dataset
39 and which are not, otherwise direct comparisons can exaggerate uncertainties (Macknick, 2011;
40 Andrew, 2020). Independent top-down observational constraints are, therefore, particularly useful to
41 bound total emission estimates, but are not yet capable of verifying emission levels or trends (Petrescu
42 et al., 2021a; b). Similarly, uncertainty estimates are influenced by specific modelling choices. For
43 example, uncertainty estimates from studies on the propagation of uncertainties associated with key
44 input parameters (activity data, emissions factors) following the IPCC Guidelines (IPCC, 2006) are
45 strongly determined by assumptions on how these parameters are correlated between sectors, countries,
46 and regions (Solazzo et al., 2021; Janssens-Maenhout et al., 2019). Assuming (full) covariance between
47 source categories, and therefore dependence between them, increases uncertainty estimates. Estimates

1 allowing for some covariance as in Sollazzo et al. (2021) also tend to yield higher estimates than the
2 range of values from ensemble of dependent inventories (Saunois et al., 2016, 2020).

3 For this report, a comprehensive assessment of uncertainties is provided in the Supplementary Material
4 (SM2.2) to this chapter based on Minx et al. (2021). The uncertainties reported here combine statistical
5 analysis, comparisons of global emissions inventories and an expert judgement of the likelihood of
6 results lying outside a defined confidence interval, rooted in an understanding gained from the relevant
7 literature. This literature has improved considerably since AR5 with a growing number of studies that
8 assess uncertainties based on multiple lines of evidence (Petrescu et al., 2021a; b; Tian et al., 2020;
9 Saunois et al., 2016, 2020).

10 To report the uncertainties in GHG emissions estimates, a 90% confidence interval (5th-95th percentile)
11 is adopted, i.e., there is a 90 % likelihood that the true value will be within the provided range if the
12 errors have a Gaussian distribution, and no bias is assumed. This is in line with previous reporting in
13 IPCC AR5 (Ciais et al., 2014; Blanco et al., 2014). Note that national emissions inventory submissions
14 to the UNFCCC are requested to report uncertainty using a 95% confidence interval. The use of this
15 broader uncertainty interval implies, however, a relatively high degree of knowledge about
16 the uncertainty structure of the associated data, particularly regarding the distribution of uncertainty in
17 the tails of the probability distributions. Such a high degree of knowledge is not present over all regions,
18 emission sectors and species considered here.

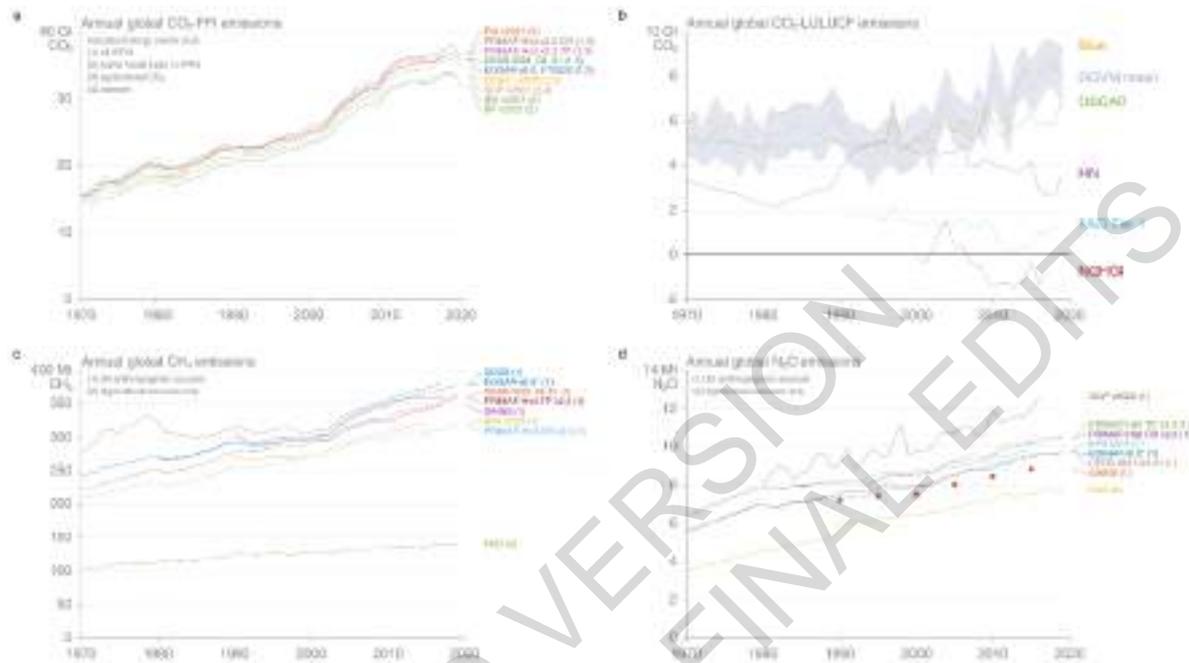

19 Based on this assessment of relevant uncertainties above, a constant, relative, global uncertainty
20 estimates for GHGs is applied at a 90% confidence interval that range from relatively low values for
21 CO₂-FFI ($\pm 8\%$), to intermediate values for CH₄ and F-gases ($\pm 30\%$), to higher values for N₂O ($\pm 60\%$)
22 and CO₂-LULUCF ($\pm 70\%$). Uncertainties for aggregated total GHG emissions in terms of CO₂eq
23 emissions are calculated as the square root of the squared sums of absolute uncertainties for individual
24 gases (taking F-gases together), using 100-year Global Warming Potentials (GWP100) to weight
25 emissions of non-CO₂ gases but excluding uncertainties in the metric itself.

26 This assessment of uncertainties is broadly in line with WGIII AR5 (Blanco et al., 2014), but revises
27 individual uncertainty judgements in line with the more recent literature (Friedlingstein et al., 2020;
28 Janssens-Maenhout et al., 2019; Solazzo et al., 2021; Tian et al., 2020; Saunois et al., 2016, 2020) as
29 well as the underlying synthetic analysis provided here (e.g. Figure 2.2, Figure 2.3, Minx et al. (2021)).
30 As such, reported changes in these estimates do not reflect changes in the underlying uncertainties, but
31 rather a change in expert judgement based on an improved evidence base in the scientific literature.
32 Uncertainty estimates for CO₂-FFI and N₂O remain unchanged compared to AR5. The change in the
33 uncertainty estimates for CH₄ from 20% to 30% is justified by larger uncertainties reported for EDGAR
34 emissions (Solazzo et al., 2021; Janssens-Maenhout et al., 2019) as well as the wider literature (Tubiello
35 et al., 2015; Kirschke et al., 2013; Saunois et al., 2020, 2016). As AR6 – in contrast to AR5 - uses CO₂-
36 LULUCF data from global bookkeeping models, the respective uncertainty estimate is based on the
37 reporting in the underlying literature (Friedlingstein et al., 2020) as well as Working Group I (Canadell
38 et al., 2021). The 70% uncertainty value is at the higher end of the range considered in AR5 (Blanco et
39 al., 2014).

40 Finally, for F-gas emissions top-down atmospheric measurements from the 2018 World Meteorological
41 Organisation's (WMO) Scientific Assessment of Ozone Depletion (see Engel and Rigby, 2018;
42 Montzka and Velders, 2018) are compared to the data used in this report (Minx et al., 2021; Crippa et
43 al., 2021) as shown in Figure 2.3. Due to the general absence of natural F-gas fluxes, there is a sound
44 understanding of global and regional F-gas emissions from top-down estimates of atmospheric
45 measurements with small and well-understood measurement, lifetime and transport model uncertainties
46 (see Engel and Rigby, 2018; Montzka and Velders, 2018). However, when species are aggregated into
47 total F-gas emissions, EDGARv6 emissions are around 10% lower than the WMO 2018 values
48 throughout, with larger differences for individual f-gas species, and further discrepancies when

1 comparing to older EDGAR versions. Based on this, the overall uncertainties for aggregate F-gas
 2 emissions is judged conservatively at 30% - 10 percentage points higher than in AR5 (Blanco et al.,
 3 2014).

4 Aggregate uncertainty across all greenhouse gases is approximately $\pm 11\%$ depending on the
 5 composition of gases in a particular year. AR5 applied a constant uncertainty estimates of $\pm 10\%$ for
 6 total GHG emissions. The upwards revision applied to the uncertainties of CO₂-LULUCF, CH₄ and F-
 7 gas emissions therefore has a limited overall effect on the assessment of GHG emissions.

16 GHG emissions metrics such as GWP-100 have themselves uncertainties, which has been largely
 17 neglected in the literature so far. Minx et al. (2021) report the uncertainty in GWP-100 metric values as
 18 $\pm 50\%$ for methane and other SLCFs, and $\pm 40\%$ for non-CO₂ gases with longer atmospheric lifetimes
 19 (specifically, those with lifetimes longer than 20 years). If uncertainties in GHG metrics are considered,
 20 and are assumed independent (which may lead to an underestimate) the overall uncertainty of total GHG
 21 emissions in 2019 increases from $\pm 11\%$ to $\pm 13\%$. Metric uncertainties are not further considered in this
 22 chapter (but see Cross-chapter Box 2 and Chapter 2 Supplementary Material on GHG metrics (SM2.3)).

23 The most appropriate metric to aggregate GHG emissions depends on the objective (see Cross-chapter
 24 Box 2). One such objective can be to understand the contribution of emissions in any given year to
 25 warming, while another can be to understand the contribution of cumulative emissions over an extended

1 time period to warming. In Figure 2.4 the modelled warming from emissions of each gas or group of
 2 gases is also shown - calculated using the reduced-complexity climate model FAIRv1.6, which has been
 3 calibrated to match several aspects of the overall WGI assessment (Forster et al., 2021a; specifically
 4 Cross-Chapter Box 7 in Chapter 10 therein). Additionally, its temperature response to emissions with
 5 shorter atmospheric lifetimes such as aerosols, methane or ozone has been adjusted to broadly match
 6 those presented in Naik et al. (2021a). There are some differences in actual warming compared to the
 7 GWP-100 weighted emissions of each gas (Figure 2.4), in particular a greater contribution from CH₄
 8 emissions to historical warming. This is consistent with warming from CH₄ being short-lived and hence
 9 having a more pronounced effect in the near-term during a period of rising emissions. Nonetheless,
 10 Figure 2.4 highlights that emissions weighted by GWP-100 do not provide a fundamentally different
 11 information about the contribution of individual gases than modelled actual warming over the historical
 12 period, when emissions of most GHGs have been rising continuously, with CO₂ being the dominant and
 13 CH₄ being the second most important contributor to GHG-induced warming. Other metrics such as
 14 GWP* (Cain et al., 2019) offer an even closer resemblance between cumulative CO₂eq emissions and
 15 temperature change. Such a metric may be more appropriate when the key objective is to track
 16 temperature change when emissions are falling, as in mitigation scenarios.

START CROSS CHAPTER BOX 2 HERE**Cross-Chapter Box 2 GHG emission metrics**

Authors: Andy Reisinger (New Zealand), Alaa Al Khourdajie (United Kingdom/Syria), Kornelis Blok (the Netherlands), Harry Clark (New Zealand), Annette Cowie (Australia), Jan S. Fuglestedt (Norway), Oliver Geden (Germany), Veronika Ginzburg (the Russian Federation), Celine Guivarch (France), Joanna House (United Kingdom), Jan Christoph Minx (Germany), Rachid Mrabet (Morocco), Gert-Jan Nabuurs (the Netherlands), Glen P. Peters (Norway/Australia), Keywan Riahi (Austria), Roberto Schaeffer (Brazil), Raphael Slade (United Kingdom), Anders Hammer Strømman (Norway), Detlef van Vuuren (the Netherlands)

Comprehensive mitigation policy relies on consideration of all anthropogenic forcing agents, which differ widely in their atmospheric lifetimes and impacts on the climate system. GHG emission metrics⁶ provide simplified information about the effects that emissions of different GHGs have on global temperature or other aspects of climate, usually expressed relative to the effect of emitting CO₂ (see glossary). This information can inform prioritisation and management of trade-offs in mitigation policies and emission targets for non-CO₂ gases relative to CO₂, as well as for baskets of gases expressed in CO₂-eq. This assessment builds on the evaluation of GHG emission metrics from a physical science perspective by Working Group I (Forster et al., 2021b). For additional details and supporting references, see Chapter 2 Supplementary Material (SM2.3) and Annex II 8.

The Global Warming Potential (GWP) and the Global Temperature change Potential (GTP) were the main metrics assessed in AR5 (Myhre et al., 2013; Kolstad et al., 2014). The GWP with a lifetime of 100 years (GWP₁₀₀) continues to be the dominant metric used in the scientific literature on mitigation assessed by WGIII. The assessment by Working Group I (Forster et al., 2021) includes updated values for these metrics based on updated scientific understanding of the response of the climate system to emissions of different gases, including changing background concentrations. It also assesses new metrics published since AR5. Metric values in the AR6 include climate-carbon cycle feedbacks by default; this provides an important update and clarification from the AR5 which reported metric values both with and without such feedbacks.

The choice of metric, including time horizon, should reflect the policy objectives for which the metric is applied (Plattner et al., 2009). Recent studies confirm earlier findings that the GWP is consistent with a cost-benefit framework (Kolstad et al., 2014), which implies weighting each emission based on the economic damages that this emission will cause over time, or conversely, the avoided damages from avoiding that emission. The GWP time horizon can be linked to the discount rate used to evaluate economic damages from each emission. For methane, GWP₁₀₀ implies a social discount rate of about 3-5% depending on the assumed damage function, whereas GWP₂₀ implies a much higher discount rate, greater than 10% (*medium confidence*; Mallapragada and Mignone 2019; Sarofim and Giordano 2018). The dynamic GTP is aligned with a cost-effectiveness framework, as it weights each emission based on its contribution to global warming in a specified future year (e.g. the expected year of peak warming for a given temperature goal). This implies a shrinking time horizon and increasing relative importance of SLCF emissions as the target year is approached (Johansson, 2011; Aaheim and Mideksa, 2017). The GTP with a static time horizon (e.g. GTP₁₀₀) is not well-matched to either a cost-benefit or a cost-effectiveness framework, as the year for which the temperature outcome is evaluated would not match

FOOTNOTE⁶ Emission metrics also exist for aerosols, but these are not commonly used in climate policy. This assessment focuses on GHG emission metrics only.

1 the year of peak warming, nor the overall damages caused by each emission (Mallapragada and
2 Mignone, 2017; Edwards and Trancik, 2014; Strefler et al., 2014).

3 A number of studies since the AR5 have evaluated the impact of various GHG emission metrics and
4 time horizons on the global economic costs of limiting global average temperature change to a pre-
5 determined level (e.g. Strefler et al. 2014; Harmsen et al. 2016; Tanaka et al. 2021; see SM2.3 for
6 additional detail). These studies indicate that for mitigation pathways that *likely* limit warming to 2°C
7 above pre-industrial levels or lower, using GWP₁₀₀ to inform cost-effective abatement choices between
8 gases would achieve such long-term temperature goals at close to least global cost within a few percent
9 (*high confidence*). Using the dynamic GTP instead of GWP₁₀₀ could reduce global mitigation costs by
10 a few percent in theory (*high confidence*), but the ability to realise those cost savings depends on the
11 temperature limit, policy foresight and flexibility in abatement choices as the weighting of SLCF
12 emissions increases over time (*medium confidence*; van den Berg et al. 2015; Huntingford et al. 2015).
13 Similar benefits as for the dynamic GTP might be obtained by regularly reviewing and potentially
14 updating the time horizon used for GWP in light of actual emission trends compared to climate goals
15 (Tanaka et al., 2020).

16 The choice of metric and time horizon can affect the distribution of costs and the timing of abatement
17 between countries and sectors in cost-effective mitigation strategies. Sector-specific lifecycle
18 assessments find that different emission metrics and different time horizons can lead to divergent
19 conclusions about the effectiveness of mitigation strategies that involve reductions of one gas but an
20 increase of another gas with a different lifetime (e.g. Tanaka et al. 2019). Assessing the sensitivity of
21 conclusions to different emission metrics and time horizons can support more robust decision-making
22 (Levasseur et al. 2016; Balcombe et al. 2018; see SM2.3 for details). Sectoral and national perspectives
23 on GHG emission metrics may differ from a global least-cost perspective, depending on other policy
24 objectives and equity considerations, but the literature does not provide a consistent framework for
25 assessing GHG emission metrics based on equity principles.

26 Literature since the AR5 has emphasized that the GWP₁₀₀ is not well suited to estimating the warming
27 effect at specific points in time from sustained SLCF emissions (e.g. Allen et al. 2016; Cain et al. 2019;
28 Collins et al. 2019). This is because the warming caused by an individual SLCF emission pulse
29 diminishes over time and hence, unlike CO₂, the warming from SLCF emissions that are sustained over
30 multiple decades to centuries depends mostly on their ongoing rate of emissions rather than their
31 cumulative emissions. Treating all gases interchangeably based on GWP₁₀₀ within a stated emissions
32 target therefore creates ambiguity about actual global temperature outcomes (Fuglestvedt et al., 2018;
33 Denison et al., 2019). Supplementing economy-wide emission targets with information about the
34 expected contribution from individual gases to such targets would reduce the ambiguity in global
35 temperature outcomes.

36 Recently developed step/pulse metrics such as the CGTP (Combined Global Temperature Change
37 Potential; Collins et al. 2019) and GWP* (referred to as GWP-star; Allen et al. 2018; Cain et al. 2019)
38 recognise that a sustained increase/decrease in the rate of SLCF emissions has a similar effect on global
39 surface temperature over multiple decades as a one-off pulse emission/removal of CO₂. These metrics
40 use this relationship to calculate the CO₂ emissions or removals that would result in roughly the same
41 temperature change as a sustained change in the rate of SLCF emissions (CGTP) over a given time
42 period, or as a varying time series of CH₄ emissions (GWP*). From a mitigation perspective, these
43 metrics indicate greater climate benefits from rapid and sustained methane reductions over the next few
44 decades than if such reductions are weighted by GWP₁₀₀, while conversely, sustained methane increases
45 have greater adverse climate impacts (Lynch et al., 2020; Collins et al., 2019). The ability of these
46 metrics to relate changes in emission rates of short-lived gases to cumulative CO₂ emissions makes
47 them well-suited, in principle, to estimating the effect on the remaining carbon budget from more, or

1 less, ambitious SLCF mitigation over multiple decades compared to a given reference scenario (*high*
2 *confidence*; Collins et al. 2019; Forster et al. 2021).

3 The potential application of GWP* in wider climate policy (e.g. to inform equitable and ambitious
4 emission targets or to support sector-specific mitigation policies) is contested, although relevant
5 literature is still limited (Rogelj and Schleussner, 2019; Schleussner et al., 2019; Cain et al., 2021;
6 Rogelj and Schleussner, 2021; Allen et al., 2021). Whereas GWP and GTP describe the marginal effect
7 of each emission relative to the absence of that emission, GWP* describes the equivalent CO₂ emissions
8 that would give the same temperature change as an emissions trajectory of the gas considered, starting
9 at a (user-determined) reference point. The warming based on those cumulative CO₂-equivalent
10 emission at any point in time is relative to the warming caused by emissions of that gas before the
11 reference point. Because of their different focus, GWP* and GWP₁₀₀ can equate radically different CO₂
12 emissions to the same CH₄ emissions: rapidly declining CH₄ emissions have a negative CO₂-warming-
13 equivalent value based on GWP* (rapidly declining SLCF emissions result in declining temperature,
14 relative to the warming caused by past SLCF emissions at a previous point in time) but a positive CO₂-
15 equivalent value based on GWP or GTP (each SLCF emission from any source results in increased
16 future radiative forcing and global average temperature than without this emission, regardless whether
17 the rate of SLCF emissions is rising or declining). The different focus in these metrics can have
18 important distributional consequences, depending on how they are used to inform emission targets
19 (Reisinger et al., 2021; Lynch et al., 2021), but this has only begun to be explored in the scientific
20 literature.

21 A key insight from WGI is that for a given emissions scenario, different metric choices can alter the
22 time at which net zero GHG emissions are calculated to be reached, or whether net zero GHG emissions
23 are reached at all (see SM2.3 for details). From a mitigation perspective, this implies that changing
24 GHG emission metrics but retaining the same numerical CO₂-equivalent emissions targets would result
25 in different climate outcomes. For example, achieving a balance of global anthropogenic GHG
26 emissions and removals as stated in Article 4.1 of the Paris Agreement could, depending on the GHG
27 emission metric used, result in different peak temperatures and in either stable or slowly or rapidly
28 declining temperature after the peak (Tanaka and O'Neill, 2018; Allen et al., 2018; Fuglestvedt et al.,
29 2018; Schleussner et al., 2019). A fundamental change in GHG emission metrics used to monitor
30 achievement of existing emission targets could therefore inadvertently change their intended climate
31 outcomes or ambition, unless existing emission targets are re-evaluated at the same time (*very high*
32 *confidence*).

33 The WGIII contribution to the AR6 reports aggregate emissions and removals using updated GWP₁₀₀
34 values from AR6 WGI unless stated otherwise. This choice was made on both scientific grounds (the
35 alignment of GWP₁₀₀ with a cost-benefit perspective under social discount rates and its performance
36 from a global cost-effectiveness perspective) and for procedural reasons, including continuity with past
37 IPCC reports and alignment with decisions under the Paris Agreement Rulebook (see Annex II.8 for
38 further detail). A key constraint in the choice of metric is also that the literature assessed by WGIII
39 predominantly uses GWP₁₀₀ and often does not provide sufficient detail on emissions and abatement
40 of individual gases to allow translation into different metrics. Presenting such information routinely in
41 mitigation studies would enable the application of more diverse GHG emission metrics in future
42 assessments to evaluate their contribution to different policy objectives.

43 All metrics have limitations and uncertainties, given that they simplify the complexity of the physical
44 climate system and its response to past and future GHG emissions. No single metric is well-suited to
45 all applications in climate policy. For this reason, the WGIII contribution to the AR6 reports emissions
46 and mitigation options for individual gases where possible; CO₂-equivalent emissions are reported in
47 addition to individual gas emissions where this is judged to be policy-relevant. This approach aims to

1 reduce the ambiguity regarding mitigation potentials for specific gases and actual climate outcomes
2 over time arising from the use of any specific GHG emission metric.

3 4 **END CROSS CHAPTER BOX 2 HERE** 5

6 **2.2.2 Trends in the global GHG emissions trajectories and short-lived climate forcers**

7 **2.2.2.1 Anthropogenic greenhouse gas emissions trends**

8 Global GHG emissions continued to rise since AR5, but the rate of emissions growth slowed (*high*
9 *confidence*). GHG emissions reached 59 ± 6.6 GtCO₂eq in 2019 (Table 2.1 and Figure 2.5). In 2019, CO₂
10 emissions from FFI were $38 (\pm 3.0)$ Gt, CO₂ from LULUCF 6.6 ± 4.6 Gt, CH₄ 11 ± 3.2 GtCO₂eq, N₂O
11 2.7 ± 1.6 GtCO₂eq and F-gases 1.4 ± 0.41 GtCO₂eq. There is *high confidence* that average annual GHG
12 emissions for the last decade (2010-2019) were the highest on record in terms of aggregate CO₂eq
13 emissions, but *low confidence* for annual emissions in 2019 as uncertainties are large considering the
14 size and composition of observed increases in the most recent years (Minx et al., 2021; UNEP, 2020a).

15 2019 GHG emissions levels were higher compared to 10 and 30 years ago (*high confidence*): about
16 12% (6.5 GtCO₂eq) higher than in 2010 (53 ± 5.7 GtCO₂eq) (AR5 reference year) and about 54% (21
17 GtCO₂eq) higher than in 1990 (38 ± 4.8 GtCO₂eq) (Kyoto Protocol reference year and frequent NDC
18 reference). GHG emissions growth slowed compared to the previous decade (*high confidence*): From
19 2010 to 2019 GHG emissions grew on average by about 1.3% per year compared to an average annual
20 growth of 2.1% between 2000 and 2009. Nevertheless the absolute increase in average annual GHG
21 emissions for 2010-2019 compared to 2000-2009 was 9.1 GtCO₂eq and, as such, the largest observed
22 in the data since 1970 (Table 2.1) – and most likely in human history (Friedlingstein et al., 2020;
23 Gütschow et al., 2021b). Decade-by- decade growth in average annual GHG emissions was observed
24 across all (groups of) gas as shown in Table 2.1, but for N₂O and CO₂-LULUCF emissions this is much
25 more uncertain.

26
27 **Table 2.1 Total anthropogenic GHG emissions (GtCO₂eq yr⁻¹) 1990-2019**

28 **CO₂ from fossil fuel combustion and industrial processes (FFI); CO₂ from Land Use, Land Use Change**
29 **and Forestry (LULUCF); methane (CH₄); nitrous oxide (N₂O); fluorinated gases (F-gases: HFCs, PFCs,**
30 **SF₆, NF₃). Aggregate GHG emission trends by groups of gases reported in Gt CO₂eq converted based on**
31 **global warming potentials with a 100-year time horizon (GWP-100) from the IPCC Sixth Assessment**
32 **Report. Uncertainties are reported for a 90% confidence interval.**

33 Source: Minx et al. (2021)

	Average annual emissions (GtCO ₂ eq)					
	CO ₂ FFI	CO ₂ LULUCF	CH ₄	N ₂ O	Fluorinated gases	GHG
2019	38±3.0	6.6±4.6	11±3.2	2.7±1.6	1.4±0.41	59±6.6
2010-2019	36±2.9	5.7±4.0	10±3.0	2.6±1.5	1.2±0.35	56±6.0

34
35 Reported total annual GHG emission estimates differ between the Working Group III contributions in
36 AR5 (Blanco et al., 2014) and AR6 (this chapter) mainly due to differing global warming potentials

1 (*high confidence*). For the year 2010, total GHG emissions were estimated at 49 ± 4.9 Gt CO₂eq in AR5
2 (Blanco et al., 2014), while we report 53 ± 5.7 Gt CO₂eq here. However, in AR5 total GHG emissions
3 were weighted based on GWP-100 values from IPCC SAR. Applying those GWP values to the 2010
4 emissions from AR6 yields 50 Gt CO₂eq (Forster et al., 2021a). Hence, observed differences are mainly
5 due to the use of most recent GWP values, which have higher warming potentials for methane (29%
6 higher for biogenic and 42% higher for fugitive methane) and 12% lower values for nitrous oxide (see
7 Cross-Chapter Box 2 in this chapter).

8 Emissions growth has been persistent but varied in pace across gases. The average annual emission
9 levels of the last decade (2010-2019) were higher than in any previous decade for each group of
10 greenhouse gases: CO₂, CH₄, N₂O, and F-gases (*high confidence*). Since 1990, CO₂-FFI have grown by
11 67% (15 GtCO₂eq), CH₄ by 29% (2.4 GtCO₂eq), and N₂O by 33% (0.65 GtCO₂eq), respectively (Figure
12 2.5). Growth in fluorinated gases (F-gas) has been by far the highest with about 250% (1.0 GtCO₂eq),
13 but it occurred from low levels. In 2019, total F-gas levels are no longer negligible with a share of 2.3%
14 of global GHG emissions. Note that the F-gases reported here do not include chlorofluorocarbons
15 (CFCs) and hydrochlorofluorocarbons (HCFCs), which are groups of substances regulated under the
16 Montreal Protocol. The aggregate CO₂eq emissions of HFCs, HCFCs and CFCs were each
17 approximately equal in 2016, with a smaller contribution from PFCs, SF₆, NF₃ and some more minor
18 F-gases. Therefore, the GWP-weighted F-gas emissions reported here (HFCs, PFCs, SF₆, NF₃), which
19 are dominated by the HFCs, represent less than half of the overall CO₂eq F-gas emissions in 2016
20 (Figure 2.3).

21 The only exception to these patterns of GHG emissions growth is net anthropogenic CO₂-LULUCF
22 emissions, where there is no statistically significant trend due to high uncertainties in estimates (Figure
23 2.2, Figure 2.5; for a discussion see Chapter 2 Supplementary Material). While the average estimate
24 from the bookkeeping models report a slightly increasing trend in emissions, NGHGI and FAOSTAT
25 estimates show a slightly decreasing trend, which diverges in recent years (Figure 2.2). Similarly, trends
26 in CO₂-LULUCF estimates from individual bookkeeping models differ: while two models (BLUE,
27 OSCAR) show a sustained increase in emissions levels since the mid 1990s, emissions from the third
28 model (HN) declined (see Figure 2.2; Friedlingstein et al., 2020). Differences in accounting approaches
29 and their impacts CO₂ emissions estimates from land use is covered in Chapter 7 and in the Chapter 2
30 Supplementary Material (SM2.2). Note that anthropogenic net emissions from bioenergy are covered
31 by the CO₂-LULUCF estimates presented here.

Emissions of greenhouse gases have continued to increase since 1990, at varying rates

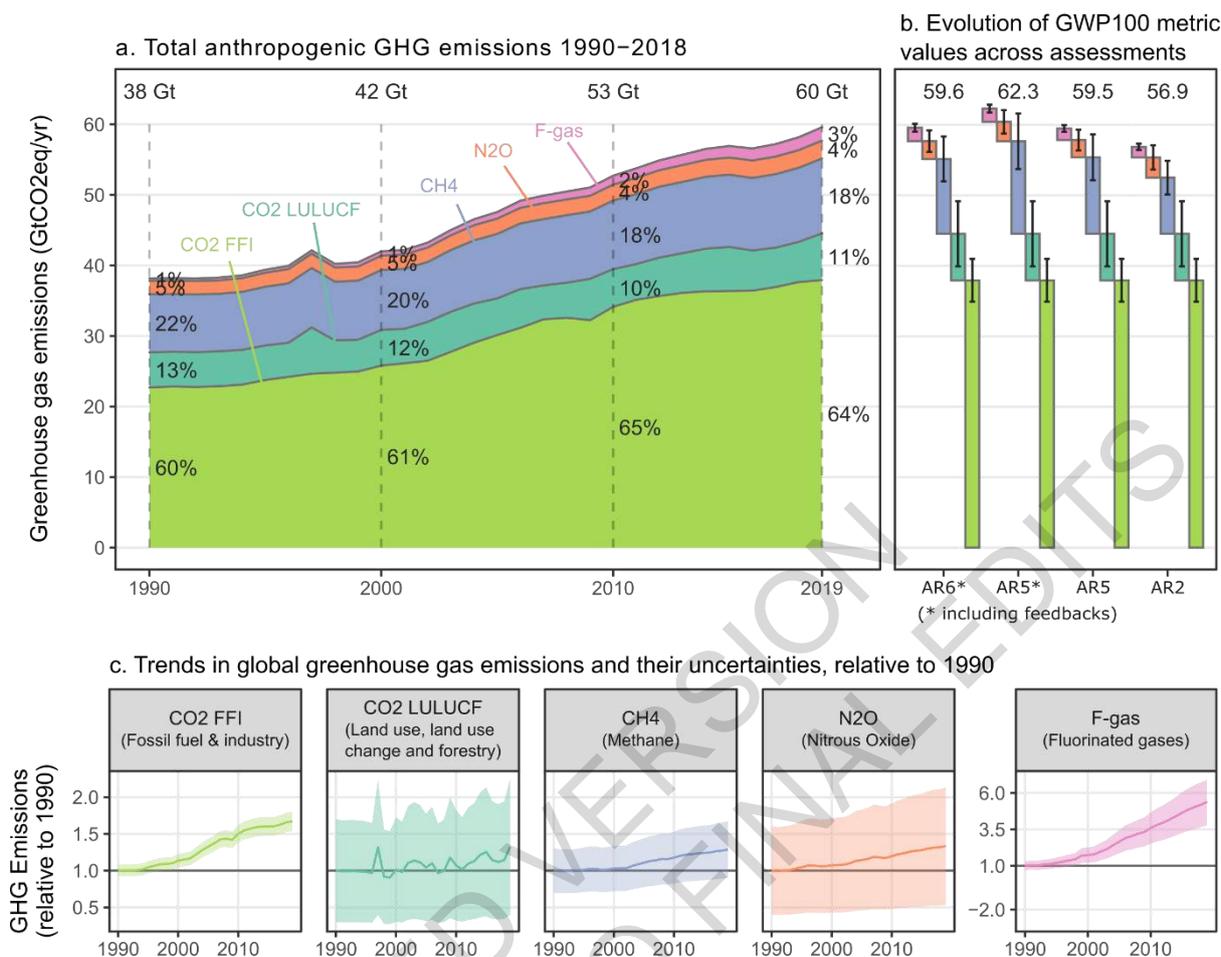

Figure 2.5 Total anthropogenic GHG emissions (Gt CO₂eq yr⁻¹) 1990-2019

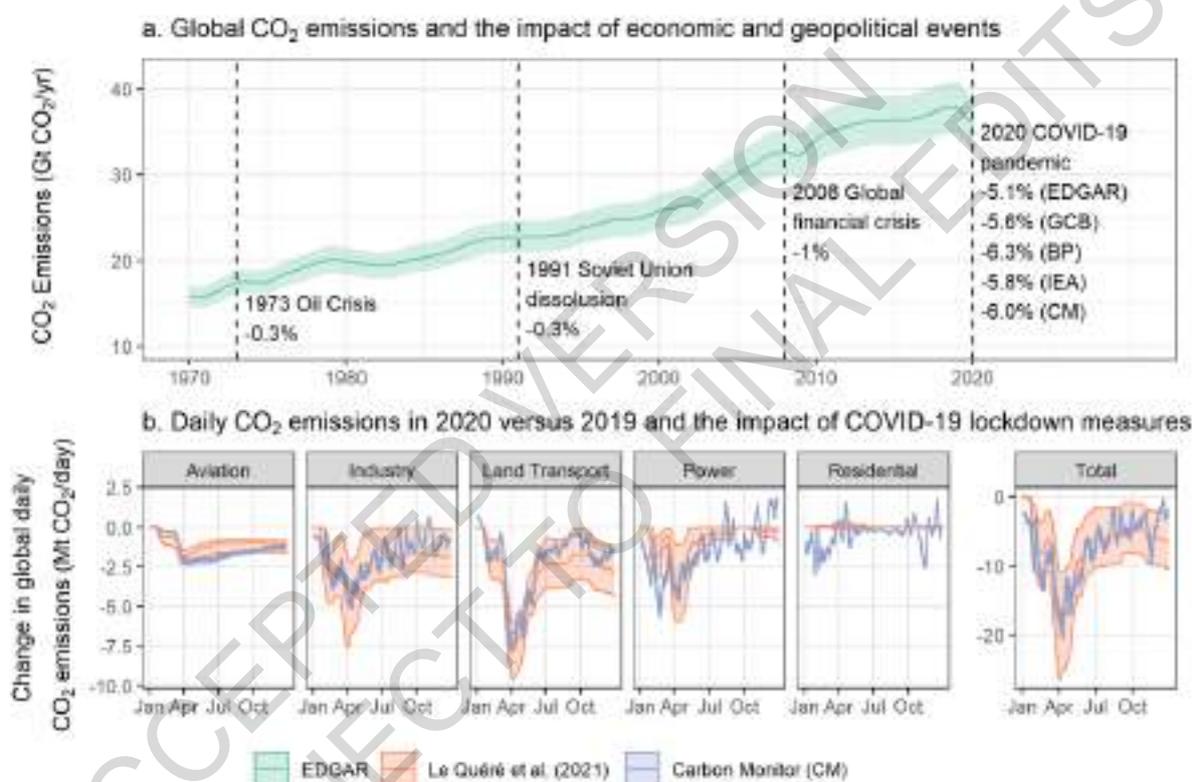

CO₂ from fossil fuel combustion and industrial processes (FFI); net CO₂ from Land Use, Land Use Change and Forestry (LULUCF); methane (CH₄); nitrous oxide (N₂O); fluorinated gases (F-gases: HFCs, PFCs, SF₆, NF₃). Panel a: Aggregate GHG emission trends by groups of gases reported in Gt CO₂eq converted based on global warming potentials with a 100-year time horizon (GWP-100) from the IPCC Sixth Assessment Report. Panel b: Waterfall diagrams juxtaposes GHG emissions for the most recent year 2019 in CO₂ equivalent units using GWP-100 values from the IPCC's Second, Fifth, and Sixth Assessment Report, respectively. Error bars show the associated uncertainties at a 90% confidence interval. Panel c: individual trends in CO₂-FFI, CO₂-AFOLU, CH₄, N₂O and F-gas emissions for the period 1990-2019, normalised to 1 in 1990.

Source: Data from Minx et al., 2021

The CO₂-FFI share in total CO₂eq emissions has plateaued at about 65% in recent years and its growth has slowed considerably since AR5 (*high confidence*). CO₂-FFI emissions grew at 1.1% during the 1990s and 2.5% during the 2000s. For the last decade (2010s) - not covered by AR5 - this rate dropped to 1.2%. This included a short period between 2014-2016 with little or no growth in CO₂-FFI emissions mainly due to reduced emissions from coal combustion (Peters et al., 2017a; Qi et al., 2016; Jackson et al., 2016; Canadell et al., 2021). Subsequently, CO₂-FFI emissions started to rise again (Peters et al., 2017b; Figueres et al., 2018; Peters et al., 2020).

Starting in the spring of 2020 a major break in global emissions trends was observed due to lockdown policies implemented in response to the COVID-19 pandemic (*high confidence*) (Quéré et al., 2020; Le Quéré et al., 2021; Liu et al., 2020d; Forster et al., 2020; Bertram et al., 2021). Overall, global CO₂-FFI emissions are estimated to have declined by 5.8% [5.1%-6.3%] in 2020, or about 2.2 (1.9-2.4) GtCO₂

1 in total (Crippa et al., 2021; Friedlingstein et al., 2020; Liu et al., 2020d; IEA, 2021a; BP, 2021). This
 2 exceeds any previous global emissions decline since 1970, both in relative and absolute terms (Figure
 3 2.6). Daily emissions, estimated based on activity and power-generation data, declined substantially
 4 compared to 2019 during periods of economic lockdown, particularly in April 2020—as shown in Figure
 5 2.6 – but rebounded by the end of 2020 (Le Quéré et al., 2021; Liu et al., 2020d; Quéré et al., 2020).
 6 Impacts were differentiated by sector, with road transport and aviation particularly affected. Inventories
 7 estimate the total power sector CO₂ reduction from 2019 to 2020 at 3% (IEA, 2021a) and 4.5% (Crippa
 8 et al., 2021). Approaches that predict near real-time estimates of the power sector reduction are more
 9 uncertain and estimates range more widely, between 1.8% (Le Quéré et al., 2021; Quéré et al., 2020),
 10 4.1% (Liu et al., 2020d) and 6.8% (Bertram et al., 2021); the latter taking into account the over-
 11 proportional reduction of coal generation due to low gas prices and merit order effects. Due to the very
 12 recent nature of this event, it remains unclear what the exact short and long-term impacts on future
 13 global emissions trends will be.

14
 15 **Figure 2.6 Global CO₂ emissions from fossil fuel combustion and industry (FFI) in 2020 and the impact of**
 16 **COVID-19**

17 **Panel a depicts CO₂-FFI emissions over the past 5 decades (GtCO₂yr⁻¹). The single year declines in**
 18 **emissions following major economic and geopolitical events are shown, as well as the decline recorded in**
 19 **5 different datasets for emissions in 2020 (COVID-19) compared to 2019 (no COVID-19). Panel b depicts**
 20 **the change in global daily carbon emissions (MtCO₂ per day) in 2020 compared to 2019, showing the**
 21 **impact of COVID-19 lockdown policies.**

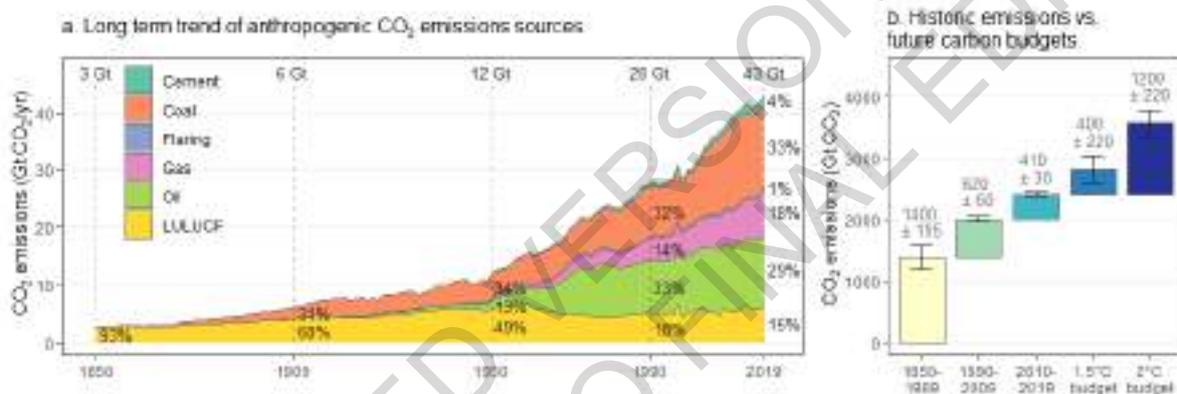

22 Source: Crippa et al. (2021), Friedlingstein et al. (2020), BP (BP, 2021), IEA (IEA, 2021a), Carbon Monitor
 23 (Liu et al., 2020d), Le Quéré et al. (Quéré et al., 2020).

24 From 1850 until around 1950, anthropogenic CO₂ emissions were mainly (>50%) from land-use, land
 25 use change and forestry (Figure 2.7). Over the past half-century CO₂ emissions from LULUCF have
 26 remained relatively constant around 5.1±3.6 GtCO₂ but with a large spread across estimates (Le Quéré
 27 et al., 2018a; Friedlingstein et al., 2020, 2019). By contrast, global annual FFI-CO₂ emissions have

1 continuously grown since 1850 and since the 1960s from a decadal average of 11 ± 0.9 GtCO₂ to 36 ± 2.9
 2 GtCO₂ during 2010–2019 (see Table 2.1).

3 Cumulative CO₂ emissions since 1850 reached 2400 ± 240 GtCO₂ in 2019 (*high confidence*)⁷. More than
 4 half (62%) of total emissions from 1850 to 2019 occurred since 1970 (1500 ± 140 GtCO₂), about 42%
 5 since 1990 (1000 ± 90 GtCO₂) and about 17% since 2010 (410 ± 30 GtCO₂) (Friedlingstein et al., 2020;
 6 Canadell et al., 2021; Friedlingstein et al., 2019) (Figure 2.7). Emissions in the last decade are about
 7 the same size as the remaining carbon budget of 400 ± 220 (500, 650) GtCO₂ for limiting global warming
 8 to 1.5°C and between one third and half the 1150 ± 220 (1350, 1700) GtCO₂ for limiting global warming
 9 below 2°C with a 67% (50%, 33%) probability, respectively (Canadell et al., 2021). At current (2019)
 10 levels of emissions, it would only take 8 (2–15) and 25 (18–35) years to emit the equivalent amount of
 11 CO₂ for a 67th percentile 1.5°C and 2°C remaining carbon budget, respectively. Related discussions of
 12 carbon budgets, short-term ambition in the context of NDCs, pathways to limiting warming to well
 13 below 2°C and carbon dioxide removals are mainly discussed in Chapters 3, 4, and 12, but also Section
 14 2.7 of this chapter.

25

Sources: Friedlingstein et al. (2020) and Canadell et al. (2021).

26 Comparisons between historic GHG emissions and baseline projections provide increased evidence that
 27 global emissions are not tracking high-end scenarios (Hausfather and Peters, 2020), and rather followed
 28 “middle-of-the-road” scenario narratives in the earlier series, and by combinations of “global-
 29 sustainability” and “middle-of-the-road” narratives in the most recent series (SRES and SSP-baselines)
 30 (Strandsbjerg Tristan Pedersen et al., 2021; Pedersen et al., 2020). As countries increasingly implement
 31 climate policies and technology costs continue to evolve, it is expected emissions will continually shift
 32 away from scenarios that assume no climate policy but remain insufficient to limit warming to below
 33 2°C (Hausfather and Peters, 2020; Vrontisi et al., 2018; UNEP, 2020b; Roelfsema et al., 2020).

FOOTNOTE ⁷ For consistency with WG1, uncertainties in this paragraph are reported at a 68% confidence interval. This reflects the difficulty in the WG1 context of characterizing the uncertainty in the CO₂ fluxes between the atmosphere and the ocean and land reservoirs individually, particularly on an annual basis, as well as the difficulty of updating the emissions from land use change.

1 The literature since AR5 suggests that compared to historical trends baseline scenarios might be biased
2 towards higher levels of fossil fuel use compared to what is observed historically (Ritchie and
3 Dowlatabadi, 2017; Ritchie, 2019; Ritchie and Dowlatabadi, 2018; Creutzig et al., 2021). Ritchie and
4 Dowlatabadi (2017) show that per-capita primary energy consumption in baseline scenarios tends to
5 increase at rates faster than those observed in the long-term historical evidence – particularly in terms
6 of coal use. For example, SSP5 envisions a 6-fold increase in per capita coal use by 2100 – against flat
7 long-term historical observations – while the most optimistic baseline scenario SSP1-Sustainability is
8 associated with coal consumption that is broadly in line with historical long-term trends (Ritchie and
9 Dowlatabadi, 2017). In contrast, models have struggled to reproduce historical upscaling of wind and
10 solar and other granular energy technologies (Creutzig et al., 2017; Wilson et al., 2020b; Sweerts et al.,
11 2020; Wilson et al., 2013; van Sluisveld et al., 2015; Shiraki and Sugiyama, 2020).

12 **2.2.2.2 Other short-lived climate forcers**

13 There are other emissions with shorter atmospheric lifetimes that contribute to climate changes. Some
14 of them like aerosols, sulphur emissions or organic carbon reduce forcing, while others like black
15 carbon, carbon monoxide or non-methane organic compounds (NMVOC) contribute to warming (also
16 see Figure 2.4) as assessed in Working Group I (Forster et al., 2021c; Naik et al., 2021a). Many of these
17 other short-lived climate forcers (SLCFs) are co-emitted during combustion processes in power plants,
18 cars, trucks, airplanes, but also during wildfires and household activities such as traditional cooking
19 with open biomass burning. As these co-emissions have implications for net warming, they are also
20 considered in long-term emission reduction scenarios as covered in the literature (Smith et al., 2020;
21 Rauner et al., 2020b; Vandyck et al., 2020; Harmsen et al., 2020) as well as Chapter 3 of this report.
22 These air pollutants are also detrimental to human health (e.g. Lelieveld et al., 2015, 2018; Vohra et al.,
23 2021). For example, Lelieveld et al. (2015) estimates a total of 3.3 (1.6-4.8) million pre-mature deaths
24 in 2010 from outdoor air pollution. Reducing air-pollutants in the context of climate policies therefore
25 lead to substantial co-benefits of mitigation efforts (Rauner et al., 2020a; Rao et al., 2017; Von Stechow
26 et al., 2015; Lelieveld et al., 2019). Here we only briefly outline the major trends in emissions of short-
27 lived climate forcers.

28 Conventional air pollutants that are subject to significant emission controls in many countries include
29 SO₂, NO_x, BC and CO. From 2015 to 2019, global SO₂ and NO_x emissions have declined, mainly due
30 to reductions in energy systems (Figure 2.8). Reductions in BC and CO emissions appear to have
31 occurred over the same period, but trends are less certain due to the large contribution of emissions
32 from poorly quantified traditional biofuel use. Emissions of CH₄, OC and NMVOC have remained
33 relatively stable in the past five years. OC and NMVOC may have plateaued, although there is
34 additional uncertainty due to sources of NMVOCs that may be missing in current inventories
35 (McDonald et al., 2018).

36

2.2.3 Regional GHG emissions trends

Regional contributions to global GHG emissions have shifted since the beginning of the international climate negotiations in the 1990s (*high confidence*). As shown in Figure 2.9, developed countries as a group have not managed to reduce GHG emissions substantially, with fairly stable levels at about 15 GtCO₂eq yr⁻¹ between 1990 and 2010, while countries in Asia and the Developing Pacific have rapidly increased their share of global GHG emissions – particularly since the 2000s (Jackson et al., 2019; Peters et al., 2020; UNEP, 2020c; Crippa et al., 2021; IEA, 2021b).

Most global GHG emission growth occurred in Asia and Developing Pacific, which accounted for 77% of the net 21 GtCO₂eq increase in GHG emissions since 1990, and 83% of the net 6.5 GtCO₂eq increase since 2010.⁸ Africa contributed 11% of GHG emissions growth since 1990 (2.3 GtCO₂eq) and 10% (0.7 GtCO₂eq) since 2010. The Middle East contributed 10% of GHG emissions growth since 1990 (2.1 GtCO₂eq) and also 10% (0.7 GtCO₂eq) since 2010. Latin America and the Caribbean contributed 11% of GHG emissions growth since 1990 (2.2 GtCO₂eq), and 5% (0.3 GtCO₂eq) since 2010. Two regions, Developed Countries, and Eastern Europe and West-Central Asia, reduced emissions overall since 1990, by -1.6 GtCO₂eq and -0.8 GtCO₂eq, respectively. However, emissions in the latter region started to grow again since 2010, contributing to 5% of the global GHG emissions change (0.3 GtCO₂eq).

Average annual GHG emission growth across all regions slowed between 2010-2019 compared to 1990-2010, with the exception of Eastern Europe and West-Central Asia. Global emissions changes tend to be driven by a limited number of countries, principally the G20 group (UNEP, 2020c; Xia et al., 2021; Friedlingstein et al., 2020). For instance, the slowing of global GHG emissions between 2010-

FOOTNOTE⁸ Note that GHG emissions from international aviation and shipping could not be attributed to individual regions, while CO₂ emissions from AFOLU could not be attributed to individual countries. Change in GHG emissions that can be easily assigned to regions is 20.3 of 20.8 GtCO₂eq for 1990-2019 and 6.3 of 6.5 GtCO₂eq for 2010-2019.

1 2019, compared to the previous decade, was primarily triggered by substantial reductions in GHG
2 emissions growth in China. Two countries (China, India) contributed more than 50% to the net 6.5
3 GtCO₂eqyr⁻¹ increase in GHG emissions during 2010-2019 (at 39% and 14%, respectively), while ten
4 countries (China, India, Indonesia, Vietnam, Iran, Turkey, Saudi Arabia, Pakistan, Russian Federation,
5 Brazil) jointly contributed about 75% (Figure 2.9) (see also Minx et al., 2021; Crippa et al., 2021).

6 GHG and CO₂-FFI levels diverge starkly between countries and regions (*high confidence*) (UNEP,
7 2020c; Jackson et al., 2019; Friedlingstein et al., 2020; Crippa et al., 2021). Developed Countries
8 sustained high levels of per capita CO₂-FFI emissions at 9.5 t CO₂/cap in 2019 (but with a wide range
9 of 1.9-16 tCO₂/cap). This is more than double that of three developing regions – 4.4 (0.3-12.8) tCO₂/cap
10 in Asia and Developing Pacific, 1.2 (0.03-8.5) tCO₂/cap in Africa, and 2.7 (0.3-24) tCO₂/cap in Latin
11 America⁹. Per capita CO₂-FFI emissions were 9.9 (0.89-15) tCO₂/cap in Eastern Europe and West-
12 Central Asia, and 8.6 (0.36-38) tCO₂/cap in the Middle East. CO₂-FFI emissions in the three developing
13 regions together grew by 26% between 2010 and 2019, compared to 260% between 1990 and 2010,
14 while in Developed Countries emissions contracted by 9.9% between 2010-2019 and by 9.6% between
15 1990-2010.

16 Least developed countries contributed only a negligible proportion of historic GHG emissions growth
17 and have the lowest per capita emissions. As of 2019 they contribute 3.3% of global GHG emissions,
18 excluding LULUCF CO₂, despite making up 13.5% of the global population. Since the start of the
19 industrial revolution in 1850 up until 2019, they contributed 0.4% of total cumulative CO₂ emissions
20 (Figure 2.10). Conversely, Developed Countries have the highest share of historic cumulative emissions
21 (Matthews, 2016; Gütschow et al., 2016; Rocha et al., 2015), contributing approximately 57% (Figure
22 2.10), followed by Asia and developing Pacific (21%), Eastern Europe and West-Central Asia (9%),
23 Latin America and the Caribbean (4%), the Middle East (3%), and Africa (3%). Developed Countries
24 still have the highest share of historic cumulative emissions (45%) when CO₂-LULUCF emissions are
25 included, which typically account for a higher proportion of emissions in developing regions (Figure
26 2.10).

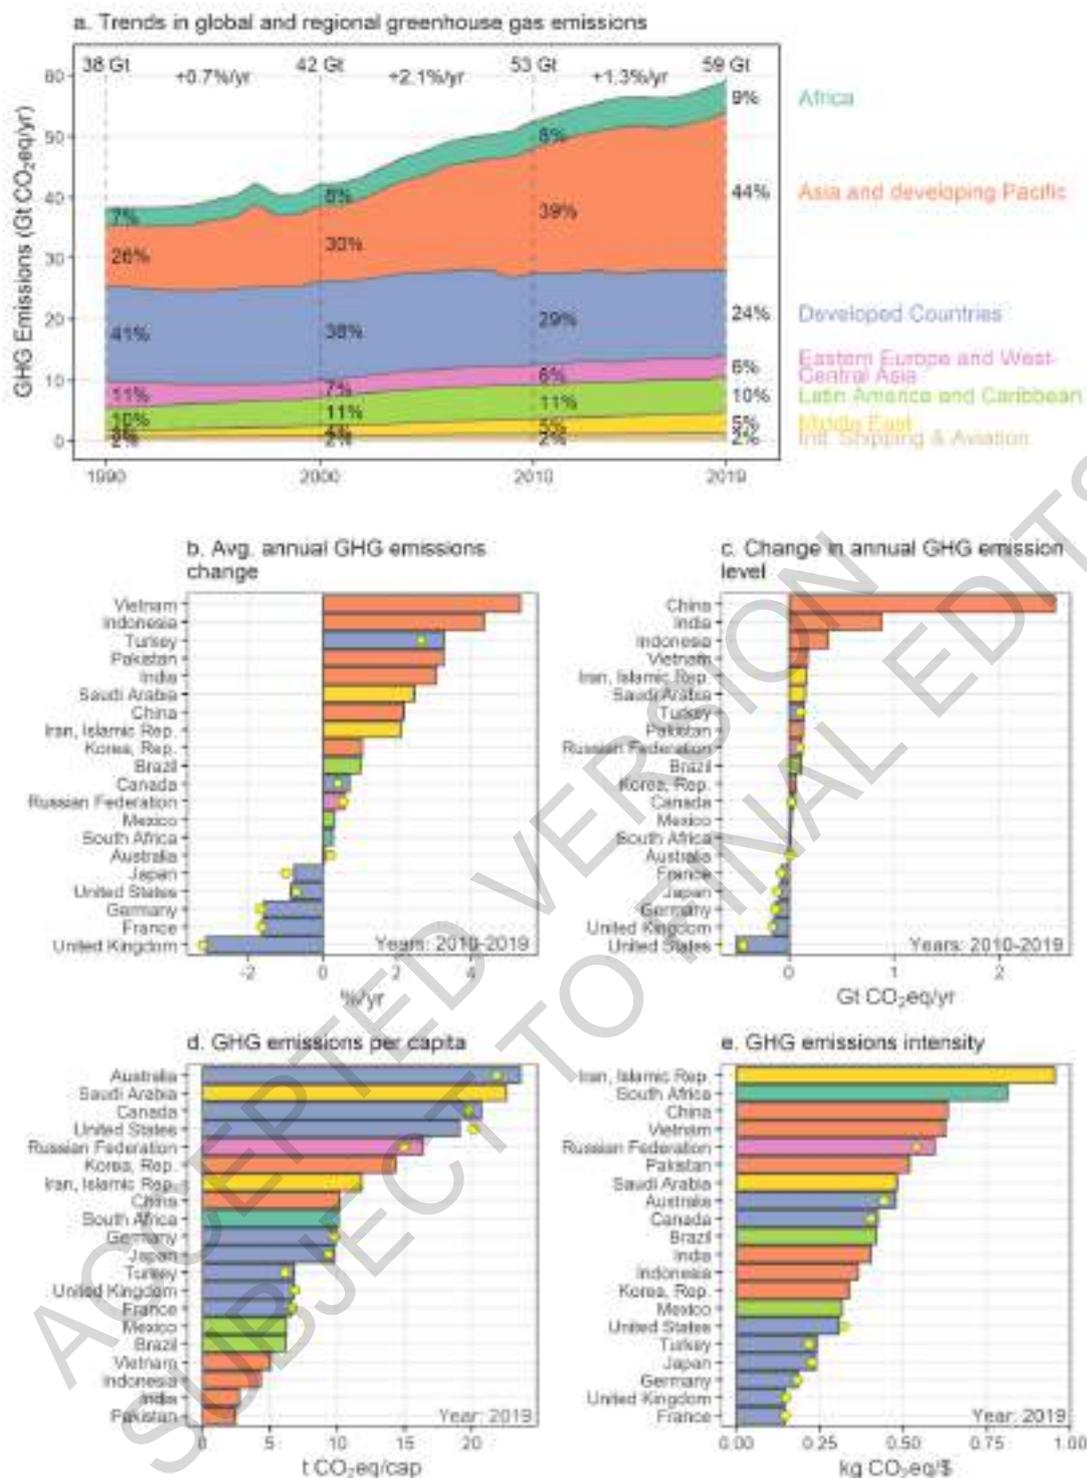

27 A growing number of countries have reduced CO₂ and GHG emissions for longer than 10 years (*medium*
28 *confidence*) (Le Quéré et al., 2019; Lamb et al., 2021a; Wu et al., 2021; Burck et al., 2021). Data up to
29 2018 indicates that about 24 countries have reduced territorial CO₂ and GHG emissions (excluding
30 LULUCF CO₂), as well as consumption-based CO₂ emissions, for at least 10 years (Lamb et al., 2021a).
31 Uncertainties in emissions levels and changes over time prevents a precise assessment of reductions in
32 some cases. Of these 24 countries, 12 peaked emissions in the 2000s; 6 have sustained longer reductions
33 since the 1970s; and 6 are former members of the Eastern Bloc, where emissions dropped rapidly in the
34 1990s and continued declining at a slower pace thereafter. Country emissions reductions have been
35 driven by both climate and non-climate policies and factors, including structural changes. To date, most
36 territorial emissions reductions were realised in the electricity and heat sector, followed by industry and
37 buildings, while in many cases transport emissions have increased since countries reached their overall
38 emissions peak (Climate Transparency, 2021; Lamb et al., 2021a). One estimate of the total reduction
39 in annual GHG emissions – from peak years to 2018 – sums to 3.2 GtCO₂eq across all decarbonising
40 countries (Lamb et al., 2021a). These reductions have therefore been far outweighed by recent emissions
41 growth. However, climate policy related reductions may be even larger when compared against a
42 counterfactual case of emissions growth across different sectors (Eskander and Fankhauser, 2020b)
43 (Cross-Chapter Box 1 in Chapter 1; Section 2.8).

44 The recent (2010-2019) emissions changes of some countries are in line with pathways that limit *likely*
45 warming to below 2°C (e.g. -4% average annual reductions) (Figure 2.10). Overall, there are first

FOOTNOTE⁹ In all cases, constraining countries within the emissions range to those larger than 1 million population.

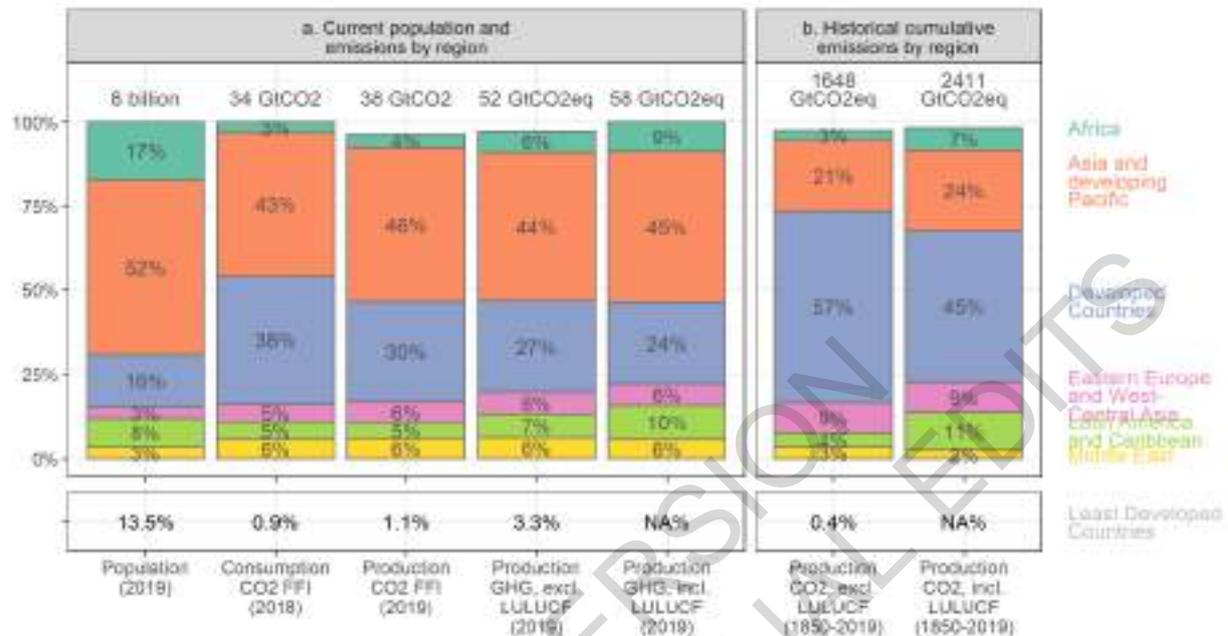

1 country cases emerging that highlight the feasibility of sustained emission reductions outside of periods
2 of economic disruption (Lamb et al., 2021a). However, such pathways will need to be taken by many
3 more countries for keeping the goals of the Paris Agreement in reach (Höhne et al., 2020; Kriegler et
4 al., 2018a; Roelfsema et al., 2020; den Elzen et al., 2019) as analysed by Chapter 4 of this report.
5 Moreover, observed reductions are not yet consistent and long-term, nor achieved across all sectors, nor
6 fully aligned with country NDC targets (Le Quéré et al., 2019; Lamb et al., 2021a; den Elzen et al.,
7 2019; Climate Transparency, 2021; Burck et al., 2021).

2.2.4 Sectoral GHG emission trends

12

In 2019, 34% (20 GtCO₂eq) of the 59 GtCO₂eq GHG emissions came from the energy sector, 24% (14 GtCO₂eq) from industry, 22% (13 GtCO₂eq) from AFOLU, 15% (8.7 GtCO₂eq) from transport and 6% (3.3 GtCO₂eq) from buildings (Figure 2.12). The relative size of each sector depends on the exact definition of sector boundaries (de la Rue du Can et al., 2015; Lamb et al., 2021b). The largest individual sub-sector contributing to global GHG emissions in 2019 was electricity and heat generation at 14 GtCO₂eq. This subsector can be reallocated to consuming sectors as indirect (Scope 2) emissions to emphasize the role of final energy demand and demand-side solutions in climate change mitigation (Creutzig et al., 2018) (Chapter 5). This increases the emission share of the industry sector to 34% and of the buildings sector to 16%.

Average annual GHG emissions growth has been fastest in the transport sector with about 1.8% for the most recent period 2010-2019, followed by direct emissions in the industry sector (1.4%) and the energy sector (1%) (Figure 2.13). This is different to growth patterns observed in the previous decade as reported in AR5 (IPCC, 2014a; Blanco et al., 2014). Between 2000 and 2009 fastest GHG emissions growth was observed for industry with 3.4% followed by the energy sector with 2.3%. GHG emission growth in the transport sector has been stable across both periods at about 1.8%, while direct building emissions growth averaged below 1% during 2010-2019. Ranking of high emitting sectors by direct emissions highlights the importance of the LULUCF CO₂ (6.6 GtCO₂eq), road transport (6.1 GtCO₂eq), metals (3.1 GtCO₂eq), and other industry (4.4 GtCO₂eq) sub-sectors. Overall, some of the fastest growing sources of sub-sector emissions from 2010 to 2019 have been international aviation (+3.4%)¹⁰,

2 3 4 **2.3 Past and present trends of consumption-based CO₂ emissions (CBEs)** 5 **and emissions embodied in trade**

6 **2.3.1 Scope, variability, and uncertainty of CBEs**

7 Consumption is increasingly met by global supply chains often involving large geographical distances
8 and causing emissions in producing countries (Hubacek et al., 2014, 2016; Wiedmann and Lenzen,
9 2018). Therefore, accounting of emissions of production along the entire supply chain to fulfil final
10 demand, so-called consumption-based emissions (CBEs) is necessary to understand why emissions
11 occur and to what extent consumption choices and associated supply chains contribute to total
12 emissions, and ultimately how to influence consumption to achieve climate mitigation targets and
13 environmental justice (Vasconcellos, 2019).

14 Production-based emissions (PBEs) and territorial emissions resulting from the production and
15 consumption of goods and services within a region as well as for export production are often used by
16 authorities to report carbon emissions (Peters, 2008) (see also Section 2.2). PBEs also include emissions
17 from international activities (e.g., international aviation/shipping and non-resident activities), which are
18 excluded from territorial emissions (Karstensen et al., 2018; Shan et al., 2018). In contrast, CBEs refer
19 to emissions along the entire supply chains induced by consumption irrespective of the place of
20 production (Liu et al., 2015b). This reflects a shared understanding that a wider system boundary going
21 beyond territorial emissions is important to avoid outsourcing of pollution and to achieve global
22 decarbonisation. CBEs allow to identify new policy levers through providing information on a country's
23 trade balance of embodied emissions, households' carbon implications of their lifestyle choices,
24 companies' upstream emissions as input for supply chain management, and cities' footprints outside
25 their administrative boundaries (Davis and Caldeira, 2010; Feng et al., 2013). Kander et al., (2015)
26 proposed a technology-adjusted consumption-based emission accounting (TCBA) approach to address
27 the issue of carbon intensity in exports. TCBA incorporates emissions embodied in trade but also adjust
28 for differences in carbon efficiency in exports of different countries. Unlike PBEs, there are no
29 internationally agreed upon approaches to calculate CBEs, making it a major drawback for
30 mainstreaming the use of this indicator in policy making.

31 There are other proposed emission accounting approaches used in different circumstances. Historical
32 cumulative emissions (HCEs) are used when analysing countries' historic contribution to emissions and
33 responsibility for emission reduction. HCEs account for a country's cumulative past emissions, which
34 may be significantly different from the country's current annual emissions (Botzen et al., 2008; Ritchie
35 2019b), but are sensitive to the choice of cut-off period. For example, the United States and EU-27
36 countries plus the United Kingdom contributed respectively 13.4% and 8.7% to global PBEs in 2019
37 (Crippa et al., 2020), however, they emitted around 25% and 22% of global historical PBEs since 1751
38 (Ritchie, 2019). In contrast, extraction-based emissions (EBEs) accounting allocates all emissions from
39 burning fossil fuels throughout the supply chains to the country where the fuels were extracted
40 (Steininger and Schinko, 2015). EBEs can be calculated by multiplying primary energy extraction of
41 fossil fuels with their respective carbon content adjusting for the fraction of fossil fuels that is not
42 combusted (Erickson and Lazarus, 2013). Another approach for accounting emissions is income-based
43 emission accounting (IBE), which traces emissions throughout all supply chains and allocates emissions
44 to primary inputs (e.g., capital and labour). In other words, IBEs investigates a country's direct and
45 indirect downstream GHG emissions enabled by its primary inputs (Liang et al., 2017a). All these

1 approaches provide complementary information and different angles to assigning responsibility for
2 emissions reductions.

3

4 **START BOX 2.2 HERE**

5

6 **Box 2.2 Policy applications of consumption-based emissions**

- 7 • Consumption-based emissions provide additional or complementary information to
8 production-based emissions that can be used for a variety of policy applications. These
9 include: Complementary national-level emissions accounting and target or budget setting
10 • Raising awareness and increasing understanding of the GHG effects of consumption
11 • Accounting for and understanding of distributional and responsibility issues in GHG emissions
12 mitigation, both nationally and internationally.
13 • Incentives to change consumption patterns or reduce consumption (e.g., through taxation
14 policies)
15 • Accounting for and understanding of carbon leakage and emissions embodied in trade*)
16 • International emissions trading schemes or linked national schemes
17 • Trade policies addressing emissions embodied in trade and international supply chains (e.g.,
18 border tax adjustments and clean technology transfers, carbon offsetting or financing, etc.)
19 • Including embodied emissions in product performance standards and labelling
20 • Policies of public and private procurement
21 • Agreements with international suppliers
22 • Discussing the climate impacts of lifestyles and inequalities in consumption and associated
23 emissions

24 Above points are based on a synopsis of studies (Steininger et al., 2014; Afionis et al., 2017; Hubacek
25 et al., 2017b; Wang and Zhou, 2018; Bolea et al., 2020)

26 * Note, however, that comparing embodied emissions in trade between countries is further complicated
27 by the fact that emission intensities differ across countries. Approaches to adjust for these differences
28 and facilitate comparisons have been suggested, e.g., by (Baumert et al., 2019; Dietzenbacher et al.,
29 2020; Jakob, 2020; Kander et al., 2015). Many different approaches on how to share responsibility
30 between producers and consumers have been proposed in designing effective integrated global climate
31 policies (Yang et al., 2015; Liu and Fan, 2017; Zhu et al., 2018; Khajehpour et al., 2019; Jakob et al.,
32 2021). Ultimately, assigning responsibility is normative.

33 **END BOX 2.2 HERE**

34

35 The dominant method for calculating CBEs of nations is global multi-region input-output (GMRIO)
36 analysis (Wiedmann and Lenzen, 2018), with other methods playing a minor role, e.g. analysing
37 bilateral trade flows of products and their life-cycle emission factors (Sato, 2014). Generally, the
38 uncertainties associated with CBEs depends on the choice of the dataset/model used for calculation,
39 which differs according to a) the national economic and trade data used, b) the emissions data used, c)
40 the sector or product-level aggregation, d) the regional aggregation, e) the conceptual scope (e.g.,
41 residential vs territorial accounting principle) and f) the model construction techniques, which include
42 table balancing algorithms and ways of dealing with missing or conflicting data (Moran and Wood,
43 2014; Owen, 2017; Wieland et al., 2018; Wood et al., 2018b, 2019a). When excluding systematic error

1 sources, research has shown that the stochastic relative standard variation (RSD) of total national CBE
 2 is not significantly different to that from PBE accounts and in the region of 5-15% (Lenzen et al., 2010;
 3 Wood et al., 2018b, 2019a)

4 Six global accounts for consumption-based GHG emissions at the country level are widely used (Table
 5 2.2). Each dataset has been constructed by different teams of researchers, covers different time periods
 6 and contains CBEs estimates for different sets of countries and regions (Owen, 2017).

7

8 **Table 2.2 Features of six global datasets for consumption-based emissions accounts**

Name of consumption-based account datasets (and references)	Years available	Number of countries/regions	Number of sectors

Global Carbon Budget (Friedlingstein et al., 2020)	1990-2018	118	N/A

9

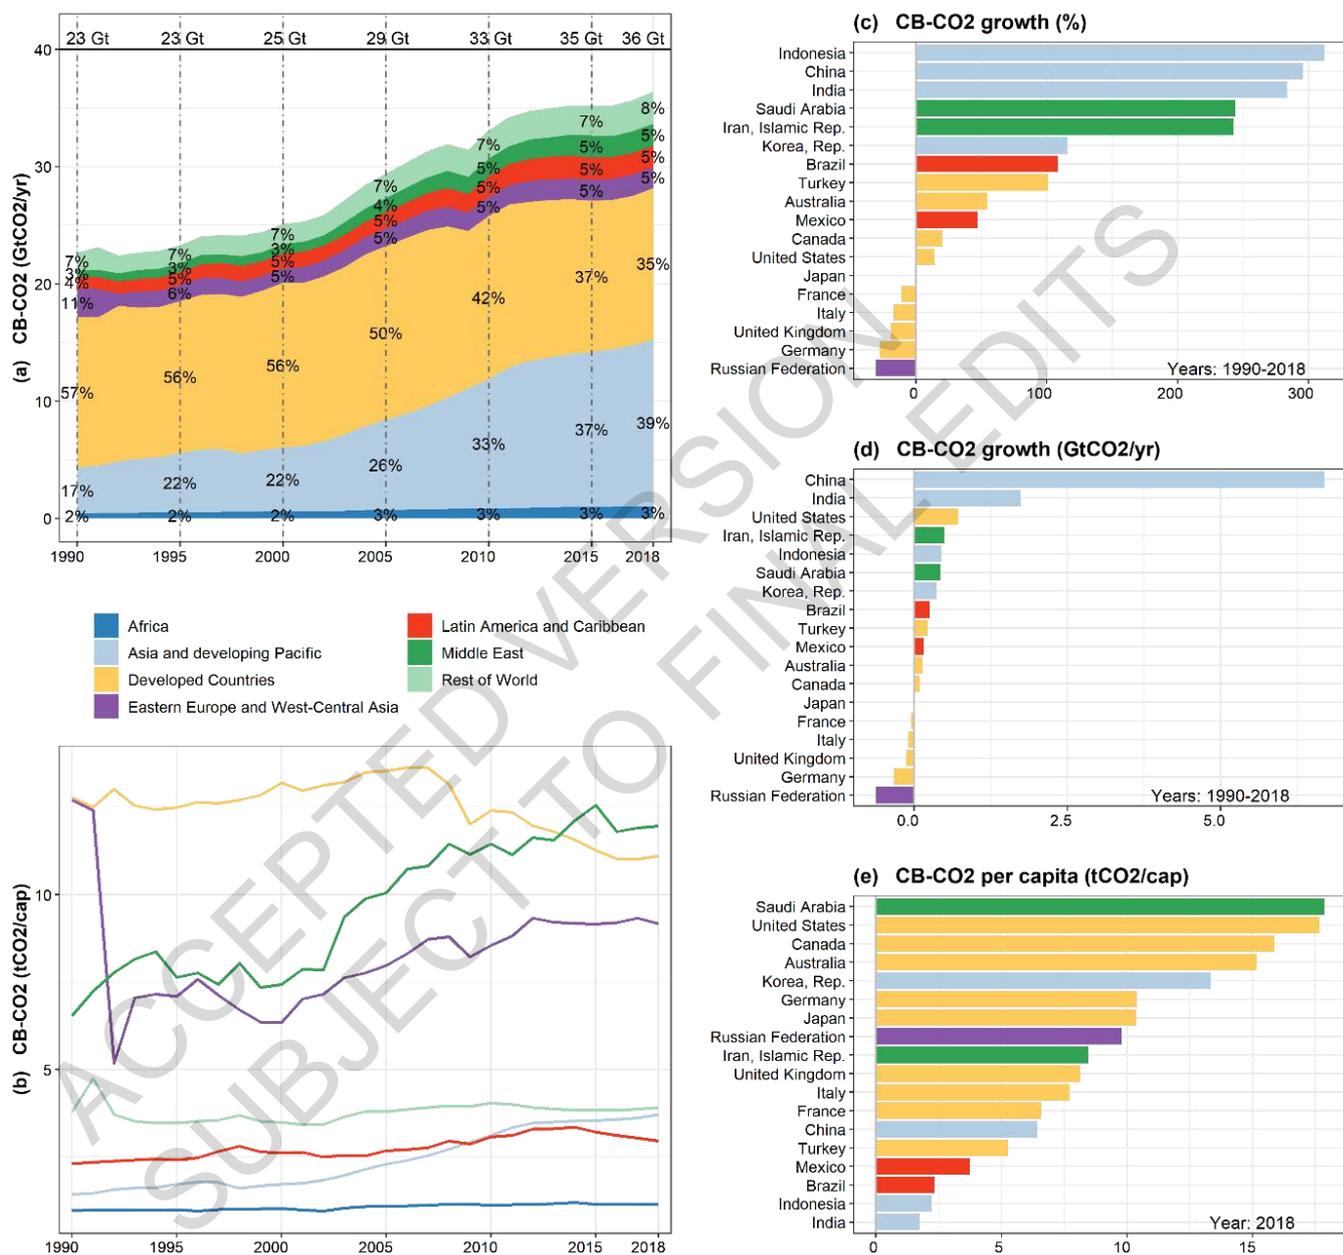

10 Wood et al. (2019b) present the first comprehensive and systematic model intercomparison and find a
 11 variation of 5-10% for both PBEs and CBEs accounts of major economies and country groups (e.g.,
 12 EU28, OECD). The estimates for the US were the most closely aligned, with 3.7% Relative Standard
 13 Deviation (RSD). For smaller countries, variability is in the order of 20-30% and can reach more than
 14 40% in cases of very small, highly trade-exposed countries such as Singapore and Luxembourg (Wood
 15 et al., 2019a). It is recommended to interpret CBE results for such countries with care.

16 Overall, production accounts showed a slightly higher convergence (8% average of RSD) than
 17 consumption-based accounts (12%). The variation across model results can be approximately halved,
 18 when normalising national totals to one common value for a selected base year. The difference between
 19 PBE result variation (4% average RSD after normalisation) and CBEs results (7%) remains after
 20 normalisation.

21 In general, the largest contributors to uncertainty of CBEs results are - in descending order of priority -
 22 the total of territorial GHG emission accounts, the allocation of emissions to economic sectors, the total
 23 and composition of final demand, and lastly the structure of the economy. Harmonising territorial
 24 emissions across GMRIO datasets is the single most important factor that reduces uncertainty by about
 25 50% (Tukker et al., 2020). More work is required to optimise or even institutionalise the compilation
 26 of multi-region input-output data and models to enhance the accuracy of consumption-based accounting
 27 (Tukker et al., 2018; Wood et al., 2018).

1 **2.3.2 Trends in global and regional CBEs trajectories**

2 In comparison to territorial emissions discussed in Section 2.2, Figure 2.14 shows the trends of global
 3 and regional CBEs from 1990 to 2018. This section uses the PBEs and CBEs data from the latest Global
 4 Carbon Budget (Friedlingstein et al., 2020), which are slightly different from the PBEs used in Section
 5 2.2. The Global Carbon Budget only includes CO₂ emissions from fossil fuels and cement production.

6
 7 **Figure 2.14 Consumption-based CO₂ emission trends for the period 1990-2018. The CBEs of countries are**
 8 **collected from the Global Carbon Budget 2020 (Friedlingstein et al., 2020)**
 9 Source: This figure is modified based on Hubacek et al. (2021).

10 The left two panels in Figure 2.14 show total and per capita CBEs for six regions. The three panels on
 11 the right show additional information for the 18 top-emitting countries with the highest CBEs in 2018.
 12 In developed countries, consumption-based CO₂ emissions peaked at 15 GtCO₂ in 2007 with a

1 subsequent 16% decline until 2016 (to 12.7 GtCO₂) and a slight rebound of 1.6% until 2018 (to 12.9
 2 GtCO₂). Asia and Developing Pacific has been a major contributor to consumption-based CO₂
 3 emissions growth since 2000 and exceeded developed countries as the global largest emissions source
 4 in 2015. From 1990 to 2018, the average growth rate of Asia and Developing Pacific was 4.8% per year,
 5 while in other regions emissions declined by -1.1%-4.3%/year on average. In 2018, 35% of global
 6 consumption-based CO₂ emissions were from developed countries and 39% from Asia and Developing
 7 Pacific, 5% from Latin American and Caribbean, 5% from Eastern Europe and West-Central Asia, 5%
 8 from Middle East, and 3% from Africa (Hubacek et al., 2021). Global CBEs kept growing over the
 9 period with a short-lived decline in 2008 due to the global financial crisis. In 2020, lockdowns
 10 associated with COVID-19 significantly reduced global emissions (Section 2.2.2), including CBEs
 11 (Shan et al., 2020).

12 2.3.3 Decoupling of emissions from economic growth

13 There has been a long-standing discussion on whether environmental impacts such as carbon emissions
 14 and use of natural resources can be decoupled from economic growth. It is controversial whether
 15 absolute decoupling can be achieved at a global scale (Ward et al., 2016; Hickel and Kallis, 2020).
 16 However, a number of studies found that it is feasible to achieve decoupling at the national level and
 17 have explored the reasons for such decoupling (Ward et al., 2016; Zhao et al., 2016; Schandl et al.,
 18 2016; Deutch, 2017; Roinioti and Koroneos, 2017; Li et al., 2019; Vadén et al., 2020; Habimana Simbi
 19 et al., 2021; Shan et al., 2021).

20 Table 2.3 shows the extent of decoupling of CBEs and GDP of countries based on CBEs from the
 21 Global Carbon Budget (Friedlingstein et al., 2020) and GDP data from the World Bank. Table 2.4 also
 22 presents countries' degree of decoupling of PBEs and GDP. These data allow a comparison of
 23 decoupling between GDP and both PBEs and CBEs. Absolute decoupling refers to a decline of
 24 emissions in absolute terms or as being stable while GDP grows (i.e., a decoupling index¹¹ greater than
 25 1); relative decoupling refers to growth of emissions being lower than growth of GDP (a decoupling
 26 index between 0 and 1); and no decoupling, which refers to a situation where emissions grow to the
 27 same extent or faster than GDP (a decoupling index of less than 0) (Wu et al., 2018).

28 **Table 2.3 Country groups with different degree of CBE-GDP decoupling from 2015 to 2018**

		Absolute decoupling	Relative decoupling	No decoupling	Economic recession
Number of countries		23	67	19	6
CBEs (gigatons)	Total	5.40	25.33	1.93	0.85
	Global share	16.1%	75.6%	5.8%	2.5%
PBEs (gigatons)	Total	4.84	25.73	2.16	0.84
	Global share	14.4%	76.6%	6.4%	2.5%
Population (million)	Total	625	5195	768	270
	Global share	9.1%	75.7%	11.2%	3.9%
GDP (billion)	Total	19,891	54,240	2,300	2,997
	Global share	25.0%	68.3%	2.9%	3.8%
Average		31.45	16.29	6.57	17.78
Median		23.55	8.03	2.56	13.12

FOOTNOTE¹¹ The decoupling index can be calculated based on changes of a country's GDP and CO₂ emissions (Wu et al., 2018; Akizu-Gardoki et al., 2018), see the equation below. *DI* refers to decoupling index; *G*₁ refers to the GDP of reporting year while *G*₀ refers to the base year; *E*₁ refers to emissions of the reporting year while *E*₀ refers to emissions of the base year.

$$DI = \frac{\Delta G\% - \Delta E\%}{\Delta G\%} = \left(\frac{G_1 - G_0}{G_0} - \frac{E_1 - E_0}{E_0} \right) / \frac{G_1 - G_0}{G_0}$$

Per capita GDP (thousand USD in 2010 prices)	Max	110.70	79.23	63.93	33.11
	Min	1.31	0.49	0.52	5.80
Per capita CBEs (tons)	Average	10.27	5.30	4.47	12.55
	Median	8.87	4.13	1.67	11.33
	Max	37.95	17.65	25.35	23.21
	Min	0.64	0.09	0.18	2.33
CBE intensity (tons per thousand USD in 2010 prices)	Average	0.45	0.50	0.93	0.66

	Max	20.13	16.65	39.27	27.24
	Min	0.30	0.09	0.01	2.23

PBEs intensity (tons per thousand USD in 2010 prices)	Average	0.33	0.45	0.71	0.75
	Median	0.20	0.31	0.44	0.68
	Max	1.47	1.76	4.83	1.80
	Min	0.05	0.10	0.13	0.20

Note: CBEs are obtained from the Global Carbon Budget 2020 (Friedlingstein et al., 2020), GDP and population are from the World Bank. One country (Venezuela) does not have GDP data after 2015, so the degree of decoupling was only calculated for 115 countries. In order to be consistent with the results of CBEs, we calculate the decoupling of PBE until 2018. The latest PBE data of 2019 may not change the key messages.

During the most recent three-year period from 2015 to 2018, 23 countries (or 20% of the 116 sample countries) have achieved absolute decoupling of CBEs and GDP, while 32 countries (or 28%) achieved absolute decoupling of PBEs and GDP. 14 of them (e.g., the UK, Japan, and the Netherlands) also decoupled PBEs and GDP. Countries with absolute decoupling of CBEs tend to achieve decoupling at relatively high levels of economic development and high per capita emissions. Most of EU and North American countries are in this group. Decoupling was not only achieved by outsourcing carbon intensive production, but also improvements in production efficiency and energy mix, leading to a decline of emissions. Structural Decomposition Analysis shows that the main driver for decoupling has been a reduction in carbon intensity (that is change in energy mix and energy efficiency) from both domestic production and imports (Hubacek et al., 2021). Similarly, Wood et al., (2019c) found that EU countries have reduced their overall consumption-based GHG emissions by 8% between 1995 and 2015, mainly due to the use of more efficient technology. The literature also shows that changes in the structure of economy with a shift to tertiary sectors of production may contribute to such decoupling (Xu and Ang, 2013; Kanitkar et al., 2015; Su and Ang, 2016).

67 (or 58%) countries, including China and India, have relatively decoupled GDP and CBEs between 2015 and 2018, reflecting a slower growth in emissions than GDP. It is worth noting that the USA shows relative decoupling of emissions (both CBEs and PBEs) and GDP over the most recent period, although it strongly decoupled economic growth from emissions between 2005 and 2015. Thus decoupling can be temporary and countries' emissions may again increase after a period of decoupling.

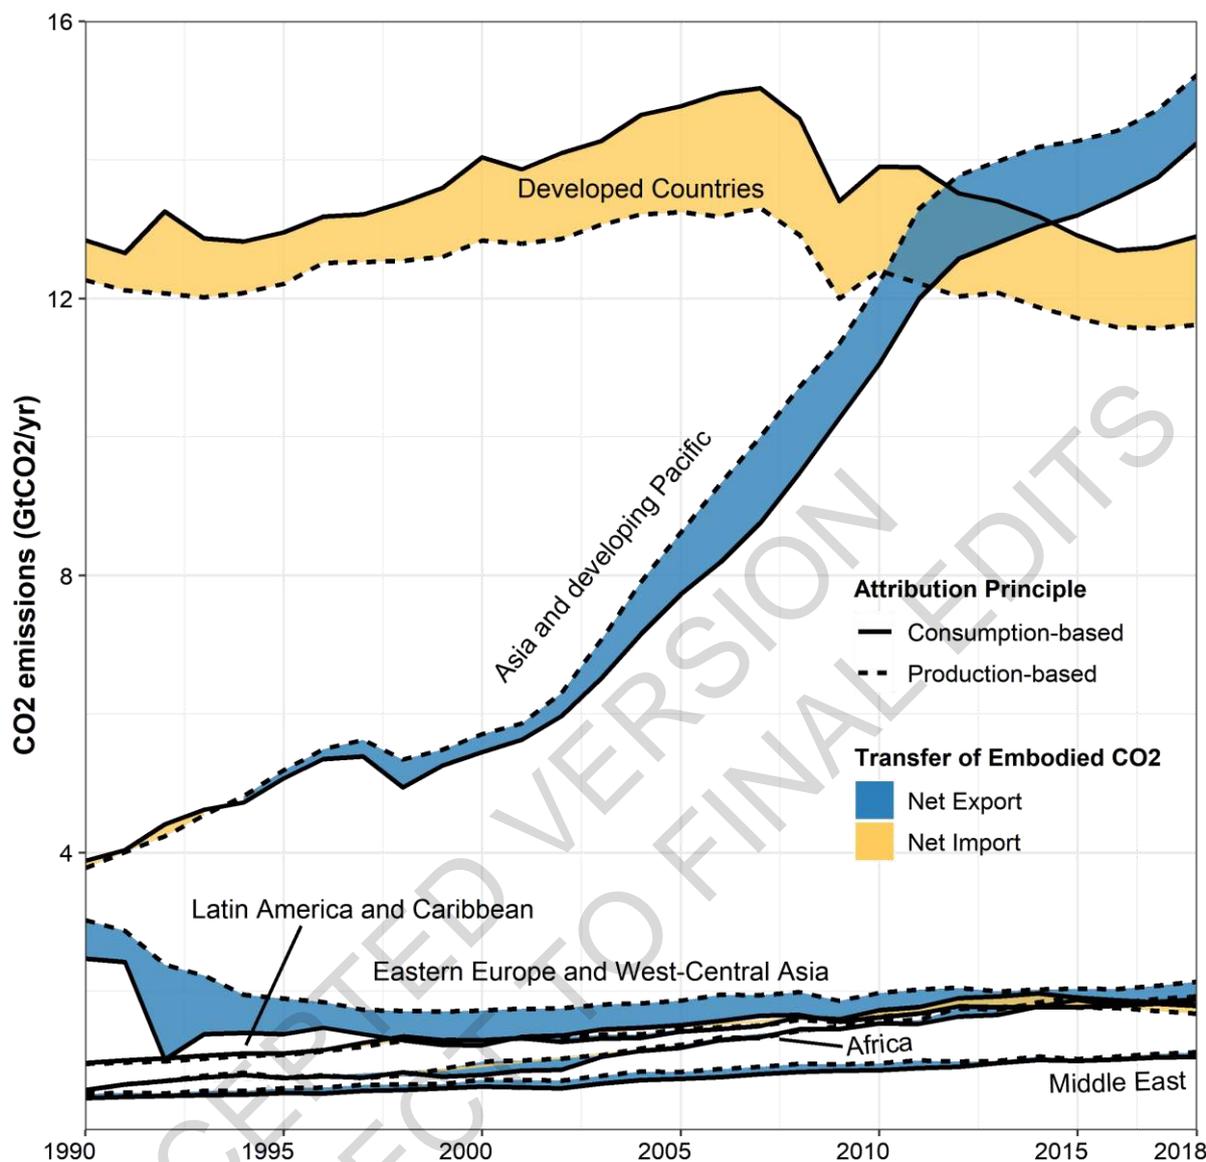

Another 19 (or 16%) countries, such as South Africa and Nepal, have experienced no decoupling between GDP and CBEs from 2015 to 2018, meaning the growth of their GDP is closely tied with the consumption of emission-intensive goods. As a result, a further increase of GDP in these countries will likely lead to higher emissions, if they follow the historical trend without substantive improvement in efficiency of production and energy use.

It is important to note that a country's degree of decoupling changes over time. For example, 32 countries achieved absolute decoupling from 2010 to 2015 but only 10 of them remained decoupled over the next three years. More importantly, although absolute decoupling has reduced annual emissions, the remaining emissions are still contributing to an increase in atmospheric carbon concentration. Absolute decoupling is not sufficient to avoid consuming the remaining CO₂ emission budget under the global warming limit of 1.5°C or 2°C and to avoid climate breakdown (Stoknes and Rockström, 2018; Hickel and Kallis, 2020). Even if all countries decouple in absolute terms this might still not be sufficient and thus can only serve as one of the indicators and steps toward fully decarbonizing the economy and society.

2.3.4 Emissions embodied in trade (EET)

As global trade patterns have changed over recent decades, so have emissions embodied in trade (EET) (Jiang & Green, 2017). EET refers to emissions associated with production of traded goods and services and is equal to the difference between PBEs and CBEs (Wiebe and Yamano, 2016). EET includes two parts: emissions embodied in imports (EEI) and emissions embodied in exports (EEE). For a given

1 country or region with CBEs higher than PBEs, a country is a net importer with a higher EEI than EEE,
 2 and vice versa.

3 **Figure 2.15 Total annual CO₂ emissions for 116 countries by global region based on consumption and**
 4 **production-based emissions**

5 The shaded areas are the net CO₂ trade balances (differences) between each of the regions. Yellow
 6 shading indicates that the region is a net importer of embodied CO₂ emissions, leading to consumption-
 7 based emission estimates that are higher than traditional territorial emission estimates. Blue shading
 8 indicates the reverse. Production-based emissions are collected from EDGAR and consumption-based
 9 emissions from the Global Carbon Budget 2020 (Friedlingstein et al., 2020).

10 Source: This figure is modified based on Hubacek et al. (2021).
 11

12 EET have been rising faster since the 1980s due to an increase in trade volume (Xu and Dietzenbacher,
 13 2014; Wood et al., 2018b; Zhong et al., 2018). CO₂ emissions from the production of internationally
 14 traded products peaked in 2006 at about 26% of global CO₂ emissions. Since then, international CO₂
 15 emissions transfers declined but are likely to remain an important part of the climate policy agenda
 16 (Wood et al., 2019c). About 24% of global economic output and 25% of global CO₂ emissions are
 17 embodied in the international trade of goods and services as of 2014 (Hubacek et al., 2021).

2.3.4.1 *Net emission transfers*

Located downstream in global supply chains, developed countries (mostly in Western Europe and North America) tend to be net emission importers, i.e., EEI are larger than EEE. For example, over 40% of national CO₂ footprints in France, Germany, Italy, and Spain are from imports (Fan et al., 2017). Developing countries tend to be net emission exporters with higher PBEs than their CBEs (Peters et al., 2011b; Le Quéré et al., 2018), especially for Asia and Developing Pacific (as shown in Figure 2.15). That is to say, there is a net emission transfer and outsourcing of carbon-intensive production from developed to developing economies via global trade (Jiang et al., 2018), mainly caused by cheap labour costs (Tate and Bals, 2017) and cheap raw materials (Mukherjee, 2018). Increasing openness to trade (Fernández-Amador et al., 2016) and less stringent environmental legislation (acting as so-called pollution havens) are also possible reasons (Hoekstra et al., 2016; Malik and Lan, 2016; Banerjee and Murshed, 2020).

Net emissions transferred between developing and developed countries peaked at 7.3% of global CO₂ emissions in 2006 and then subsequently decline (Wood et al., 2019c). The main reason for the decline was an improvement in the carbon intensity of traded products of about 40% between 1995 and 2015, rather than a decline in trade volume (Wood et al., 2019c). Despite continued improvements, developing economies tend to have higher emission intensity than developed economies due to less efficient technologies and a carbon-intensive fuel mix (Liu et al., 2015a; Jiang and Guan, 2017).

2.3.4.2 *Geographical shifts of trade embodied emissions*

With the rapid growth of developing countries, the geographical centre of global trade as well as trade embodied emissions is changing. The fast growth of Asian countries is shifting the global trade centre from Europe to Asia (Zhang et al., 2019). Asian exports in monetary units increased by 235% from 1996 to 2011, and its share in global exports increased from 25% to 46%, whereas Europe's share in global exports decreased from 51% in 1996 to 39% in 2011. After 2011, global trade has stalled, but Asia's share of global exports further increased to 42% in 2020 (UNCTAD, 2021).

In addition to changes in trade volume, trading patterns have also been changing significantly in Asian countries. These countries are replacing traditional trading hubs (such as Russia and Germany) due to the fast growth in trade flows, especially with countries of the global South (Zhang et al., 2019). The largest geographical shifts in trade-embodied emissions between 1995 and 2011 occurred in high-tech, electronics, and machinery (Malik and Lan, 2016; Jiang et al., 2018a). For example, China is shifting its exports to include more low-carbon and higher value-added goods and services. As a result, China's exported emissions declined by 20% from 2008 to 2015 (Mi et al., 2018).

As a result, developing countries are increasingly playing an important role in global trade. Emissions embodied in trade between developing countries, so-called South-South trade, has more than doubled between 2004 (0.47 Gt) and 2011 (1.11 Gt), which is seen as a reflection of a new phase of globalisation (Meng et al., 2018). Developing countries, therefore, have gained importance as global suppliers of goods and services and have also become more relevant as global consumers as they grow their domestic demand (Fernández-Amador et al., 2016). Since 2014, CO₂ emission transfer between developing countries has plateaued and then slightly declined and seems to have stabilised at around the same level of transfers between non-OECD and OECD countries at around 2.4 GtCO₂ yr⁻¹ (Wood et al., 2019a). In both cases, a decrease in carbon intensity of trade just about offset increased trade volumes (Wood et al., 2019a).

2.4 Economic Drivers and Their Trends by Regions and Sectors

This section provides a summary of the main economic drivers of GHG emissions (mostly territorial) by regions and sectors, including those that are more indirect drivers related to economic activity, such

1 as inequality and rapid urbanisation. Trade as a driver of global GHG emissions is described in the
2 Chapter 2 Supplementary Material. Socio-demographic drivers are described in Section 2.6. The Kaya
3 decomposition presented in this section is based on the IEA and EDGAR v6 databases and tracks global,
4 regional, and sectoral GHG emissions from 1990 to 2019 (Crippa et al., 2021; Minx et al., 2021; Lamb
5 et al., 2021b; IEA, 2021c). It shows main contributors to GHG emissions as independent factors,
6 although these factors also interact with each other.

7 2.4.1 Economic Drivers at Global and Regional Levels

8 Economic growth (measured as GDP) and its main components, GDP per capita and population growth,
9 remained the strongest drivers of GHG emissions in the last decade, following a long-term trend (*robust
10 evidence, high agreement*) (Liddle, 2015; Malik et al., 2016; Sanchez and Stern, 2016; Chang et al.,
11 2019; Dong et al., 2019; Liobikiene and Butkus, 2019; Liu et al., 2019a; Mardani et al., 2019; Pan et
12 al., 2019; Dong et al., 2020; Parker and Bhatti, 2020; Xia et al., 2021). Globally, GDP per capita
13 remained by far the strongest upward driver, increasing almost in tandem with energy consumption and
14 CO₂ emissions up until 2015, after which some modest decoupling occurred (Deutch, 2017; Wood et
15 al., 2018b) (Section 2.3.3). The main counteracting, yet insufficient, factor that led to emissions
16 reductions was decreased energy use per unit of GDP in almost all regions (-2.0% yr⁻¹ between 2010
17 and 2019 globally (Figure 2.16), see also (Lamb et al., 2021b) (*robust evidence, high agreement*). These
18 reductions in energy intensity are a result of technological innovation, structural changes, regulation,
19 fiscal support, and direct investment, as well as increased economic efficiency in underlying sectors
20 (Yao et al., 2015; Sanchez and Stern, 2016; Chang et al., 2019; Dong et al., 2019a; Mohammed et al.,
21 2019; Stern, 2019; Azhgaliyeva et al., 2020; Goldemberg, 2020; Gao et al., 2021; Liddle and
22 Huntington, 2021; Xia et al., 2021; Liu et al., 2019b).

23 The decades-long trend that efficiency gains were outpaced by an increase in worldwide GDP (or
24 income) per capita continued unabated in the last ten years (*robust evidence, high agreement*)
25 (Wiedmann et al., 2020; Xia et al., 2021). In addition, the emissions-reducing effects of energy
26 efficiency improvements are diminished by the energy rebound effect, which has been found in several
27 studies to largely offset any energy savings (*robust evidence, high agreement*) (Rausch and Schwerin,
28 2018; Bruns et al., 2021; Colmenares et al., 2020; Stern, 2020; Brockway et al., 2021). The rebound
29 effect is discussed extensively in Section 9.9.2.

30 A significant decarbonisation of the energy system was only noticeable in North America, Europe and
31 Eurasia. Globally, the amount of CO₂ per unit of energy used has practically remained unchanged over
32 the last three decades (Chang et al., 2019; Tavakoli, 2018), although it is expected to decrease more
33 consistently in the future (Xia et al., 2021). Population growth has also remained a strong and persistent
34 upward driver in almost all regions (+1.2% yr⁻¹ globally from 2010 to 2019, Figure 2.16, see also Lamb
35 et al., 2021), although per capita emission levels are very uneven across world regions. Therefore,
36 modest population increases in wealthy countries may have a similar impact on emissions as high
37 population increases in regions with low per capita emission levels.

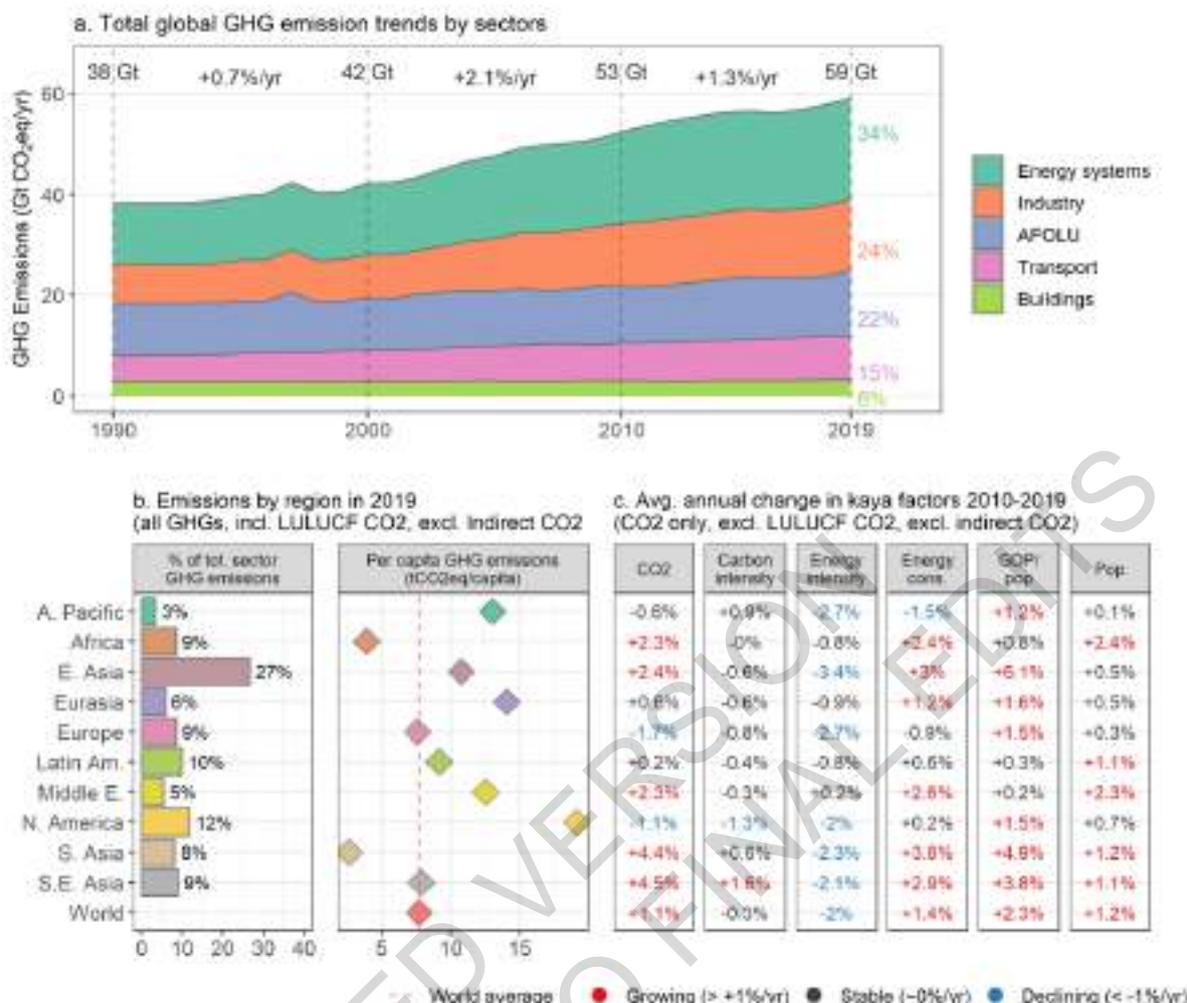

Figure 2.16 Trends and drivers of global GHG emissions, including a) trends of GHG emissions by sectors 1990–2019, b) share of total and per capita GHG emissions by world region in 2019, and c) Kaya decomposition of CO₂ emissions drivers

The Kaya decomposition is based on the equation $F = P(G/P)(E/G)(F/E)$, where F is CO₂ emissions, P is population, G/P is GDP per capita, E/G is the energy intensity of GDP and F/E is the carbon intensity of energy. The indicated annual growth rates are averaged across the years 2010–2019 (in panel c, these are for fossil fuel CO₂ emissions only, in order to ensure compatibility with underlying energy data). Note that the energy consumption by itself (primary energy supply) is not part of the decomposition, but is listed here for comparison with the Kaya factors.

Source: Data from Crippa et al. (2021), IEA (IEA, 2021c), Minx et al. (2021)

Developing countries remained major accelerators of global CO₂ emissions growth since 2010, mostly driven by increased consumption and production, in particular in East Asia (*robust evidence, high agreement*) (Jiborn et al., 2020). While energy intensity declined to a similar extent in countries of the OECD (Organisation for Economic Co-operation and Development) and non-OECD countries over the last 30 years, economic growth has been much stronger in non-OECD countries (González-Torres et al., 2021). This led to an average annual growth rate of 2.8% of CO₂ emissions in these countries, whereas they decreased by 0.3% yr⁻¹ in OECD countries (UNEP, 2019). The majority of developed economies reduced both production-based and consumption-based CO₂ emissions modestly (Jiborn et al., 2020; Xia et al., 2021). This was due to slower economic growth, increased energy efficiency (less energy per unit of GDP), fuel switching from coal to gas (mostly in North America) (Wang et al.,

1 2020b), and the use of less and cleaner energy from renewables in Europe (Peters et al., 2017;
2 Karstensen et al., 2018; Chang et al., 2019; Wood et al., 2019c).

3 Economic growth as the main driver of GHG emissions plays out particularly strong in China and India
4 (*robust evidence, high agreement*) (Liu et al., 2019b; Ortega-Ruiz et al., 2020; Wang et al., 2020c; Yang
5 et al., 2020; Zheng et al., 2020; Xia et al., 2021), although both countries show signs of relative
6 decoupling because of structural changes (Marin and Mazzanti, 2019). A change in China's production
7 structure (with relatively less heavy industry and lower-carbon manufacturing) and consumption
8 patterns (i.e., the type of goods and services consumed) has become the main moderating factor of
9 emissions after 2010, while economic growth, consumption levels, and investment remain the
10 dominating factors driving up emissions (Wang and Jiang, 2019; Jiborn et al., 2020; Zheng et al., 2020).
11 In India, an expansion of production and trade as well as a higher energy intensity between 2010 and
12 2014 caused growth of emissions (Kanitkar et al., 2015; Wang and Zhou, 2020; (Wang et al., 2020d)).

13 2.4.2 Sectoral Drivers

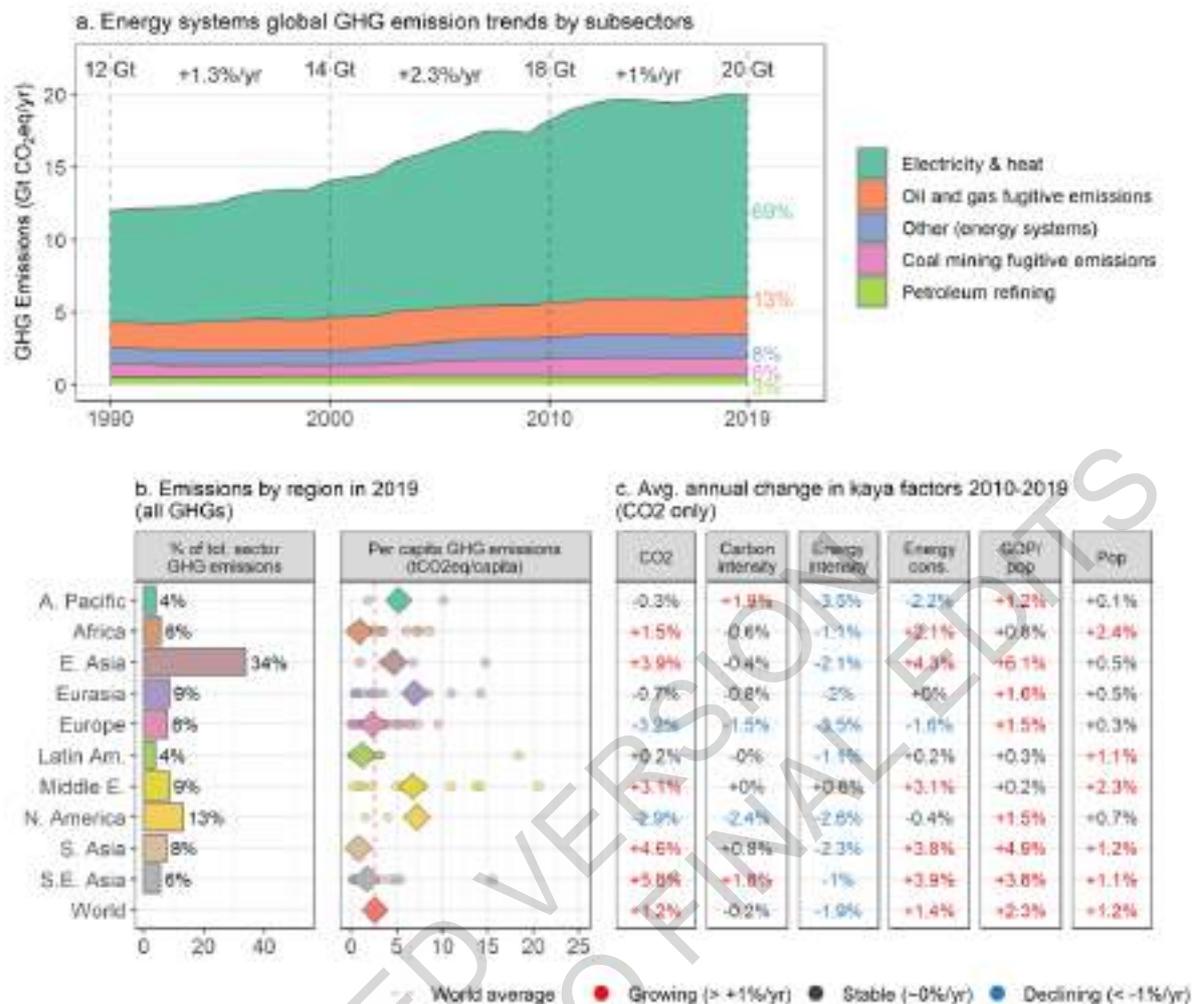

14 GHG emissions continued to rise since 2010 across all sectors and subsectors, most rapidly in electricity
15 production, industry, and transport. Decarbonisation gains from improvements in energy efficiency
16 across different sectors and worldwide have been largely wiped out by increases in demand for goods
17 and services. Prevailing consumption patterns have also tended to aggravate energy use and emissions,
18 with the long-term trend led by developed regions. Decarbonisation trends in some developed regions
19 are limited in size and geographically. Globally, there are enormous unexploited mitigation potentials
20 from adopting best available technologies.

21 The following subsections discuss main emissions drivers by sector. More detailed analyses of sectoral
22 emissions and mitigation options are presented in Chapters 6–11.

23 2.4.2.1 Energy systems

24 Global energy system emissions growth has slowed down in recent years, but global oil and gas use
25 was still growing (Jackson et al., 2019) and the sector remained the single largest contributor to global
26 GHG emissions in 2019 with 20 GtCO₂-eq (34%) (*high confidence*) (Figure 2.17). Most of the 14
27 GtCO₂-eq from electricity and heat generation (23% of global GHG emissions in 2019) were due to
28 energy use in industry and in buildings, making these two sectors also prominent targets for mitigation
29 (Davis et al., 2018; Crippa et al., 2019) (see subsections below).

30 Growth in CO₂ emissions from energy systems has closely tracked rising GDP per capita globally
31 (Lamb et al., 2021b), affirming the substantial literature describing the mutual relationship between
32 economic growth and demand for energy and electricity (*robust evidence, high agreement*) (Khanna
33 and Rao, 2009; Stern, 2011). This relationship has played out strongly in developing regions,
34 particularly in Asia, where a massive scale up of energy supply has accompanied economic growth –
35 with average annual increases of energy demand between 3.8 and 4.3% in 2010–2019 (Figure 2.17).
36 The key driver for slowing the growth of energy systems CO₂ emissions has been declining energy
37 intensities in almost all regions. Annually, 1.9% less energy per unit of GDP was used globally between
38 2010 and 2019.

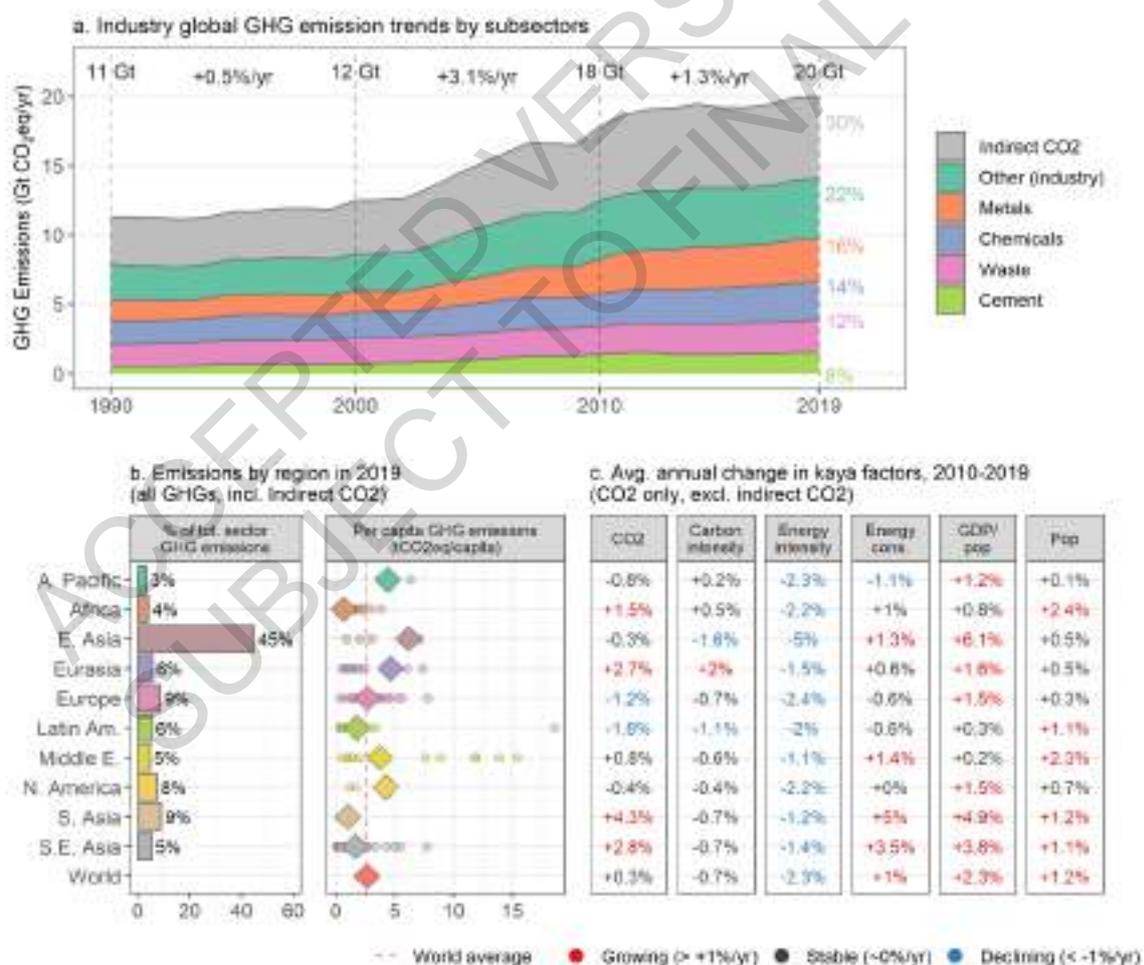

1
2 **Figure 2.17 Trends and drivers of global energy sector emissions (see caption of Figure 2.16 for details)**
3 **Energy is here measured as primary energy supply.**

4
5 The carbon intensity of power generation varies widely between (and also within) regions (see also
6 Chapter 6). In North America, both a switch from coal to gas for power generation (Peters et al., 2017,
7 2020; Feng, 2019; Mohlin et al., 2019) as well as an overall decline in the share of fossil fuels in
8 electricity production (from 66% in 2010 to 59% in 2018) (Mohlin et al., 2019) has decreased carbon
9 intensity and CO₂ emissions. Since 2007, Europe's carbon intensity improvements have been driven by
10 the steady expansion of renewables in the share of electricity generation (*medium evidence, high*
11 *agreement*) (Peters et al., 2017, 2020; Le Quéré et al., 2019; Rodrigues et al., 2020). Some studies
12 attribute these effects to climate policies, such as the carbon floor price in the UK, the EU emissions
13 trading scheme, and generous renewable energy subsidies across the continent (Dyrstad et al., 2019;
14 Wang et al., 2020a). South-East Asian and Asia-Pacific developed countries stand out in contrast to
15 other developed regions, with an increase of regional carbon intensity of 1.8 and 1.9% yr⁻¹, respectively
16 (Figure 2.17). Generally, the use of natural gas for electricity production is growing strongly in most
17 countries and gas has contributed to the largest increase in global fossil CO₂ emissions in recent years
18 (Jackson et al., 2019; Peters et al., 2020). Furthermore, gas brings the risk of increased CH₄ emissions
19 from fugitive sources, as well as large cumulative emissions over the lifetime of new gas power plants
20 that may erase early carbon intensity reductions (Shearer et al., 2020).

1 The growth of emissions from coal power slowed after 2010, and even declined between 2011 and
 2 2019, primarily due to a slowdown of economic growth and fewer coal capacity additions in China
 3 (Peters et al., 2020; Friedlingstein et al., 2019). Discussions of a global ‘peak coal’, however, may be
 4 premature, as further growth was observed in 2019 (Peters et al., 2020; Friedlingstein et al., 2019).
 5 Large ongoing and planned capacity increases in India, Turkey, Indonesia, Vietnam, South Africa, and
 6 other countries have become a driver of thermal coal use after 2014 (UNEP, 2017; Steckel et al., 2019;
 7 Edenhofer et al., 2018).

8 2.4.2.2 *Industry sector*

9 When indirect emissions from electricity and heat production are included, industry becomes the single
 10 highest emitting sector of GHGs (20.0 GtCO₂-eq in 2019) (*high confidence*). Facilitated by
 11 globalisation, East Asia has been the main source and primary driver of global industry emissions
 12 growth since 2000 (*robust evidence, high agreement*) (Lamb et al., 2021). However, while East Asia
 13 has emitted 45% of the world’s industry GHG emissions in 2019, a remarkable decrease of 5.0% yr⁻¹ in
 14 energy intensity and 1.6% in carbon intensity helped to stabilise direct industrial CO₂ emissions in this
 15 region (-0.3% yr⁻¹ between 2010 and 2019; Figure 2.18). Direct industry CO₂ emissions have also
 16 declined in Latin America, Europe and Asia-Pacific developed regions and – to a smaller extent – in
 17 North America. In all other regions, they were growing – most rapidly in southern Asia (+4.3% annually
 18 for direct CO₂ emissions since 2010, Figure 2.18).

19

20 **Figure 2.18 Trends and drivers of global industry sector emissions (see caption of Figure 2.16 for details).**

21

Energy is here measured as total final energy consumption.

1

2 The main global driver of industry emissions has been a massive rise in the demand for products that
3 are indirectly used in production, such as cement, chemicals, steel, aluminium, wood, paper, plastics,
4 lubricants, fertilizers, and so on. This demand was driven by economic growth, rising affluence, and
5 consumption, as well as a rapid rise in urban populations and associated infrastructure development
6 (*robust evidence, high agreement*) (Krausmann et al., 2018). There is strong evidence that the growing
7 use of concrete, steel, and other construction materials is particularly tightly coupled to these drivers
8 (Cao et al., 2017; Pauliuk et al., 2013; Plank et al., 2018; Haberl et al., 2020; Krausmann et al., 2017).
9 Per capita stocks of cement and steel show a typical pattern of rapid take-off as countries urbanise and
10 industrialise, before slowing down to low growth at high levels of GDP. Hence, in countries that have
11 recently been industrialising and urbanising – that is Eastern, Southern and South-Eastern Asia – a
12 particularly strong increase of emissions from these subsectors can be observed. Selected wealthy
13 countries seem to stabilise at high per capita levels of stocks, although it is unclear if these stabilizations
14 persist and if they result in significant absolute reductions of material use (Wiedenhofer et al., 2015;
15 Cao et al., 2017; Krausmann et al., 2018). Opportunities for prolonging lifetimes and improving end of
16 life recycling in order to achieve absolute reductions in extraction activities are as yet unexploited
17 (Krausmann et al., 2017; Zink and Geyer, 2017).

18 On the production side, improvements in the efficiency of material extraction, processing, and
19 manufacturing have reduced industrial energy use per unit of output (Wang et al., 2019b). These
20 measures, alongside improved material substitution, lightweight designs, extended product and
21 servicing lifetimes, improved service efficiency, and increased reuse and recycling will enable
22 substantial emissions reductions in the future (Hertwich et al., 2019). In absence of these improvements
23 in energy intensity, the growth of population and GDP per capita would have driven the industrial CO₂
24 emissions to rise by more than 100% by 2017 compared with 1990, instead of 56% (Lamb et al., 2021b).
25 Nonetheless, many studies point to deep regional differences in efficiency levels and large globally
26 unexploited potentials to improve industrial energy efficiency by adopting best available technologies
27 and practices for metal, cement, and chemical production (Gutowski et al., 2013; Talaei et al., 2018;
28 Schulze et al., 2016; Hernandez et al., 2018).

29 2.4.2.3 *Buildings sector*

30 Global direct and indirect GHG emissions from the buildings sector reached 9.7 GtCO₂-eq in 2019, or
31 16% of global emissions). Most of these emissions (66%, or 6.4 GtCO₂-eq) were upstream emissions
32 from power generation and commercial heat (Figure 2.19). The remaining 33% (3.3 GtCO₂-eq) of
33 emissions were directly produced in buildings, for instance by gas and coal boilers, and cooking and
34 lighting devices that burn kerosene, biomass, and other fuels (Lamb et al., 2021). Residential buildings
35 accounted for the majority of this sector's emissions (64%, 6.3 GtCO₂-eq, including both direct and
36 indirect emissions), followed by non-residential buildings (35%, 3.5 GtCO₂-eq) (*high confidence*).

37 Global buildings sector GHG emissions increased by 0.7% yr⁻¹ between 2010 and 2019 (Figure 2.19),
38 growing the most in absolute terms in East and South Asia, whereas they declined the most in Europe,
39 mostly due to the expansion of renewables in the energy sector and increased energy efficiency (Lamb
40 et al., 2021). North America has the highest per capita GHG emissions from buildings and the second
41 highest absolute level after East Asia (Figure 2.19).

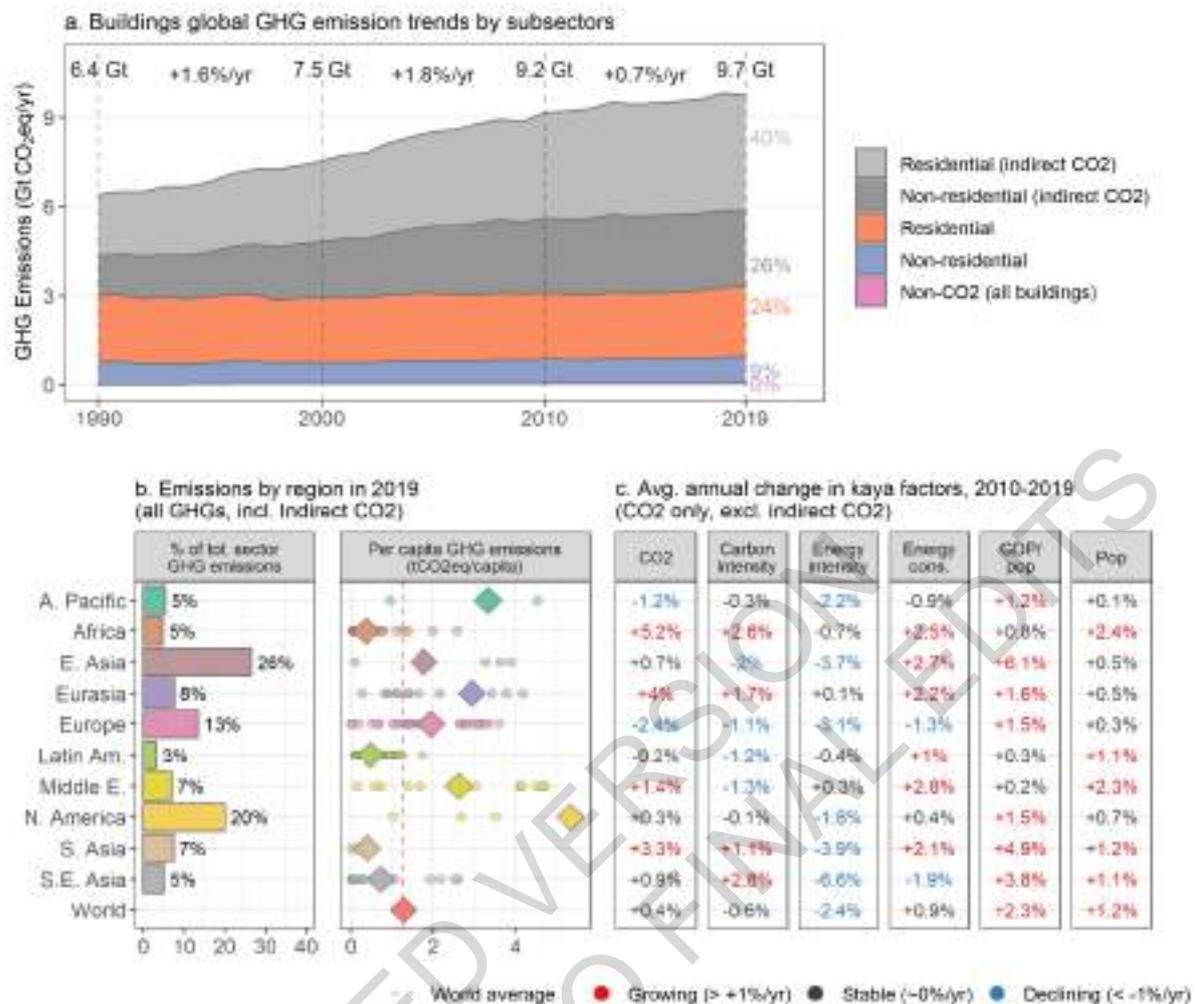

Figure 2.19 Trends and drivers of global buildings sector emissions (see caption of Figure 2.16 for details). Energy is here measured as total final energy consumption.

Rising wealth has been associated with more floor space being required to service growing demand in the retail, office, and hotel sectors (*medium evidence, high agreement*) (Daioglou et al., 2012; Deetman et al., 2020). In addition, demographic and social factors have driven a cross-national trend of increasing floor space per capita. As populations age and decrease in fertility, and as individuals seek greater privacy and autonomy, households declined in size, at least before the COVID-19 pandemic (Ellsworth-Krebs, 2020). These factors lead to increased floor space per capita, even as populations stabilise. This in turn is a key driver for building sector emissions, because building characteristics such as size and type, rather than occupant behaviour, tend to explain the majority of energy use within dwellings (Guerra Santin et al., 2009; Ürge-Vorsatz et al., 2015; Huebner and Shipworth, 2017) (see Chapter 9).

Energy activity levels further drive regional differences. In Eurasia, Europe and North America, thermal demands for space heating dominate building energy use, at 66%, 62% and 48% of residential energy demand, respectively (IEA, 2020a). In contrast, cooking has a much higher share of building energy use in regions of the global South, including China (Cao et al., 2016). And despite temperatures being on average warmer in the global South, electricity use for cooling is a more prominent factor in the global North (Waite et al., 2017). This situation is changing, however, as rapid income growth and

1 demographic changes in the global South enable households to heat and cool their homes (Ürge-Vorsatz
2 et al., 2015, 2020).

3 Steady improvements in building energy intensities across regions can be attributed to baseline
4 improvements in building fabrics, appliance efficiencies, energy prices, and fuel shifts. Many countries
5 have adopted a mix of relevant policies, such as energy labelling, building energy codes, and mandatory
6 energy performance requirements (Nie and Kemp, 2014; Nejat et al., 2015; Economidou et al., 2020).
7 Efforts towards buildings refurbishments and retrofits have also been pursued in several nations,
8 especially for historical buildings in Europe, but evidence suggests that the recent rates of retrofits have
9 not made a significant dent on emissions (Corrado and Ballarini, 2016). The Chinese central
10 government launched various policies, including command and control, economic incentives, and
11 technology measures, but a big gap remains between the total rate of building green retrofit in the nation
12 and the future retrofit potential (Liu et al., 2020a, 2020b). Still, one major global factor driving down
13 energy intensities has been the global transition from inefficient coal and biomass use in buildings for
14 heating and cooking, towards natural gas and electricity, in part led by concerted policy action in Asian
15 countries (Kerimray et al., 2017; Thoday et al., 2018; Ürge-Vorsatz et al., 2015). As developing
16 countries construct new buildings, there is sizable potential to reduce and use less carbon-intensive
17 building materials and adopt building designs and standards that lower life cycle buildings energy use
18 and allow for passive comfort. Chapter 9 describes the mitigation options of the buildings sector.

19 2.4.2.4 *Transport sector*

20 With a steady, average annual growth of +1.8% yr⁻¹ between 2010 and 2019, global transport GHG
21 emissions reached 8.9 GtCO₂-eq in 2019 and accounted for 15% of all direct and indirect emissions
22 (Figure 2.20). Road transport passenger and freight emissions represented by far the largest component
23 and source of this growth (6.1 GtCO₂-eq, 69% of all transport emissions in 2019) (*high confidence*).
24 National plus international shipping and aviation emissions together accounted for 2.0 GtCO₂-eq or
25 22% of the sector's total in 2019. North America, Europe and Eastern Asia stand out as the main
26 regional contributors to global transport emissions and together account for 50% of the sector's total.

27 The proportion of total final energy used in transport (28%) and its fast expansion over time weighs
28 heavily on climate mitigation efforts, as 92% of transport energy comes from oil-based fuels (IEA,
29 2020b). These trends situate transport as one of the most challenging sectors for climate change
30 mitigation – no country has so far been able to realise significant emissions reductions in the sector.
31 North America's absolute and per capita transport emissions are the highest amongst world regions, but
32 those of South, South-East and East Asia are growing the fastest (between +4.6% and +5.2% yr⁻¹ for
33 CO₂ between 2010 and 2019, Figure 2.20) (*high confidence*).

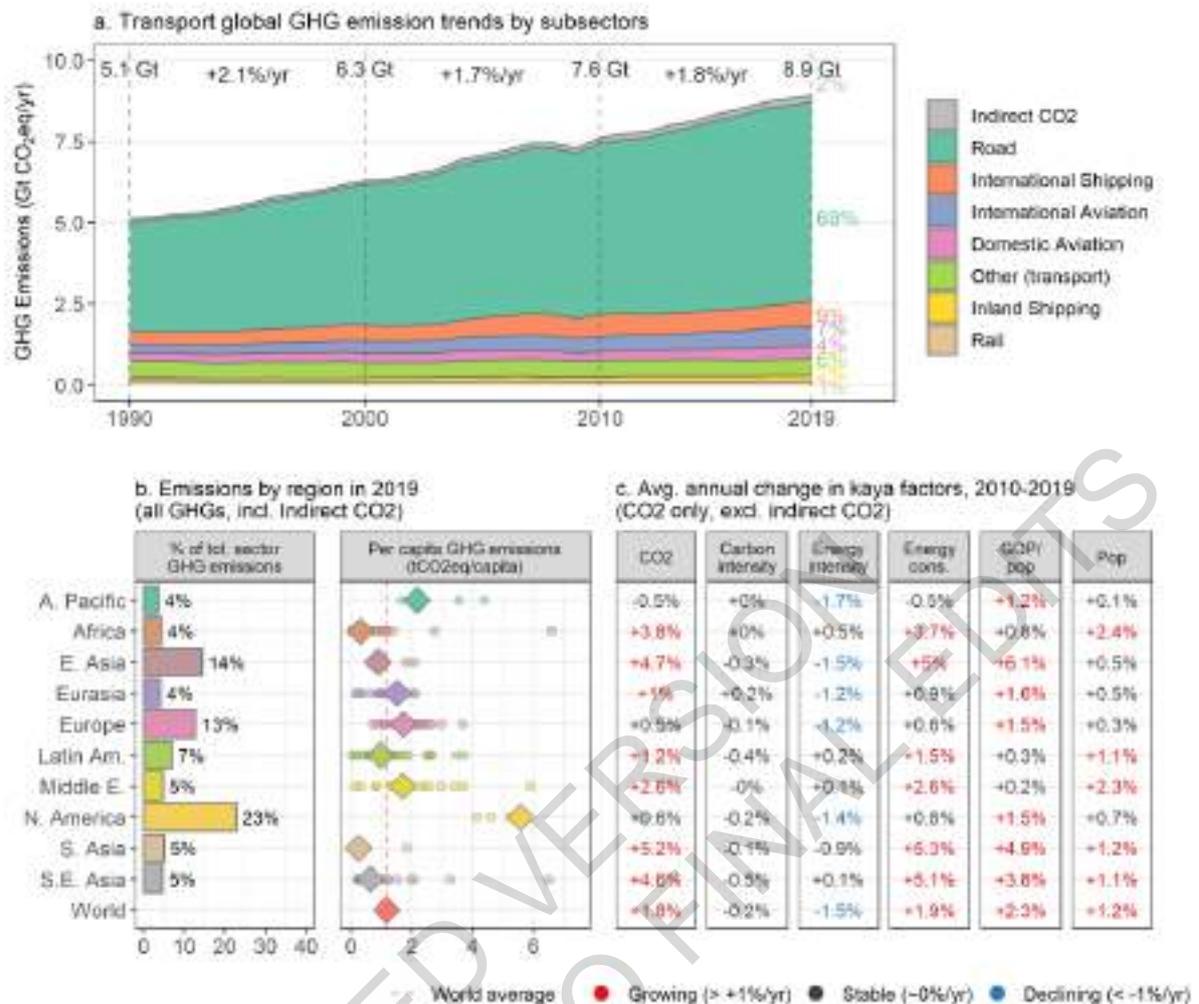

Figure 2.20 Trends and drivers of global transport sector emissions (see caption of Figure 2.16 for details). Energy is here measured as total final energy consumption.

More so than any other sector, transport energy use has tracked GDP per capita growth (Figure 2.20), (Lamb et al., 2021). With the exception of road gasoline demand in OECD countries, the demand for all road fuels generally increases at least as fast as the rate at which GDP per capita increases (Liddle and Huntington, 2020). Developments since 1990 continue a historical trend of increasing travel distances and a shift from low- to high-speed transport modes that goes along with GDP growth (Schäfer et al., 2009; Gota et al., 2019). Modest improvements in energy efficiency have been realised between 2010 and 2019, averaging $-1.5\% \text{ yr}^{-1}$ in energy intensity globally, while carbon intensities of the transport sector have remained stable in all world regions (Figure 2.20). Overall, global increases in passenger and freight travel activity levels have outpaced energy efficiency and fuel economy improvements, continuing a long-term trend for the transport sector (Gucwa and Schäfer, 2013; Grübler, 2015; McKinnon, 2016) (*medium evidence, high agreement*).

Despite some policy achievements, energy use in the global transport system remains to the present deeply rooted in fossil fuels (*robust evidence, high agreement*) (IEA, 2019; Figueroa et al., 2014). In part this is due to the increasing adoption of larger, heavier combustion-based vehicles in some regions, which have tended to far outpace electric and hybrid vehicle sales (Chapter 10). Yet, stringent material

1 efficiency and lightweight design of passenger vehicles alone would have the potential to cut cumulative
2 global GHG emissions until 2060 by 16–39 GtCO₂-eq (Pauliuk et al., 2020).

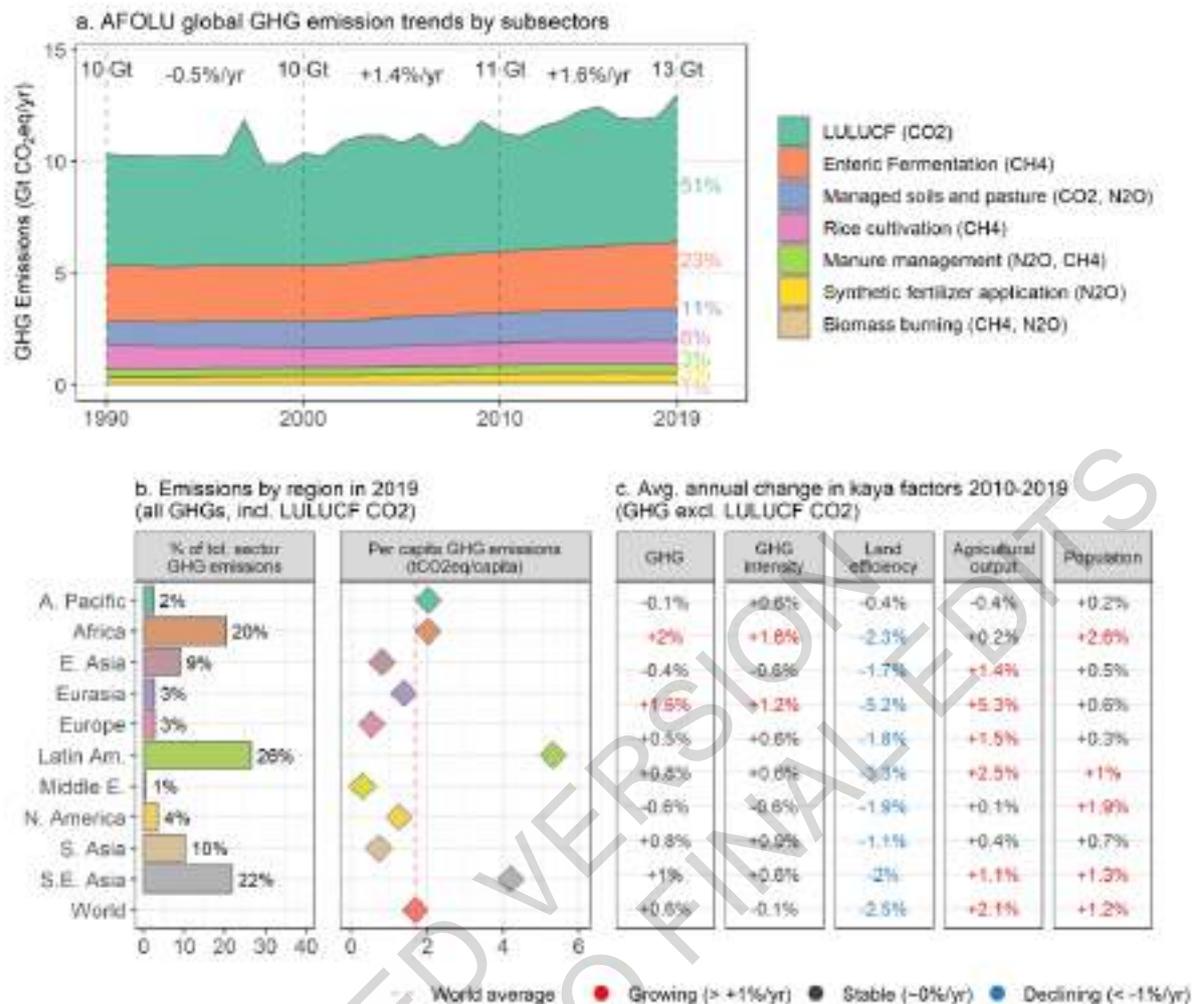

3 While global passenger activity has expanded in all world regions, great disparities exist between low
4 and high income regions, and within countries between urban and rural areas (ITF, 2019). While private
5 car use is dominant in OECD countries (EC, 2019), the growth of passenger-km (the product of number
6 of travellers and distance travelled) has considerably slowed there, down to an increase of just 1% yr⁻¹
7 between 2000 and 2017 (SLoCaT, 2018) (Chapter 10). Meanwhile, emerging economies in the global
8 South are becoming more car-dependent, with rapidly growing motorisation, on-demand private
9 transport services, urban sprawl, and the emergence of local automotive production, while public
10 transport struggles to provide adequate services (Dargay et al., 2007; Hansen and Nielsen, 2017; Pojani
11 and Stead, 2017).

12 Freight travel activity grew across the globe by 68% in the last two decades driven by global GDP
13 increases, together with the proliferation of online commerce and rapid (i.e., same-day and next-day)
14 delivery (SLoCaT, 2018). Growth has been particularly rapid in heavy-duty road freight transport.

15 While accounting for a small share of total GHG emissions, domestic and international aviation have
16 been growing faster than road transport emissions, with average annual growth rates of +3.3% and
17 +3.4%, respectively, between 2010 and 2019 (Crippa et al., 2021; Minx et al., 2021;). Energy efficiency
18 improvements in aviation were considerably larger than in road transport, but were outpaced by even
19 larger increases in activity levels (SLoCaT, 2018; Lee et al., 2021) (Chapter 10).

20 2.4.2.5 *AFOLU sector*

21 GHG emissions from agriculture, forestry and land use reached 13 GtCO₂-eq globally in 2019 (Figure
22 2.21) (*medium confidence*). AFOLU trends, particularly those for CO₂-LULUCF, are subject to a high
23 degree of uncertainty (Section 2.2.1). Overall, the AFOLU sector accounts for 22% of total global GHG
24 emissions, and in several regions – Africa, Latin America, and South-East Asia – it is the single largest
25 emitting sector (which, at the same time, is also significantly affected itself by climate change; see WGI
26 Chapters 8, 11, and 12, and WGII Chapter 5). Latin America has the highest absolute and per capita
27 AFOLU GHG emissions of any world region (Figure 2.21). CO₂ emissions from land-use change and
28 CH₄ emissions from enteric fermentation together account for 74% of sector-wide GHGs. Note that
29 CO₂-LULUCF estimates included in this chapter are not necessarily comparable with country GHG
30 inventories, due to different approaches to estimate anthropogenic CO₂ sinks (Grassi et al., 2018)
31 (Chapter 7).

1

2 **Figure 2.21 Trends and drivers of global AFOLU sector emissions, including a) trends of GHG emissions**
 3 **by subsectors 1990–2019, b) share of total sector and per capita GHG emissions by world region in 2019,**
 4 **and c) Kaya decomposition of GHG emissions drivers**

5 Based on the equation $H=P(A/P)(L/A)(H/L)$, where P is population, A/P is agricultural output per capita,
 6 L/A is the land required per unit of agricultural output (land efficiency), and H/L is GHG emissions per
 7 unit of land (GHG intensity) (Hong et al., 2021). GHG emissions H comprise agricultural CH₄ and N₂O
 8 emissions from EDGAR v6.0. The indicated annual growth rates are averaged across the years 2010–2019
 9 (LULUCF CO₂ emissions are excluded in panel c). (Note: due to different datasets, the population
 10 breakdown for AFOLU emissions is slightly different than that in the other sector figures above).

11

12 Unlike all other sectors, AFOLU emissions are typically higher in developing compared to developed
 13 regions (*medium confidence*). In Africa, Latin America, and South-East Asia, CO₂ emissions associated
 14 with land-use change and management predominate, dwarfing other AFOLU and non-AFOLU sources
 15 and making AFOLU the single largest sector with more than 50% of emissions in these regions (Lamb
 16 et al., 2021b). Land-use and -management emissions there is associated with the expansion of
 17 agriculture into carbon-dense tropical forest areas (Vancutsem et al., 2021), where large quantities of
 18 CO₂ emissions result from the removal and burning of biomass and draining of carbon rich soils
 19 (Pearson et al., 2017; IPCC, 2018; Hong et al., 2021). Ruminant livestock rearing takes place on vast
 20 tracts of pasture land worldwide, contributing to large quantities of CH₄ emissions from enteric
 21 fermentation in Latin America (0.8 GtCO₂-eq in 2018), Southern Asia (0.6 GtCO₂-eq), and Africa (0.5

1 GtCO₂-eq), while also playing a sizable role in the total AFOLU emissions of most other regions (Lamb
2 et al., 2021b).

3 In all regions, the amount of land required per unit of agricultural output has decreased significantly
4 from 2010 to 2019, with a global average of -2.5% yr⁻¹ (land efficiency metric in Figure 2.21). This
5 reflects agricultural intensification and technological progress. However, in most regions this was
6 mirrored by an increase in output per capita, meaning that absolute GHG emissions in most regions
7 increased over the last decade. A significant increase in total AFOLU emissions occurred in Africa,
8 driven by both increased GHG emissions per unit of land and increased populations (Figure 2.21).

9 The AFOLU sector and its emissions impacts are closely tied to global supply chains, with countries in
10 Latin America and South-East Asia using large portions of their land for agricultural and forestry
11 products exported to other countries (see Chapter 7). The strong increases in production per capita and
12 associated GHG emissions seen in these regions are at least partly attributable to growing exports and
13 not national food system or dietary changes. At the same time, efforts to promote environmental
14 sustainability in regions like the EU and the USA (but also fast-growing emerging economies such as
15 China) can take place at the cost of increasing land displacement elsewhere to meet their own demand
16 (Meyfroidt et al., 2010; Yu et al., 2013; Creutzig et al., 2019).

17 Global diets are a key driver of production per capita, and thus land pressure and AFOLU emissions
18 (Chapter 7). As per capita incomes rise and populations urbanise, traditional, low-calorie diets that
19 emphasise starchy foods, legumes, and vegetables transition towards energy-intensive products such as
20 refined sugars, fats, oils, and meat (Tilman and Clark, 2014; Pradhan et al., 2013). At a certain point in
21 national development, affluence and associated diets thus override population growth as the main driver
22 of AFOLU emissions (Kastner et al., 2012). Very high calorie diets have high total GHG emissions per
23 capita (Heller and Keoleian, 2015) and are common in the developed world (Pradhan et al., 2013). Over
24 the last few decades, a “westernisation” of diets has also been occurring in developing countries
25 (Pradhan et al., 2013). Low- and middle-income countries such as India, Brazil, Egypt, Mexico, and
26 South Africa have experienced a rapid dietary shift towards western-style diets (De Carvalho et al.,
27 2013; Pradhan et al., 2013; Popkin, 2015). Another driver of higher food requirements per capita is food
28 waste, the amounts of which increased more or less continuously since the 1960s in all regions but
29 Europe (Porter and Reay, 2016).

30 2.4.3 Poverty and Inequality

31 Increasing economic inequality globally has given rise to concern that unequal societies may be more
32 likely to pollute and degrade their environments (Chancel, 2020; Hailemariam et al., 2020; Millward-
33 Hopkins and Oswald, 2021; Masud et al., 2018). The nature of this relationship has important
34 implications for the design of income redistribution policies aiming to reduce inequalities (Section 2.6
35 presents evidence on how affluence and high consumption relate to emissions). Income inequality and
36 carbon intensity of consumption differs across countries and individuals (Baležentis et al., 2020)
37 (Section 2.3.3). Reduced income inequality between nations can reduce emissions intensity of global
38 income growth, if energy intensity reductions from income growth in some nations offset increases in
39 energy and emissions from higher growth in other nations (Rao and Min, 2018). Increasing income
40 inequality between individuals can translate into larger energy and emissions inequality if higher
41 incomes are spent on more energy-intensive consumption and affluent lifestyles (Oswald et al., 2020;
42 Wiedmann et al., 2020) (Section 2.6).

43 Literature shows that more equitable income distributions can improve environmental quality, but the
44 nature of this relationship can vary by level of development (*low evidence, medium agreement*) (Knight
45 et al., 2017; Chen et al., 2020; Hailemariam et al., 2020; Huang and Duan, 2020; Liobikienė and
46 Rimkuvienė, 2020; Rojas-Vallejos and Lastuka, 2020; Uddin et al., 2020). Differences in the energy
47 and carbon intensities of consumption and the composition of consumption baskets across populations

1 and nations matter for emissions. (Jorgenson et al., 2016; Grunewald et al., 2017). There is evidence to
2 suggest that more equal societies place a higher value on environmental public goods (Baumgärtner et
3 al., 2017; Drupp et al., 2018). Additional research shows that reducing top income inequality in OECD
4 countries can reduce carbon emissions and improve environmental quality (Hailemariam et al., 2020)
5 and that the effect of wealth inequality, measured as the wealth share of the top decile, on per capita
6 emissions in high-income countries is positive (Knight et al., 2017). Evidence from 40 sub-Saharan
7 African countries suggests that a rise in income inequality contributed to increasing CO₂ emissions
8 between 2010 and 2016, controlling for other drivers like economic growth, population size, and
9 inflation (Baloch et al., 2020).

10 The key development objective of eradicating extreme poverty (Hubacek et al., 2017a; Chakravarty and
11 Tavoni, 2013; Malerba, 2020) and providing universal access to modern energy services (Pachauri et
12 al., 2018, 2013; Singh et al., 2017; Pachauri, 2014) only marginally effect carbon emissions (*robust
13 evidence, medium agreement*). Shifts from biomass to more efficient energy sources and collective
14 provisioning systems for safe water, health, and education are associated with reduced energy demand
15 (Baltruszewicz et al., 2021). Efforts to alleviate multi-dimensional poverty by providing decent living
16 standards universally, however, may require more energy and resources. Recent estimates of the
17 additional energy needed are still within bounds of projections of energy demand under climate
18 stabilisation scenarios (Rao et al., 2019; Pascale et al., 2020; Hubacek et al., 2017b; a); Kikstra et al.,
19 2021). Bottom-up estimates suggest that achieving decent living standards requires 13–40 GJ per capita
20 annually, much less than the current world average energy consumption of 80 GJ per capita in 2020
21 (Millward-Hopkins et al., 2020) (*medium evidence, high agreement*). Aggregate top-down estimates
22 suggest that achieving a high Human Development Index (HDI) score above 0.8 requires energy
23 consumption between 30–100 GJ per capita yr⁻¹ (Lamb and Rao, 2015). There is some evidence,
24 however, of a decoupling between energy consumption and HDI over time (Akizu-Gardoki et al., 2018).
25 The emissions consequences of poverty alleviation and decent living also depend on whether
26 improvements in well-being occur via energy- and carbon-intensive industrialisation or low-carbon
27 development (Semieniuk and Yakovenko, 2020; Fu et al., 2021; Huang and Tian, 2021).

28 2.4.4 Rapid and Large-scale Urbanisation as a Driver of GHG Emissions

29 Economic growth and urbanisation go hand in hand and are both influencing GHG emissions. However,
30 the exact role of urban development in driving emissions is multi-faceted and heterogeneous, depending
31 on development status and other regional factors (*medium evidence, high agreement*) (Jorgenson et al.,
32 2014; Lamb et al., 2014; Liddle and Lung, 2014; Creutzig et al., 2015; Pincetl, 2017; Azizalrahman and
33 Hasyimi, 2019; Muñoz et al., 2020). This calls for a differentiated assessment. This section assesses the
34 process of rapid urban growth in developing countries and how emissions change over time when cities
35 grow rapidly, that is, when urban populations and infrastructure expand at fast speed and at a massive
36 scale (Seto et al., 2017; Elmqvist et al., 2021). To distinguish, Section 2.6 includes the carbon footprint
37 of urban lifestyles and the difference in emissions profiles between already urbanised and less urbanised
38 areas. Chapter 8 deals with urban strategies for climate change mitigation.

39 Urban development is most significant and rapid in developing and transition countries, accompanied
40 by a substantial migration of rural populations to urban areas (Apergis and Li, 2016; Azizalrahman and
41 Hasyimi, 2019; Wang et al., 2019c) and associated impacts on land use (Richardson et al., 2015). If the
42 trend of developing countries following infrastructure stock patterns in industrialised nations continues
43 until 2050, this could cause approximately 350 GtCO₂ from the production of materials (Müller et al.,
44 2013). This would be equivalent to 70% of the 500 GtCO₂ estimated remaining carbon budget from the
45 beginning of 2020 to limit global warming to 1.5°C with a likelihood of 50% (IPCC, 2021b).

46 In many developing countries across the world, the process of urban expansion leads to higher per capita
47 consumption-based GHG emissions (*medium evidence, high agreement*) (Jorgenson et al., 2014; Yao
48 et al., 2015; Zhang et al., 2016; Wood et al., 2018a; Muñoz et al., 2020). The high disparity between

1 rural and urban personal carbon footprints in these countries (Wiedenhofer et al., 2017) (see Section
2 2.6) means that migration to urban areas increases overall emissions as levels of income and expenditure
3 rise, leading to further economic growth and infrastructure development in urban areas (Müller et al.,
4 2013; Li et al., 2015; Wang and Yang, 2016; Zhang et al., 2016; Wiedenhofer et al., 2017; Cetin and
5 Bakirtas, 2019; Fan et al. 2019; Li and Zhou, 2019; Xia et al., 2019; Sarkodie et al., 2020).

6 For total production-based emissions in general, urbanisation is thought to have a smaller effect than
7 changes in population, GDP per capita, and energy and emissions intensities, which are all more
8 influential (Lin et al., 2017). Another driver of urban emissions is rising ambient air temperature caused
9 by urban land expansion, which will likely drive a substantive increase in air conditioning use and cold
10 storage for food (Huang et al., 2019). Specific emission drivers, however, depend on city- and place-
11 specific circumstances such as income, household size, density, or local climate (Baiocchi et al., 2015;
12 Wang et al., 2019a). Geographical factors, urban form, and transport/fuel costs are dependent on each
13 other, and, together with economic activity, have been found to explain 37% of urban direct energy use
14 and 88% of urban transport energy use in a global sample of 274 cities (Creutzig et al., 2015).

17 **2.5 Technological Change is Key to Reducing Emissions**

18 Technological change for climate change mitigation involves improvement in and adoption of
19 technologies, primarily those associated with energy production and use. Technological change has had
20 a mitigating effect on emissions over the long term and is central to efforts to achieving climate goals
21 (*high confidence*). Progress since AR5 shows multiple low-carbon technologies are improving and
22 falling in cost (*high confidence*); technology adoption is reaching substantial shares, and small-scale
23 technologies are particularly promising on both (*medium confidence*). Faster adoption and continued
24 technological progress can play a crucial role in accelerating the energy transition. However, the
25 historical pace of technological change is still insufficient to catalyse a complete and timely transition
26 to a low-carbon energy system; technological change needs to accelerate (*high confidence*). This section
27 assesses the role of technological change in driving emissions reductions and the factors that drive
28 technological change, with an emphasis on the speed of transitions. Incentives and support for
29 technological change affect technology outcomes (Sivaram et al., 2018; Wilson et al., 2020a). Work
30 since AR5 has focused on evaluating the effectiveness of policies, both those that accelerate
31 technological change by enhancing knowledge – technology push – and those that increase market
32 opportunities for successful technologies – demand pull – (Nemet, 2013), as well as the importance of
33 tailoring support to country contexts (Rosenbloom et al., 2020; Barido et al., 2020), including the limits
34 of policies to date that price carbon (Lilliestam et al., 2020). Section 2.8 and Chapter 13 describe how
35 these policies affect emissions, Cross-Chapter box 12 in Chapter 16 and Chapter 14 discuss transition
36 dynamics, and Chapter 16 provides a more detailed assessment of the evolution and mitigation impacts
37 of technology development, innovation, and transfer.

38 **2.5.1 Technological Change Has Reduced Emissions**

39 Technological change that facilitates efficient energy utilisation from production to its final conversion
40 into end-use services is a critical driver of carbon emissions reductions (*high confidence*). Technological
41 change can facilitate stringent mitigation, but it also can reduce these effects by changing consumer
42 behaviour such as through rebound effects (see Section 2.6 and Chapter 16). AR6 includes an entire
43 chapter on innovation, technology development, and transfer (Chapter 16). A focus gained in this
44 section is the extent to which aligned, credible, and durable policies can accelerate technological change
45 factors to put emissions reductions on a trajectory compatible with reaching UNFCCC goals.

1 Technological change has facilitated the provision of more diverse and efficient energy services
2 (heating, cooling, lighting, and mobility) while generating fewer emissions per unit of service. As seen
3 in Section 2.4, in Kaya identity terms (Lima et al., 2016) (see Glossary): population and economic
4 growth are factors that have increased emissions, while technological change has reduced emissions
5 (Peters et al., 2017). These Kaya statistics show that while technological change can facilitate the
6 transition to a low-carbon economy, it needs to proceed at a much faster pace than historical trends
7 (Peters et al., 2017).

8 Multiple challenges exist in accelerating the past rate of technological change. First, an array of physical
9 assets in the energy system are long-lived and thus involve substantial committed carbon (see Section
10 2.7) (Knapp, 1999; Cui et al., 2019). A process of “exnovation,” accelerating the phase-out of incumbent
11 technology through intentional policy (e.g., by pricing carbon), provides a means to address long
12 lifetimes (Davidson, 2019; Rosenbloom and Rinscheid, 2020). Second, countries may not have the
13 capacity to absorb the flows of ideas and research results from international knowledge spillovers due
14 to weak infrastructure, limited research capacity, lack of credit facilities (see Chapter 15, Section 15.5),
15 and other barriers to technology transfer (Adenle et al., 2015). In a developing country context,
16 processes of innovation and diffusion need to include competence-building systems (Lema et al., 2015;
17 Perrot and Sanni, 2018; Stender et al., 2020). Third, public policy is central to stimulating technological
18 change to reduce emissions; policy depends on creating credible expectations of future market
19 opportunities (Alkemade and Suurs, 2012), but the historical evidence shows that, despite recent
20 progress, policies related to energy and climate over the long term have been inconsistent (Taylor, 2012;
21 Nemet et al., 2013; Koch et al., 2016). Bolstering the credibility and durability of policies related to
22 low-carbon technology are crucial to accelerating technological change and inducing the private sector
23 investment required (Helm et al., 2003; Habermacher et al., 2020).

24 **2.5.2 A Low-Carbon Energy Transition Needs to Occur Faster Than Previous** 25 **Transitions**

26 An illuminating debate on the possibility of faster transitions has emerged since AR5 – with diverging
27 assumptions about future technological change at the core of the discourse (Bazilian et al., 2020; Lu
28 and Nemet, 2020). Table 2.5 summarises these arguments.

29 **2.5.2.1 Energy transitions can occur faster than in the past**

30 Recent studies have identified examples supporting fast energy transitions (Sovacool, 2016; Bond et
31 al., 2019; Reed et al., 2019). One describes five rapid national-scale transitions in end-use technologies,
32 including lighting in Sweden, cook-stoves in China, liquefied petroleum gas stoves in Indonesia, ethanol
33 vehicles in Brazil, and air conditioning in the USA (Sovacool, 2016). Adoption of electric vehicles in
34 Norway and in cities in China have also been rapid (Rietmann and Lieven, 2019; Li et al., 2020;
35 Fridstrøm, 2021). Examples in energy supply, include electrification in Kuwait, natural gas in the
36 Netherlands, nuclear electricity in France and Sweden, combined heat and power in Denmark,
37 renewable energy in Uruguay, and coal retirements in Ontario, Canada (Qvist and Brook, 2015).
38 Reasons that these exemplars could be applied more broadly in the future include: growing urgency on
39 climate change, shifting motivation from price response to proactive resource scarcity, and an increase
40 in the likelihood of technological breakthroughs (*medium confidence*) (Sovacool, 2016; Bazilian et al.,
41 2020). The emergence of smaller unit scale, “granular” technologies described below also creates the
42 potential for faster system change (Trancik, 2006; Grubler et al., 2018; Wilson et al., 2020a). Prices of
43 energy services and government actions that affect demand are critical to the speed and extent of energy
44 transitions (Kramer and Haigh, 2009). Reasons scholars consider for expecting a fast transition include:
45 intentional policy and alignment with goals; globalisation which diversifies sources and integrates
46 supply chains; collective action via the Paris Agreement; as well as bottom-up grassroots movements
47 and private sector initiatives (Kern and Rogge, 2016). Political support for change can also speed

1 transitions (Burke and Stephens, 2017; Stokes and Breetz, 2018), as can the credibility of transition-
2 related targets (Li and Pye, 2018; Rogge and Dütschke, 2018).

3 The important role of leader countries is often missed when looking only at global aggregates (Meckling
4 and Hughes, 2018); leaders accumulate important knowledge, provide scaled market, and set positive
5 examples for followers (*medium confidence*) (Schwerhoff, 2016; Buchholz et al., 2019). In recent years,
6 the conception of where leadership, climate-relevant innovation, and technology transfer originate has
7 shifted to considering more meaningfully direct South-South and South-North forms of technology
8 transfer, flows of capital, drivers for market access, origins of innovation, and other forms of
9 cooperation (Urban, 2018; Köhler et al., 2019). Recent evidence shows South-South trade is enabling
10 clean technology transfer (Gosens, 2020). Leaders can initiate a process of “catalytic cooperation” in
11 which they overcome collective action problems and stimulate rapid change (Hale, 2018). Similarly,
12 “sensitive intervention points” – targeted support of social movements, technologies, or policies
13 themselves – can lead to rapid and self-sustaining change (Farmer et al., 2019), such as support for
14 photovoltaics in Germany in the 2000s and student climate activism in Europe in 2019. The focus on
15 leadership, catalysts, and intervention points reflects a systemic view of transitions that emphasises
16 interactions and interdependence (Geels, 2018; Meckling and Hughes, 2018). Technological change
17 has been at the core of transitions, but is best understood as part of a system in which social aspects are
18 crucial (*medium confidence*) (Cherp et al., 2018; Köhler et al., 2019; Overland and Sovacool, 2020).

19

20 **Table 2.5 Summary reasons to expect a fast energy transition and reasons to expect a slow transition.**

	Fast transition	Slow transition
Evidentiary basis	Technology and country cases over 50 years	Historical global system over 200 years
Systems	Complementary technologies enable integration	Difficult integration with existing infrastructure
Economics	Falling costs of nascent technology	Mature incumbent technologies Up-front costs and capital constraints
Technology	Digitalisation and global supply chains More abundant innovation Granular technology	Long lifetimes of capital stock Difficult to decarbonise sectors
Actors	Proactive efforts for transition Bottom-up public concern Mobilised low-carbon interest groups	Risk-averse adopters Attributes do not appeal to consumers Rent-seeking by powerful incumbents
Governance	Leaders catalyse faster change	Collective action problems

21

22 **2.5.2.2 Reasons that transitions will occur at historical rates of change**

23 Recent work has also reasserted previous claims that the speed of a low-carbon transition will follow
24 historical patterns (*low confidence*). Broad transitions involve technological complexity, time-
25 consuming technological development, risk-averse adopters, high up-front costs, and low immediate
26 individual adoption benefits, attributes which are not all present in the examples of rapid change
27 described above (Grubler et al., 2016). Additional factors that slow transitions include: the need for the
28 transition to occur globally, thus requiring nations with unequal economic resources and development
29 circumstances to engage in near-universal participation; slow progress in recent decades; intermittence
30 of renewables, and the time involved in building supporting infrastructure (Smil, 2016); difficulty in

1 decarbonising transportation and industry (Rissman et al., 2020); and material resource constraints
2 (Davidsson et al., 2014).

3 **2.5.3 Improvements in Technologies Enable Faster Adoption**

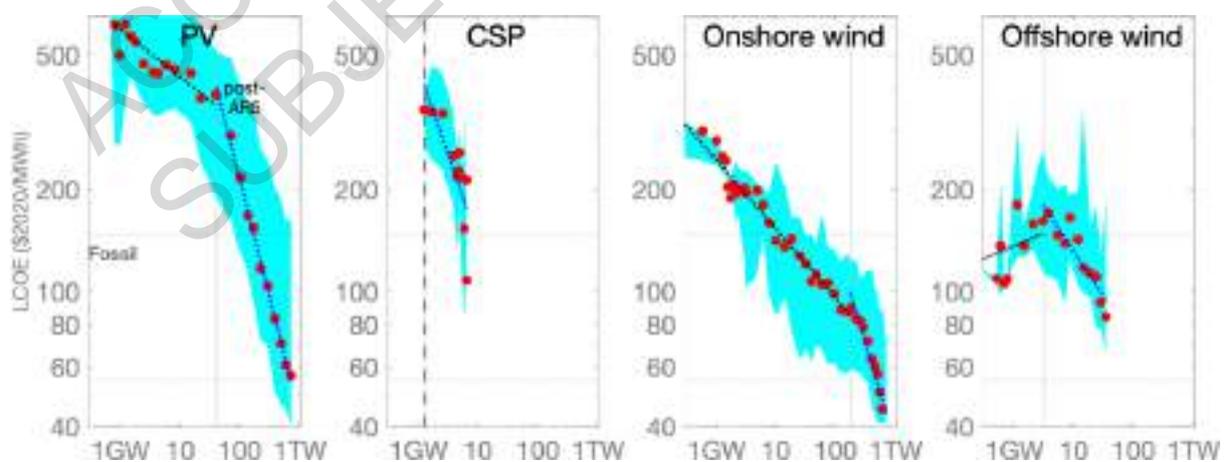

4 Since AR5, multiple low-carbon technologies have shown dramatic improvement, particularly solar
5 PV, wind, and batteries (*high confidence*). The observed pace of these changes and the likelihood of
6 their continuation support the arguments in the previous section that future energy transitions are likely
7 to occur more quickly than in the past (*medium confidence*).

8 **2.5.3.1 Technological change has produced dramatic cost reductions**

9 A wide array of technologies shows long-term improvements in performance, efficiency, and cost.
10 Among the most notable are solar photovoltaics, wind power, and batteries (*high confidence*) (see
11 Chapters 6 and 16). PV's dynamics are the most impressive, having fallen in cost by a factor of 10,000
12 from the first commercial application on a satellite in 1958 (Maycock and Wakefield, 1975) to power
13 purchase agreements signed in 2019 (IRENA, 2020). Wind has been on a nearly as steep trajectory
14 (Wiser and Bolinger, 2019) as are lithium-ion battery packs for electric vehicles (Nykvist and Nilsson,
15 2015; Service, 2019). The future potential for PV and batteries seems especially promising given that
16 neither industry has yet begun to adopt alternative materials with attractive properties as the cost
17 reductions and performance improvements associated with the current generation of each technology
18 continue (*medium confidence*) (Kwade et al., 2018). A key challenge is improving access to finance,
19 especially in developing country contexts, where the costs of financing are of crucial importance
20 (Creutzig et al., 2017; Schmidt, 2019).

21 **2.5.3.2 Technological change has accelerated since AR5**

22 Figure 2.22 shows changes in the costs of four dynamic energy technologies. One can see rapid changes
23 since AR5, cost data for which ended in 2010. Solar PV is by far the most dynamic technology, and its
24 cost since AR5 has continued on its steep decline at about the same rate of change as before AR5, but
25 now costs are well within the range of fossil fuels (*high confidence*) (see Chapter 6). Very few
26 concentrating solar power (CSP) plants had been built between the 1980s and 2012. Since AR5, 4 GW
27 have been built and costs have fallen by half. Onshore wind has continued its pace of costs reductions
28 such that it is well within the range of fossil fuels. Offshore wind has changed the most since AR5.
29 Whereas costs were increasing before AR5, they have decreased by 50% since. None of these
30 technologies shows indications of reaching a limit in their cost reductions. Crucial to their impact will
31 be extending these gains in the electricity and transportation sectors to the industrial sector (Davis et
32 al., 2018).

33
34 **Figure 2.22: Learning curves for renewable energy technologies 2000–2019**

6 **2.5.3.3 Granular technologies improve faster**

7 The array of evidence of technology learning that has accumulated both before and since AR5
8 (Thomassen et al., 2020) has prompted investigations about the factors that enable rapid technology
9 learning. From the wide variety of factors considered, unit size has generated the strongest and most
10 robust results. Smaller unit sizes, sometimes referred to as ‘granularity’, tend to be associated with faster
11 learning rates (*medium confidence*) (Sweerts et al., 2020; Wilson et al., 2020). Examples include solar
12 PV, batteries, heat pumps, and to some extent wind power. The explanatory mechanisms for these
13 observations are manifold and well established: more iterations are available with which to make
14 improvements (Trancik, 2006); mass production can be more powerful than economies of scale
15 (Dahlgren et al., 2013); project management is simpler and less risky (Wilson et al., 2020); the ease of
16 early retirement can enable risk-taking for innovative designs (Sweerts et al., 2020); and they tend to
17 be less complicated (Malhotra and Schmidt, 2020; Wilson et al., 2020). Small technologies often
18 involve iterative production processes with many opportunities for learning by doing and have much of
19 the most advanced technology in the production equipment than in the product itself. In contrast, large
20 unit scale technologies – such as full-scale nuclear power, CCS, low-carbon steel making, and negative
21 emissions technologies such as bioenergy with carbon capture and sequestration (BECCS) – are often
22 primarily built on site and include thousands to millions of parts such that complexity and system
23 integration issues are paramount (Nemet, 2019). Despite the accumulating evidence of the benefits of
24 granularity, these studies are careful to acknowledge the role of other factors in explaining learning. In
25 a study of 41 energy technologies (Figure 2.23), unit size explained 22% of the variation in learning
26 rates (Sweerts et al., 2020) and a study of 31 low-carbon technologies showed unit size explained 33%
27 (Wilson et al., 2020). Attributing that amount of variation to a single factor is rare in studies of
28 technological change. The large residual has motivated studies, which find that small-scale technologies
29 provide opportunities for rapid change, but they do not make rapid change inevitable; a supportive
30 context, including supportive policy and complementary technologies, can stimulate more favourable
31 technology outcomes (*high confidence*).

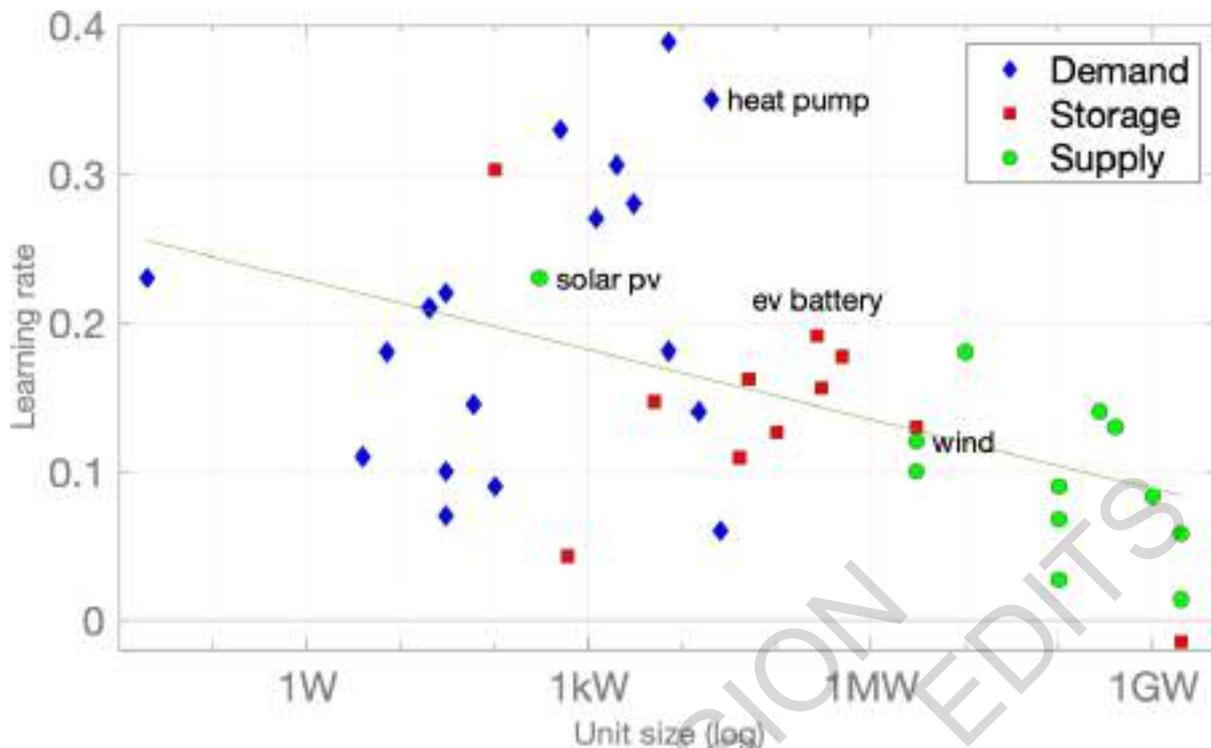

Figure 2.23 Learning rates for 41 energy demand, supply, and storage technologies

Source: Sweerts et al. (2020).

There is also evidence that small technologies not only learn but get adopted faster than large technologies (*medium confidence*) (Wilson et al., 2020b). Some of the mechanisms related to the adoption rate difference are related to those for cost reductions; for example, smaller, less lumpy investments involve lower risk for adopters (Dahlgren et al., 2013; Wilson et al., 2020b). The shorter lifetimes of small technologies allow users to take advantage of new performance improvements (Knapp, 1999) and access a large set of small adopters (Finger et al., 2019). Other mechanisms for faster adoption are distinctly related to markets: modular technologies can address a wide variety of niche markets (Geels, 2018) with different willingness to pay (Nemet, 2019) and strategically find protected niches while technology is maturing (Coles et al., 2018).

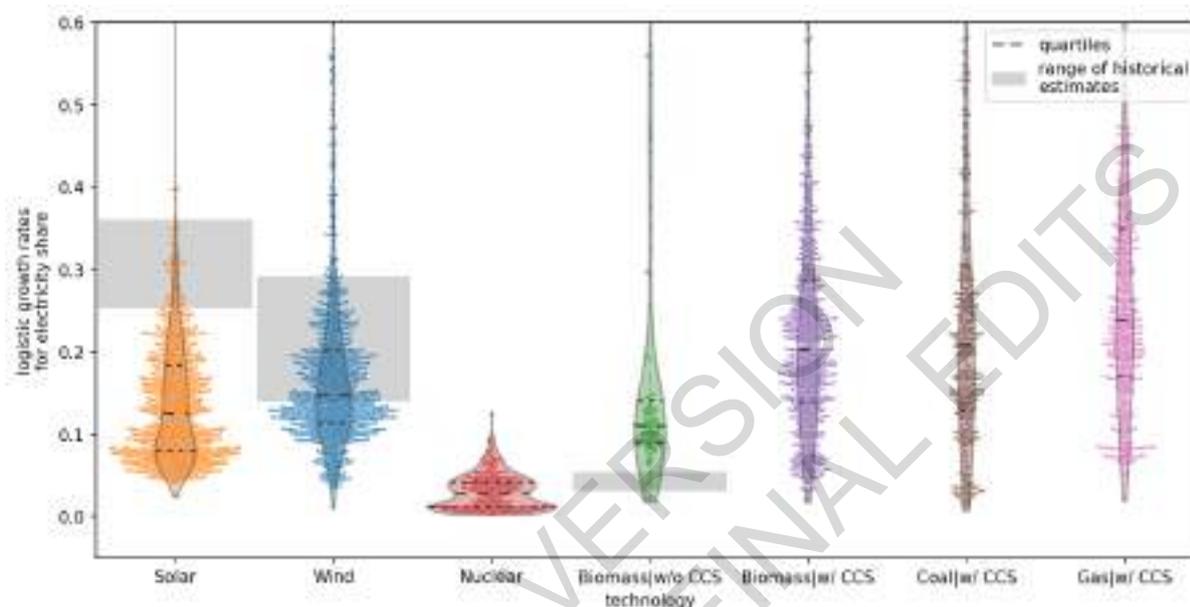

2.5.4 Rapid Adoption Accelerates Energy Transitions

The transition to a more sustainable energy system depends not just on improvement in technologies, but also on their widespread adoption. Work since AR5 has also substantiated the bidirectional causal link between technology improvement and adoption. Cost reductions facilitate adoption, which generates opportunities for further cost reductions through a process of learning by doing (*medium confidence*). The rate of adoption is thus closely related to the speed at which an energy transition is possible.

Results of integrated assessment models (IAMs) show that scale-up needs are massive for 2°C scenarios. Using logistic growth rates of energy shares as in previous work (Wilson, 2012; Cherp et al., 2021), most of these technologies include annual adoption growth rates of 20% in the 2020s and 2030s, and are in line with recent adoption of wind and solar. However, it is important to realise that IAMs include faster adoption rates for some mitigation technologies than for others (Peters et al., 2017). Growth rates in IAMs for large-scale CCS – biomass, coal, and gas – are between 15 and 30% (25th and 75th percentiles) (Figure 2.24). So few plants have been built that there is little historical data to which to compare this expected growth; with only two full scale CCS power plants built and a 7% growth rate if including industrial CCS. In contrast, IAMs indicate that they expect much lower rates of growth in

1 future years for the set of technologies that has been growing fastest in recent years (wind and solar),
2 without strong evidence for why this should occur.

3 The overall pattern shows that IAMs expect growth in small-scale renewables to fall to less than half
4 of their recent pace and large-scale CCS to more than double from the limited deployment assessed
5 (*high confidence*). The emerging work since AR5 showing the rapid adoption and faster learning in
6 small-scale technologies should prompt a keener focus on what technologies the world can depend on
7 to scale up quickly (Grubb et al., 2021). In any case, the scenario results make quite clear that climate
8 stabilisation depends on rapid adoption of low-carbon technologies throughout the 2020–2040 period.

17

18 2.6 Behavioural Choices and Lifestyles

19 2.6.1 Introduction

20 This section synthesises how behavioural choices, lifestyles, and consumption preferences affect energy
21 use and emissions. Household consumption is the largest component of a country's gross domestic
22 product (GDP) and the main contributor to greenhouse gas emissions through direct energy
23 consumption for heating and cooling or private transportation and indirectly through carbon emitted
24 during production of final consumption items. There is great variation in individual, groups and
25 household behavior and consumption patterns within and between countries and over time. A number
26 of factors affect people's consumption patterns and associated carbon emissions, such as socio-
27 demographics, socio-economic status, infrastructure and access to public services; the regulatory frame;
28 availability, affordability and accessibility of more or less sustainable choices on markets; individual
29 values and preferences (Dietz et al., 2009).

1 **Figure 2.25 Carbon footprints per capita income and expenditure category for 109 countries ranked by**
2 **per capita income (consumption-based emissions)**

3 **Notes: Countries and income categories are dependent on data availability. Blue dots represent income**
4 **quintiles (lowest, low, middle, higher, and highest) of EU countries and the United States. Orange dots are**
5 **for the developing country group provided by the World Bank for 4 expenditure categories: lowest, low,**
6 **middle and higher (Hubacek et al., 2017b). Red diamonds represent average per capita carbon footprints.**
7 **Countries are ranked from the lowest per capita income (bottom) to the highest income (top) within each**
8 **country group. Countries are grouped using the IPCC's six categories high-level classification. Footprint**
9 **values for higher income groups in the World Bank data are less reliable.**

10
11 Carbon footprints vary between and within countries and show an uneven distribution because of
12 differences in development levels, economic structure, economic cycle, available public infrastructure,
13 climate and residential lifestyles (Bruckner et al., 2021). Similar emission characteristics can also be
14 found within a country, see, for example for China (Feng et al., 2013), for the US (Pizer et al., 2010;
15 Wang et al., 2018; Mieke et al., 2016; Feng et al., 2013; Hubacek et al., 2017b) for Brazil (Sanches-
16 Pereira et al., 2016), for Latin American countries (Zhong et al., 2020).

17 In western countries, the largest contribution to the household carbon footprint is from transportation,
18 housing, and consumption of food (Druckman and Jackson, 2015). These three items' joint contribution
19 varies in different countries depending on consumption patterns and account for 58.5%, on average, in
20 EU 25 countries. (Tukker and Jansen, 2006). However, different countries and even regions within
21 countries may have different emission patterns due to differences in income, lifestyle, geography,
22 infrastructure, political and economic situation. For example, the main contributors to the average US
23 household is private transport (19.6%), followed by electricity (14.8%) and meat (5.2%) (Jones and
24 Kammen, 2011), while the UK households have 24.6% emissions on energy and housing, 13.7%
25 emissions on food, and 12.2% emissions on consumables (Gough et al., 2011). A study of 49 Japanese
26 cities found that energy (31%), food (27%), and accommodation (15%) were the largest sources of
27 household emissions (Long et al., 2017). An overview investigation of Japan's household emissions
28 found that energy, food, and utility are the three main emissions sources, but their shares are dependent
29 on age (Shigetomi et al., 2014). See section 12.4 in chapter 12 and Box 5.4 in chapter 5 for more in-
30 depth discussion on food systems and dietary shifts towards lower emission food.

31 In terms of rapidly growing economies, China is the most extensively researched country. China's
32 household emissions were primarily derived from electricity and coal consumption, as well as residents'
33 consumption of emission-intensive products, such as housing (33.4%), food (23.6%), private
34 transportation and communications (14.8%) (Wang et al., 2018). Space heating was the largest
35 contributor among various daily energy uses in northern cities (Yang and Liu, 2017). In comparison,
36 Indonesian rural households have a larger emission share on foods and a much smaller share on services
37 and recreation than urban households (Irfany and Klasen, 2017). Urban Indonesian households have a
38 much larger share of transport related emissions (Irfany and Klasen, 2017). Analysis from the
39 Philippines shows that on average households in urban areas emit twice as much as rural ones because
40 of much lower direct energy use in homes and for transport in rural areas (Serino, 2017). In other
41 emerging economies, such as India, Brazil, Turkey and South Africa, a high share of transport related
42 carbon emissions among urban middle- and high-income households is evident (Huang and Tian, 2021).

43
44 **2.6.2 Factors affecting household consumption patterns and behavioural choices**

45 Households' carbon emissions are closely linked to activities and consumption patterns of individuals
46 and as a group in households. Individual and group behaviour, in turn, is shaped by economic,
47 technological, and psychological factors, social contexts (such as family ties, friends and peer-pressure)
48 and cultural contexts (social identity, status, and norms) as well as the natural environment (number of

1 heating and cooling days) and physical infrastructure, or geography (Jorgenson et al., 2019). For
2 example, a city with an excellent bicycle infrastructure will make it safer and easier for citizens to
3 become highly mobile by using their bikes; a city that has less density and is dominated by automobile
4 infrastructure induces more people to travel by car (see Chapter 8 and 10). As a consequence, many
5 climate relevant consumption acts are not consciously decided upon or deliberately made part of a
6 lifestyle but are strongly influenced by the factors listed above. Chapter 5 provides more in-depth
7 discussion on behavioural drivers and examples of behavioural interventions and policies that can be
8 used to reduce emissions.

9 Demographic characteristics such as age, sex, and education constitute an important set of determinants
10 influencing emissions patterns. People of different genders have different consumption patterns. For
11 example, men tend to consume more food (especially meat) than women, leading to higher food-related
12 emissions. Also, men spend more money on vehicles and driving (Wang et al., 2018). Similar evidence
13 has been found in Germany, Greece, Norway, and Sweden, where men's energy use is 8%, 39%, 6%,
14 and 22% higher than women's, respectively (Räty and Carlsson-Kanyama, 2010).

15 **Income.** Due to the differences that shape individuals' consumption patterns there are enormous
16 differences in carbon footprints associated with income being one of the most important predictors.
17 Globally, households with income in the top 10% (income higher than USD23.03 PPP per capita per
18 day) are responsible for 36% to 45% of GHG emissions, while those in the bottom 50% (income less
19 than USD2.97 PPP per capita per day) are responsible for only 13-15% of emissions depending on the
20 study (Chancel and Piketty, 2015; Semieniuk and Yakovenko, 2020; Hubacek et al., 2017b) (Figure
21 2.25). The average carbon footprint of the high household incomes is more than an order of magnitudes
22 larger than that of the lowest expenditure group (Feng et al. 2021). For example, Zhang et al. (2016)
23 analysed the impact of household consumption across different income households on the whole CO₂
24 emissions in China and concluded that the impact on CO₂ emissions generated by urban households'
25 consumption are 1.8 times as much as that of rural ones. High-income households have higher emission
26 related to transport and entertainment, such as recreational expenditure, travel, and eating out, than low-
27 income households. Low-income households tend to have a larger share on necessities such as fuel for
28 heating and cooking (Kerkhof et al., 2009). Figure 2.25, shown above, depicts the carbon footprint per
29 capita ranked by per capita income.

30 **Age.** The effect of population ageing on emissions is contested in literature. Ageing when accompanied
31 by shrinking household size and more energy-intensive consumption and activity patterns results in
32 increased emissions. However, an ageing labour force can also dampen economic growth and result in
33 less of energy-intensive activity like driving, which decreases emissions (Liddle, 2011; Liddle and
34 Lung, 2010). An ageing of the population characterises the demographic transition in both developed
35 and developing countries. The implications of ageing for emissions depend on labour force
36 participation of the elderly and difference in the consumption and investment patterns of different age
37 groups (O'Neill et al., 2012). Analysis using panel macro data from OECD countries suggests that shifts
38 in age and cohort composition have contributed to rising GHG emissions since the 1960s (Menz and
39 Welsch, 2012; Nassen, 2014). Household-level data over time for the US provides evidence that
40 residential energy consumption increases over the lifetime of household members, largely also due to
41 accompanying changes in household size (Estiri and Zagheni, 2019). Similar insights emerge from
42 Japan, where analysis shows that those in their 70s or older, a group that is growing in size in Japan,
43 have higher emissions than other age groups (Shigetomi et al., 2014, 2019, 2018). Recent analysis from
44 China suggests that the shift to smaller and ageing households is resulting in higher carbon emissions
45 because of the accompanying time-use and consumption shifts (Yu et al., 2018; Li and Zhou, 2019).
46 An increase in the dependency ratio, i.e. the proportion of children under 15 and people over 65 relative
47 to the working-age population, in other analysis, has been shown to lead to reduced CO₂ emissions in
48 China (Wei et al., 2018; Li and Zhou, 2019). Implications of the nature of this relationship are important

1 to policy discussions of working hours and retirement age that are likely to have an influence on
2 emissions. For example, children and youth tend to emit more education related emissions than adults
3 (Han et al., 2015). Older people tend to have higher emissions related to heating and cooling being more
4 sensitive to temperature (Meier and Rehdanz, 2010).

5 **Household size.** Per capita emissions tend to decrease with family size as living together becomes more
6 energy efficient (Qu et al., 2013). The household size in most countries is decreasing (Liu et al., 2011),
7 but the decrease rate differs across countries and show, for example, higher decrease rate in China than
8 Canada and UK (Maraseni et al., 2015). The evidence shows that shifts to smaller households are
9 associated with larger per-capita footprints (Liddle and Lung, 2014; Underwood and Zahran, 2015;
10 Wiedenhofer et al., 2018; Ivanova et al., 2017), at least in developed countries (Meangbua et al., 2019).

11 **Urban Living.** The carbon footprint of individuals and households is also significantly influenced by
12 urban-rural differences (Ivanova et al., 2018; Wiedenhofer et al., 2018). In some part, the difference
13 can be explained by the effect of locational and spatial configuration characteristics such as levels of
14 compactness/density, centrality, proximity and ease of access to services. In all these parameters, urban
15 areas score higher as compared with rural or peri-urban (outlying and suburban) areas, thus influencing
16 household emissions in different ways. Urban households tend to have higher emissions than rural
17 households (O'Neill et al., 2010; Liu et al., 2011), but with different energy and consumption structure.
18 For example, rural households have more diverse energy inputs, such as biomass, biogas, solar, wind,
19 small hydro and geothermal in addition to coal (Maraseni et al., 2016).

20 In terms of indirect emissions, urban households have more service related emissions, such as from
21 education and entertainment than rural households, while rural households tend to have higher
22 emissions related to food consumption or transportation (Büchs and Schnepf, 2013; Maraseni et al.,
23 2016) but this is strongly dependent on the specific situation of the respective country as in poorer
24 regions rural transport might be mainly based on public transport with lower carbon emissions per
25 capita. Centrality and location also place a role on the level of urban household emissions. Studies on
26 US households found that residents in the urban core have 20% lower household emissions than
27 residents in outlying suburbs, which show a large range of household emissions (from -50% to +60%)
28 (Kahn, 2000; Jones and Kammen, 2014). From a global average perspective, higher population density
29 is associated with lower per capita emissions (Liddle and Lung, 2014; Liu et al., 2017).

30 Location choices are a significant contributor to household emissions. Suburbanites generally purchase
31 large, spacious homes with larger heating and cooling requirements. Commuting distance and access to
32 public transportation, recreation areas, city centres, public services, and shops are other important
33 neighbourhood-specific determinants of carbon emissions (Baiocchi et al., 2010) (see more on this in
34 urban and the transport chapters 8 and 10).

35 **Time Use.** A study on the emissions implications of time use (Wiedenhofer et al., 2018) found that the
36 most carbon intensive activities are personal care, eating and drinking and commuting. Indirect
37 emissions are also high for repairs and gardening. In contrast, home-based activities such as sleep and
38 resting, cleaning and socializing at home have low carbon intensities per hour of time use. The same
39 study also found that households in cities and with higher incomes tend to substitute personal activities
40 for contracted services, thus shifting away from households to the service sector (Wiedenhofer et al.,
41 2018). Improvements in the efficiency of time or resource use are diminished by rebound effects which
42 have been shown to reduce emissions savings by 20-40% on average (Gillingham et al., 2015), while
43 other authors argue that potentially the size of the rebound effect could be larger (Saunders, 2015) (see
44 more coverage of the rebound effect in Chapters 9 and 16). Lifestyle shifts brought about by using
45 information technologies and socio-technological changes are inducing alterations in people's daily
46 activities and time-use patterns.

1 The reduction of working hours is increasingly discussed as an approach to improve well-being and
2 reduce emissions (Wiedenhofer et al., 2018; Fitzgerald et al., 2015, 2018; Melo et al., 2018; Smetschka
3 et al., 2019). For instance, analysis of differences in working hours across US states for the period 2007-
4 2013 shows that there is a strong positive relationship between carbon emissions and working hours,
5 which holds even after controlling for other differences in political, demographic and economic drivers
6 of emissions (Fitzgerald et al., 2018). In other analysis, this relationship is seen to hold in both
7 developed and developing countries (Fitzgerald et al., 2015). One recent study, however, finds evidence
8 of nonlinear relationships between working time and environmental pressure in EU-15 countries
9 between 1970 and 2010, in cases where non-work time is spent instead in carbon-intensive leisure
10 activities (Shao and Shen, 2017).

11 **Social Norms.** Evidence from experiments in the US shows that social norms can not only help in
12 reducing a household's absolute level of electricity use but also shift the time of use to periods when
13 more renewable electricity is in the system (Horne and Kennedy, 2017). Analysis from Sweden shows
14 that adoption of sustainable innovations like solar panels is influenced by perceived behaviour and
15 expectations of others (Palm, 2017). Similar conclusions emerge from analysis in the Netherlands on
16 the adoption of electric vehicles and smart energy systems (Noppers et al., 2019).

17 Broader contextual factors and cultural trends towards consumerism, individualization and defining
18 self-worth through conspicuous consumption can drive emissions up (Chancel and Piketty, 2015).
19 However, cohort and generational shifts can drive emissions down. For instance, evidence, from
20 millennials in the OECD shows that fewer younger people have driving licenses compared to older
21 generations (Kuhnimhof et al., 2012). Similar, findings are evident from analysis for the US, where
22 changing attitudes, decreased employment and rising virtual mobility explain decreased travel by
23 Millennials (McDonald, 2015). Analysis for France shows that baby boomers are higher emitters than
24 other generations (Chancel, 2014). A change in social norms is taking place with the spread of the
25 sharing economy by which consumers share or borrow goods from other consumers. Sharing
26 opportunities are more advanced within the mobility sector (Greenblatt and Shaheen, 2015). Successful
27 car and bike sharing have rapidly expanded in countries such as China, Indonesia, Mexico, Brazil and
28 Turkey. Technology and data advances are currently barriers to spreading of sharing in low- and lower
29 middle-income cities but the potential offered by these technologies to allow poor countries to leapfrog
30 to more integrated, efficient, multimodal transport systems is important (Yanocha et al., 2020). Despite
31 this potential it is unclear how much shared mobility contributes to transport decarbonization or to make
32 it worse as it takes away riders from public transit (ITF, 2019). The evidence so far shows that the
33 potential positive impacts of shared mobility with pooled rides in lowering travel costs, abating
34 congestion, and reduced GHG emissions have not materialized to date (Merlin, 2019) (See Chapter 5).

35 **Education & Environmental Knowledge.** A positive relationship was found between general and
36 carbon-specific knowledge and the attitude towards carbon-specific behaviours in US consumers
37 (Polonsky et al., 2012). One example, pertaining to students, found that the gain of environmental
38 knowledge resulted in more environmentally favourable attitude among these high school students
39 (Bradley et al., 1999). A comparison across states in the USA, for example, shows that environmental
40 awareness can be a mitigating factor of territorial GHG emissions (Dietz et al., 2015). A 1% increase
41 in 'environmentalism' – defined as the "environmental voting record of the state's Congressional
42 delegation" (Dietz et al., 2015) – leads to a 0.45% decrease in emissions.

43 Environmental knowledge is not always directly translating into decreased ecological footprint
44 (Csutora, 2012). While pro-environmental action is lagging behind, research shows that this is not
45 caused by people undervaluing the environment but rather by people structurally underestimating how
46 much others care (Bouman and Steg, 2019). Other evidence shows that there are multiple causal
47 pathways through which a more educated population can effect emissions, some of which may be
48 positive and others negative (Lutz et al., 2019). A more educated population is more productive and can

1 drive higher economic growth and therefore emissions (Lenzen and Cummins, 2013). Moreover,
2 education that is designed to specifically inform decision makers of the impacts of their decisions and
3 provide behavioural nudges can be a way to reduce emissions (Duarte et al., 2016).

4 **Status Competition.** As part of a larger consumer society and consumer culture, based on consumer-
5 oriented lifestyles, products frequently provide a source for identity and fulfilment (Stearns, 2001;
6 Baudrillard, 2017; Jorgenson et al., 2019). People pursue cultural constructs such as status, comfort,
7 convenience, hygiene, nutrition, and necessity. Consumption is, by and large, not an end in itself but a
8 means to achieve some other end, and those ends are diverse and not necessarily connected to one
9 another (Wilk, 2010). This shows that consumption patterns cannot be sufficiently understood without
10 also considering the context, for example the cultural and social contexts leading to status competition
11 and status-related consumption (Veblen, 2009; Schor and J.B., 2015; Wilk, 2017). Status seeking can
12 work to reduce emissions when ‘green products’ such as an electric car or photovoltaics on the roof
13 become a sign for high-status (Griskevicius Tybur, and Van Den Bergh, 2010). It also can work to
14 increase emissions through visible and high-carbon intensive consumption items such as larger homes,
15 fuel-inefficient SUVs cars, and long-distance vacations (Schor, 1998), driven by a notion of having ‘to
16 keep up with the Joneses’(Hamilton, 2011). This can lead to formation of new habits and needs, where
17 products and services become normalized and are quickly perceived as needed, reinforced through
18 social networks and advertisement, making it psychologically easy to convert a luxury item to a
19 perceived necessity (Assadour, 2012). For example, the share of adults who consider a microwave a
20 necessity was about one third in 1996 but had increased to more than two thirds in 2006, but retreated
21 in importance during the recession years 2008-2009 (Morin and Taylor, 2009). Similar ups and downs
22 have been observed for television sets, air conditioning, dishwasher or the clothes dryer. (Druckman
23 and Jackson, 2009). What is considered a basic need and what is a luxury is subject to change over
24 one’s lifetime and in relation to others (Horowitz, 1988). This shows that the boundaries of public’s
25 luxury-versus-necessity perceptions are malleable (Morin and Taylor, 2009).

26 **Inequality.** Global inequality within and between countries has shifted over the last decades expanding
27 consumption and consumer culture (Castilhos and Fonseca, 2016; Alvaredo et al., 2018; Short and
28 Martínez, 2020). The rise of middle class income countries, mostly in Asia, eg. China, India, Indonesia
29 and Vietnam, and the stagnating incomes of the middle classes in developed economies reduced
30 between countries income differences; meanwhile the population under extreme poverty (threshold of
31 1.9 USD per person/day) is now concentrated in Sub-Saharan Africa and South Asia (Milanović, 2016).
32 A major pulling apart between top and bottom incomes occurred in parallel within countries. Since
33 1980, the top 1% richest individuals in the world captured twice as much growth as the bottom 50%
34 individuals (Friedman and Savage, 2017; Alvaredo et al., 2018). The influence of these dual inequality
35 trends on lifestyles, new consumption patterns and carbon emissions at regional, local and global scale
36 are large and have led to the fastest growth of global carbon emissions, in particular, for fast emerging
37 economies (see section 2.2. and 2.3). Emissions remain highly concentrated, with the top 10% per capita
38 emitters contributing to between 35-45% of global emissions, while bottom 50% emitters contribute to
39 13-15% of global emissions (Hubacek et al., 2017a). Furthermore, the top 1% of income earners by
40 some estimates could have an average carbon footprint 175 times that of an average person in the bottom
41 10% (Otto et al., 2020). The top 10% high emitters live in all continents, and one third of them live in
42 emerging countries (Chancel and Piketty, 2015; Semieniuk and Yakovenko, 2020; Hubacek et al.,
43 2017a). Mitigation pathways need to consider how to minimize the impacts of inequality on climate
44 change and the different mechanisms and effects coming into play between inequality of income and
45 emissions (see 2.4.3) (Baek and Gweisah, 2013; Berthe and Elie, 2015; Hao et al., 2016; Grunewald et
46 al., 2017).

47 Inequality trends catalyses impact at a demand level, mobilizing rapid lifestyles changes, symbolic
48 consumption and ideals of material improvements and upward mobility (Castilhos et al., 2017) and

1 emulation of high-carbon emissions intensive lifestyle of the wealthy (Gough, 2017). Decoupling
2 energy use and emissions from income growth and, the decarbonisation of energy services have not
3 counteracted these trends (see 2.4.1). Alternative options to deal with carbon inequality like sharing
4 global carbon emissions among high emitters (Chakravarty et al., 2009; Chakravarty and Tavoni, 2013)
5 or addressing the discourse of income distribution and the carbon intensity of high emitters lifestyles
6 (Gössling, 2019; Otto et al., 2019; Hubacek et al., 2017b). are met with caution that such alternatives
7 may necessitate difficult and hard to implement institutional changes (Semieniuk and Yakovenko,
8 2020). Growing inequality within countries may make re-composition of emission intensive
9 consumption more difficult and, it may also exacerbate redistribution and social cohesion dilemmas
10 (Gough, 2017; Römpke et al., 2019). Climate mitigation action has different motivational departures in
11 unequal context. An emerging global 'middle class' strengthens consumption at the margin as evidence
12 by first-time purchases of white goods with likely impacts on energy demand (Wolfram et al., 2012),
13 and with a warming climate, the increased use of air conditioning (Davis and Gertler, 2015). Inequality
14 may affect the willingness of rich and poor to pay for environmental goods or accept policies to protect
15 the environment (Baumgärtner et al., 2017). Unequal departure for action is strongly manifested in cities
16 of all sizes in developing countries with low-income urban residents hardest hit in lock-in situations
17 such as lack of access to transportation and jobs (Altshuler, 2013; Mattioli, 2017), lack of green spaces
18 (Joassart-Marcelli et al., 2011), poor access to waste collection (King and Gutberlet, 2013) and to energy
19 and clean water provision. The exacerbation of these conditions constraint the feasibility for achieving
20 emissions reductions through lifestyle or behavioural changes alone (Oxfam, 2015; Baiocchi et al.,
21 2010). High inequality limits mitigation efforts, and conversely advancing mitigation should not
22 contribute to deepen existing inequalities (Rao and Min, 2018; Saheb et al., 2019). It is critically
23 important to account for varying demands and affordability across heterogeneous household groups in
24 access to quality energy, education, health, decent jobs and services, while recomposing consumption
25 and balancing societal trade-offs via policies to boost the inclusion of low income and energy poor
26 population groups (Pachauri et al., 2013). Further, there is a need to reduce inequalities and improve
27 the capabilities people have to live the lives they value (Sen, 1999; Gough et al., 2011; Gough, 2017;
28 Aranoff et al., 2019)

29 30 **2.7 Emissions associated with existing and planned long-lived** 31 **infrastructure**

32 **2.7.1 Introduction: clarification of concepts**

33 Carbon lock-in can be understood as inertia in a system that limits the rate of transformation by a path-
34 dependent process (Seto et al., 2016). For example, long lifetimes of infrastructures such as power
35 plants, roads, buildings or industrial plants may influence the rate of transformation substantially and
36 lock societies into carbon-intensive lifestyles and practices for many decades (Unruh, 2000, 2002;
37 Unruh and Carrillo-Hermosilla, 2006; Grubler, 2012; Seto et al., 2016; Sovacool, 2016). Infrastructure
38 stock evolution depends not only on technological and economic factors, but also on institutional and
39 behavioural ones that are often mutually reinforcing. That is, physical infrastructure such as the built
40 environment of urban areas can shape behaviour and practices of daily life, which in turn change the
41 demand for such infrastructure and lock-in energy demand patterns (Creutzig et al., 2016; Makido et
42 al., 2012; Banister et al., 1997; Shove and Trentmann, 2018; Seto et al., 2016).

43 There is a broad literature on carbon lock-in related to infrastructure that has analysed different
44 geographical scales and sectors, with a strong focus on the power sector (Fisch-Romito et al., 2020).
45 Available quantifications differ in the time frames of analysis that can be classified as backward-
46 looking, static for a given year, or forward-looking using scenarios (Fisch-Romito et al., 2020).
47 Quantifications also differ in the indicators used to describe carbon-lock in. Literature has assessed how

1 delays in climate policy affect the evolution of fossil-fuel infrastructure stock in the short term (Bertram
2 et al., 2015; McGlade et al., 2018; Kefford et al., 2018), overall mitigation costs (Luderer et al., 2016;
3 Riahi et al., 2015), or the transition risks from premature retirements or underutilisation of existing
4 assets (Iyer et al., 2015; van Soest et al., 2017; Lane et al., 2016; Farfan and Breyer, 2017; Cui et al.,
5 2019; Malik et al., 2020; Wang et al., 2020a; Johnson et al., 2015; Luderer et al., 2016; Kefford et al.,
6 2018; Fofrich et al., 2020; Pradhan et al., 2021). Only a few authors have relied on indicators related to
7 institutional factors such as technology scale or employment (Erickson et al., 2015; Spencer et al.,
8 2018). A complementary literature has explored how the sheer size of the world's fossil fuel reserves
9 (and resources) and financial interest of owners of these could contribute to supply-side dynamics that
10 sustain the use of fossil fuels (McGlade and Ekins, 2015; Heede and Oreskes, 2016; Jewell et al., 2013;
11 Bauer et al., 2016; Jakob and Hilaire, 2015; Welsby et al., 2021).

12 One way of quantifying potential carbon lock-in is to estimate the future CO₂ emissions from existing
13 and planned infrastructure (Davis et al., 2010; Davis and Socolow, 2014) based on historic patterns of
14 use and decommissioning. Such estimates focus on CO₂ emissions from operating infrastructure and do
15 not comprise any upstream or downstream emissions across the lifecycle, which are provided elsewhere
16 in the literature (Müller et al., 2013; Fisch-Romito, 2021; Krausmann et al., 2020; Creutzig et al., 2016).
17 Moreover, estimates tend to focus on energy, while, for example, the agricultural sector is usually not
18 covered. Another strand of literature quantifies lock-in by estimating fossil-fuel related CO₂ emissions
19 that are hard-to-avoid in future scenarios using integrated assessment models (Kriegler et al., 2018b;
20 Luderer et al., 2018). The remainder of this chapter will assess potential carbon lock-in through those
21 two related strands of literature.

22 **2.7.2 Estimates of future CO₂ emissions from long-lived infrastructures**

23 Table 2.6 summarizes studies that apply an accounting approach based on plant-level data to quantify
24 future CO₂ emissions from long-lived fossil fuel infrastructure (Davis and Socolow, 2014; Smith et al.,
25 2019; Rozenberg et al., 2015; Davis et al., 2010; Tong et al., 2019; Cui et al., 2019; Pfeiffer et al., 2018;
26 Pradhan et al., 2021; Edenhofer et al., 2018). Differences between studies arise in the scope of the
27 infrastructure covered (incl. resolution), the inclusion of new infrastructure proposals, the exact
28 estimation methodology applied as well as their assessments of uncertainties. Other studies provide
29 analysis with a sectoral focus (Vogl et al., 2021; Bullock et al., 2020) or with a regional focus on the
30 power sector (Shearer et al., 2017, 2020; Tao et al., 2020; González-Mahecha et al., 2019; Grubert,
31 2020).

32 Assuming variations in historic patterns of use and decommissioning, comprehensive estimates of
33 cumulative future CO₂ emissions from *current* fossil fuel infrastructures are 720 (550-910) GtCO₂
34 (Smith et al., 2019) and 660 (460-890) (Tong et al., 2019) (Table 2.6, Figure 2.26) (*high confidence*).
35 This is about the same size than the overall cumulative net CO₂ emissions until reaching net zero CO₂
36 of 510 (330-710) Gt in pathways that limit warming to 1.5°C with no or limited overshoot (Chapter 3).
37 About 50% of cumulative future CO₂ emissions from *current* fossil fuel infrastructures come from the
38 power sector and 70% of these (or about 40% of the total) are from coal plants only. Like global annual
39 CO₂ emissions (Friedlingstein et al., 2020; Peters et al., 2020), future CO₂ emissions from fossil-fuel
40 infrastructures have increased over time, i.e. future CO₂ emissions from fossil fuel infrastructure
41 additions in a given year are still outgrowing “savings” from infrastructure retirements (Davis and
42 Socolow, 2014; Tong et al., 2019). This could add further inertia to the system as it may require more
43 and faster retirement of fossil-based infrastructures later and leads to higher costs for meeting the
44 climate goals (e.g. Johnson et al., 2015; Bertram et al., 2015).

45 Estimates of total cumulative future CO₂ commitments from *proposed infrastructure* focus only on the
46 power sector due to data availability (Table 2.6, Figure 2.26). Infrastructure proposals can be at various
47 stages of development involving very different probabilities of implementation. About one third of the
48 currently proposed projects are more probable as they are already under construction (Cui et al., 2019).

1 Pfeiffer et al. (2018) and Tong et al. (2019) assess the cumulated CO₂ emissions from proposed
2 infrastructure in the entire power sector at 270 GtCO₂ and 190 GtCO₂ respectively. Estimates of CO₂
3 emissions implications for new coal power infrastructure plans are more frequent (Pfeiffer et al., 2018;
4 Edenhofer et al., 2018; Cui et al., 2019; Tong et al., 2019) ranging between 100 and 210 GtCO₂.
5 Differences across estimates of future CO₂ emissions from proposed power infrastructure mostly reflect
6 substantial cancellations of coal infrastructure proposals in 2017 and 2018 (Tong et al., 2019).

7

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

8

Table 2.6 - Comparing cumulative future CO₂ emissions estimates from existing and proposed long-lived infrastructures by sector.

9

Future CO₂ emissions estimates are reported from the “year of dataset”. Note that in some cases, the totals may not correspond to the sum of underlying sectors due to rounding (based on Tong et al., 2019). Initial estimates of future CO₂ emissions from fossil fuel infrastructures by Davis et al. (2010) are considerably lower than more recent estimates by Smith et al. (2019) and Tong et al. (2019) due to substantial growth in fossil energy infrastructure as represented by more recent data. Estimates presented here are rounded to two significant digits.

13

1 The global estimate of future CO₂ emissions from *current and planned* fossil-fuel infrastructures is 850
2 (600-1100) GtCO₂ (Tong et al., 2019). This already exceeds total cumulative net CO₂ emissions in
3 pathways that limit warming to 1.5°C with no or limited overshoot (see above). It is about the same size
4 than the total cumulative net CO₂ emissions of 890 (640-1160) GtCO₂ from pathways that limit *likely*
5 warming to 2°C (Chapter 3). Hence, cumulative net CO₂ emissions to limit *likely* warming to 2°C or
6 lower could already be exhausted by current and planned fossil fuel infrastructure (*medium confidence*)
7 even though this estimate only covers a fraction of all infrastructure developments over the 21st century
8 as present in mitigation pathways, does not cover all sectors (e.g. AFOLU) and does not include
9 currently infrastructure development plans in transport, buildings, and industry due to a lack of data.

10 Hence, the Paris climate goals could move out of reach unless there are dedicated efforts to early
11 decommissioning, and reduced utilization of existing fossil fuel infrastructures, cancellation of plans
12 for new fossil fuel infrastructures, or compensation efforts by removing some of the CO₂ emissions
13 from the atmosphere (Smith et al., 2019; Tong et al., 2019; Cui et al., 2019; Pradhan et al., 2021). For
14 example, Fofrich et al. (2020) suggest in a multi-model study that coal and gas power infrastructure
15 would need to be retired 30 (19-34) and 24 (21-26) years earlier than the historical averages of 39 and
16 36 years when following 1.5°C pathways and 23 (11-33) and 19 (11-16) years earlier when following
17 2°C pathways. Cui et al. (2019) arrive at more conservative estimates for coal power plants, but only
18 consider the existing and currently proposed capacity. Premature retirement of power plants pledged by
19 members of the Powering Past Coal Alliance would cut emissions by 1.6 GtCO₂, which is 150 times
20 less than future CO₂ emissions from existing coal power plants (Jewell et al., 2019).

21 Few quantifications of carbon lock-in from urban infrastructure, in particular urban form, have been
22 attempted, in part because they also relate to behaviours that are closely tied to routines and norms that
23 co-evolve with “hard infrastructures” and technologies, as well as “soft infrastructure” such as social
24 networks and markets (Seto et al., 2016). There are some notable exceptions providing early attempts
25 (Guivarch and Hallegatte, 2011; Lucon et al., 2014; Erickson and Tempest, 2015; Driscoll, 2014; IPCC,
26 2014b; Creutzig et al., 2016). Creutzig et al. (2016) attempt a synthesis of this literature and estimate
27 the total cumulative future CO₂ emissions from existing urban infrastructure at 210 Gt and from new
28 infrastructures at 495 Gt for the period 2010-2030.

1

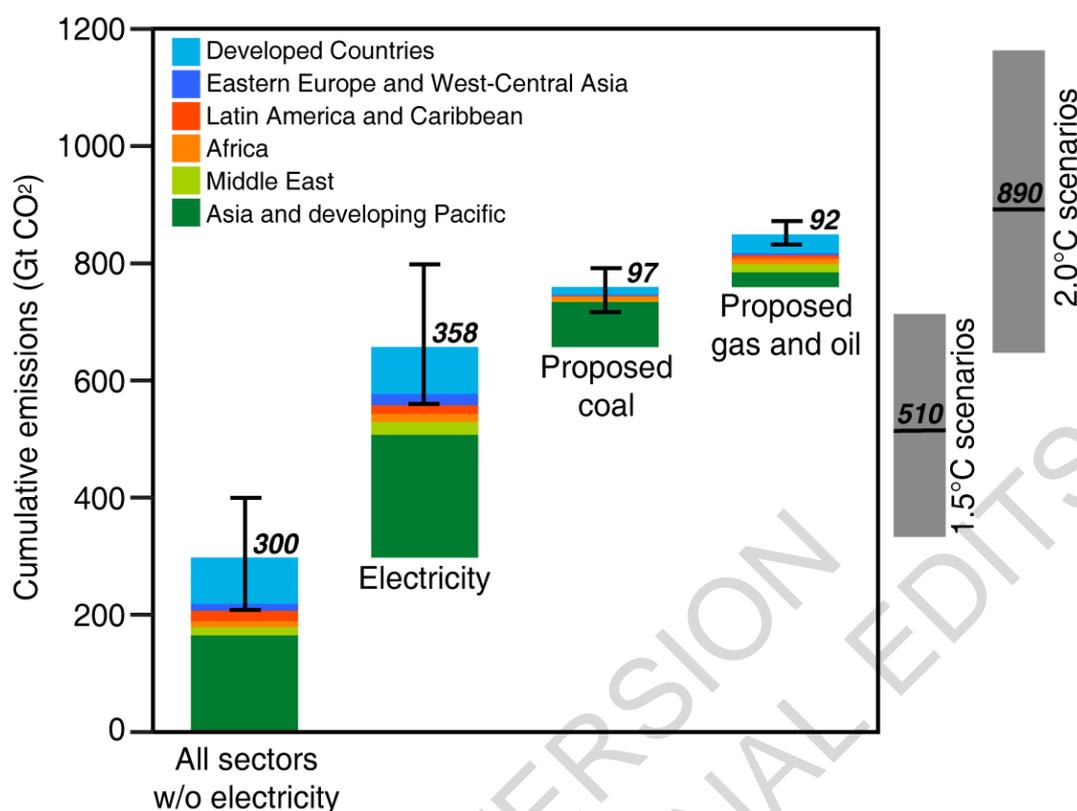

Figure 2.26 Future CO₂ emissions from existing and currently planned fossil fuel infrastructure in the context of Paris carbon budgets in GtCO₂ based on historic patterns of infrastructure lifetimes and capacity utilization. Future CO₂ emissions estimates of existing infrastructure for the electricity sector as well as all other sectors (industry, transport, buildings, other fossil fuel infrastructures) and of proposed infrastructures for coal power as well as gas and oil power. Grey bars on the right depict the range (5th – 95th percentile) in overall cumulative net CO₂ emissions until reaching net zero CO₂ in pathways that limit warming to 1.5°C with no or limited overshoot (1.5°C scenarios), and in pathways that limit likely warming to 2°C (2°C scenarios).

2.7.3 Synthesis – Comparison with estimates of residual fossil fuel CO₂ emissions

A complementary strand of literature uses Integrated Assessment Models (IAMs) to assess the cumulative gross amount of unabated CO₂ emissions from fossil fuels across decarbonisation pathways that are not removed from the system even under strong (short- and long-term) climate policy ambition. Lower bound estimates for such a minimum amount of unabated residual CO₂ emissions across the 21st century that is not removed from the system even under very ambitious climate policy assumptions may be around 600-700 GtCO₂ (Kriegler et al., 2018b). This range increases to 650-1800 GtCO₂ (Table 2.7) as soon as a broader set of policy assumptions are considered including delayed action in scenarios that limit warming to 1.5°C and 2°C respectively (Luderer et al., 2018).

Notably, the lower end of residual fossil fuel emissions in IAM scenarios (Luderer et al., 2018) is remarkably similar to global estimates from the accounting studies of the previous section as shown in Table 2.6. Yet, there are important conceptual and interpretative differences that are also reflected in the very different distribution of reported future CO₂ emissions attached to current and future fossil fuel infrastructures (Table 2.7). Accounting studies start from granular, plant-based data for existing fossil fuel infrastructure and make statements about their future CO₂ emission assuming variations of historic

1 patterns of use and decommissioning. Expansions to the future are limited to proposals for new
2 infrastructures that we know of today. Scenario studies quantifying residual fossil fuel emissions start
3 from aggregate infrastructure descriptions, but dynamically update those through new investment
4 decisions in each time step across the 21st century based on the development of energy and energy
5 service demands as well as technology availability, and guided by defined climate policy goals (or their
6 absence).

7 In accounting studies, estimated of future CO₂ emissions from current fossil fuel infrastructures are
8 dominated by the power sector with its large fossil fuel capacities today. In contrast, scenario studies
9 highlight residual emissions from non-electric energy – particularly in the transport and industry sectors.
10 Fossil-fuel infrastructure in the power sector can be much more easily retired than in those sectors,
11 where there are fewer and more costly alternatives. IAMs therefore account for continued investments
12 into fossil-based energy technologies in areas with limited decarbonisation potential, such as some areas
13 of transportation (in particular aviation, shipping and road-based freight) or some industrial processes
14 (such as cement production or feedstocks for chemicals). This explains the key discrepancies observable
15 in Table 2.7. Overall, our assessment of these available lines of evidence therefore strongly emphasises
16 the importance of decommissioning, as well as reduced utilization of existing power sector
17 infrastructure as well as continued cancellation of new power sector infrastructures in order to limit
18 warming to well below 2°C (*high confidence*) (Luderer et al., 2018; Kriegler et al., 2018b; Fofrich et
19 al., 2020; Cui et al., 2019; Chen et al., 2019). This is important as the power sector is comparatively
20 easy to decarbonise (IPCC, 2014a; Krey et al., 2014; Méjean et al., 2019; Davis et al., 2018) and it is
21 crucial to make space for residual emissions from non-electric energy end-uses that are more difficult
22 to mitigate (*high confidence*). Any further delay in climate policy substantially increases carbon lock-
23 in and mitigation challenges as well as a dependence on carbon dioxide removal technologies for
24 meeting the Paris climate goals (Kriegler et al., 2018b; Luderer et al., 2018).

Table 2.7 Residual (gross) fossil fuel emissions (GtCO₂) in climate change mitigation scenarios strengthening mitigation action after 2020 (“early strengthening”), compared to scenarios that keep NDC ambition level until 2030 and only strengthen thereafter.

Cumulative gross CO₂ emissions from fossil fuel and industry until reaching net zero CO₂ emissions are given in terms of the mean as well as minimum and maximum (in parentheses) across seven participating models: AIM/CGE, GCAM, IMAGE, MESSAGES, POLES, REMIND, WITCH. Scenario design prescribes a harmonised, global carbon price in line with long-term carbon budget. Delay scenarios follow the same price trajectory, but 10 years later. Carbon dioxide removal requirements represent ex-post calculations that subtract gross fossil fuel emissions from the carbon budget associated with the respective long-term warming limit. We take the carbon budget for limiting warming to 1.5°C with a 50% probability and to 2°C with a 67% probability (Canadell et al., 2021). Hence, carbon dioxide removal (CDR) requirements reflect a minimum amount of CDR for a given mitigation trajectory. Results are reported at 2 significant digits.

2.8 Climate and Non-Climate Policies and Measures and their Impacts on Emissions

2.8.1 Introduction

The key to achieving climate change mitigation targets includes crafting environmentally effective, economically efficient and socially equitable policies. For the purposes of this section, policies are defined broadly as actions to guide decisions to reach explicit goals and, accordingly, climate (mitigation) policies are the ones whose primary objective is to reduce GHG emissions. They include a range of domains from economic and institutional to R&D and social policies and are implemented by various instruments (e.g., market-based and regulatory in the economic domain) and measures (e.g., legal provisions and governance arrangements in the institutional domain) (see Chapter 13 and the Glossary about mitigation policies). Yet GHG emissions are also affected by policies enacted in various social, economic, and environmental areas to pursue primarily non-climatic objectives. This section presents succinct assessments of the outcomes and effectiveness of a few selected policy instruments applied in the last two decades targeting climate protection (Sections 2.8.2 and 2.8.3) and GHG emissions impacts of selected other policies primarily aiming improvements in environmental quality and natural resource management (Section 2.8.4).¹²

It is rather difficult, though not impossible, to discern the genuine impacts of climate and non-climate policies on GHG emissions. Most of current and past policies target only a small part of global emissions in a limited geographical area and/or from a small number of economic sectors. However, in addition to the targeted region or sector, policies and measures tend to affect GHG emissions in other parts of the world. Emissions leakage is the key channel by which such phenomena and complex interactions occur.¹³ Uncertainties in impacts, synergies, and trade-offs between policies and measures also complicate the evaluation of emissions impacts. These make it challenging to identify the impacts of any specific policy or measure on emissions of any specific region or sector. Rigorous statistical analyses are necessary for building strong empirical evidence, but the experience with climate-related policy experiments to date is limited.

2.8.2 Comprehensive Multinational Assessments

Comprehensive multinational evaluations with wider regional and sectoral coverage enable the assessment of emissions impacts without distortions from emissions leakage. Among the wide range of climate policy instruments, pricing carbon such as a carbon tax or an emissions trading system has been one of the most widely used and effective options to reduce GHG emissions (*robust evidence, high agreement*). In a comparison of 142 countries with and without carbon pricing, countries with a carbon price show an annual CO₂ emission growth rates of 2 percentage points lower than countries without such policies (Best et al., 2020). A more comprehensive evaluation of carbon prices shows that countries with a lower carbon pricing gap (a higher carbon price) tend to be more carbon-efficient, that is, they have a lower carbon intensity of GDP (OECD, 2018).¹⁴ An empirical analysis of the effects of

FOOTNOTE¹² This section only reviews emission impacts of selected policy instruments. Other important aspects such as equity and cost-effectiveness are assessed in Chapter 13, presenting comprehensive evaluations of policies and measures.

FOOTNOTE¹³ Refer to Chapter 13 on policies and institutions for detailed discussion of emissions leakages and complex interactions from policy mixes.

FOOTNOTE¹⁴ The OECD (2018) measures carbon prices using the *effective carbon rate* (ECR), which is the sum of three components: specific taxes on fossil fuels, carbon taxes, and prices of tradable emissions permits. The

1 environmental regulation and innovation on the carbon emissions of OECD countries during the period
2 1999–2014 indicates that a 1% increase in environmentally friendly patents reduced carbon emissions
3 by 0.017%, and a 1% increase in environmental tax revenue per capita reduced carbon emissions by
4 0.03% (Hashmi and Alam, 2019).

5 Domestic and international climate legislation have also contributed to the reduction of GHG emissions.
6 An empirical analysis of legislative activity in 133 countries over the period 1999–2016 based on panel
7 data indicates that each new law reduced annual CO₂ emissions per unit of GDP by 0.78% nationally in
8 the first three years and by 1.79% beyond three years. Additionally, climate laws as of 2016 were
9 associated with an annual reduction in global CO₂ emissions of 5.9 GtCO₂ and 38 GtCO₂ cumulatively
10 since 1999 (Eskander and Fankhauser, 2020). It is notable that 36 countries that accepted legally binding
11 targets under the Kyoto Protocol all complied (Shishlov et al., 2016). It is impossible to disentangle
12 precisely the contribution of individual mitigation policies, but it is clear that the participating countries,
13 especially those in the OECD, did make substantial policy efforts with material impact (Grubb, 2016).
14 An ex-post evaluation shows a significant impact of the Protocol on emissions reductions (Maamoun,
15 2019).

16 Renewable energy policies, such as Renewable Portfolio Standards and Feed-in-Tariff, have played an
17 essential role in the massive expansion of renewable energy capacities, another key driver of GHG
18 emissions reductions (*robust evidence, high agreement*). The drivers of decreasing CO₂ emissions in a
19 group of 18 developed economies that have decarbonised over the period 2005–2015 has been shown
20 to be the displacement of fossil fuels by renewable energy and decreases in energy use (Le Quere et al.,
21 2019). Renewable energy policies both at the EU and Member States level have played an essential role
22 in abating GHG emissions (ICF International, 2016).

23 **2.8.3 National, Sectoral, and Cross-Sectoral Policies**

24 **2.8.3.1 National and regional carbon pricing**

25 Carbon prices (e.g., carbon taxes and GHG emissions trading schemes), are among the widely used
26 climate policy instruments across the globe, together with technology support instruments (see IRENA
27 (2018)). As of May 2020, there were 61 carbon pricing schemes in place or scheduled for
28 implementation, consisting of 31 emissions trading schemes (ETSs) and 30 carbon tax regimes, covering
29 12 GtCO₂-eq or about 22% of annual global GHG emissions (World Bank, 2020). The performance of
30 carbon pricing in practice varies by countries and sectors, and depends on the policy environment (*robust
31 evidence, high agreement*).

32 The European Union Emissions Trading Scheme (EU ETS), the longest-standing regional climate policy
33 instrument to date, has reduced emissions, though the estimates of the amount vary by study, by country,
34 and by sector; ranging from 3 to 28% (McGuinness and Ellerman, 2008; Ellerman et al., 2010; Abrell
35 et al., 2011; Anderson and Di Maria, 2011; Egenhofer et al., 2011; Petrick and Wagner, 2014;
36 Arlinghaus, 2015; Martin et al., 2016). The EU ETS avoided emitting about 1.2 GtCO₂ between 2008
37 and 2016 (3.8%), almost half of what EU governments promised to reduce under their Kyoto Protocol
38 commitments (Bayer and Aklin, 2020).

39 China's emission trading pilots have resulted in a decline in carbon intensity in the pilot provinces by
40 adjusting the industrial structure (Zhou et al., 2019). The Regional Greenhouse Gas Initiative (RGGI)
41 in the USA has induced leakage in emissions through increases in electricity generation in surrounding
42 non-RGGI areas, but it has led to the reduction of emissions by way of changes in the fuel mix from
43 coal to gas (Fell and Maniloff, 2018). Actual emissions declined in six of the ten ETSs for which data

carbon pricing gap measures the difference between actual ECRs and benchmark rates. The carbon pricing gap indicates the extent to which polluters do not pay for the damage from carbon emissions.

1 is available, although other factors such as the 2009 recession, have had significant impacts on those
2 emissions as well (Haites et al., 2018).

3 The evidence of environmental effectiveness of carbon taxes in Western European countries is varied
4 depending on country and study (*robust evidence, high agreement*). A significant impact is found in
5 Finland but insignificant impacts are found in Denmark and the Netherlands, and there are mixed results
6 for Sweden (Lin and Li, 2011; Brännlund et al., 2014). Only six of the 17 taxes, where data are available,
7 have reduced actual emissions subject to the tax. Tax rates tend to be too low in many cases and the
8 scale and frequency of the rate changes has not been sufficient to stimulate further emissions reductions
9 (Haites et al., 2018).

10 **2.8.3.2 Selected sectoral climate policy instruments**

11 Many governments have implemented sector-specific policies, in addition to nationwide measures, to
12 reduce GHG emissions (*high confidence*). Examples of sectoral climate policies include carbon taxes
13 on transportation fuels, low-carbon fuel standards, and regulation of coal power generation.

14 The implementation of a carbon tax and value-added tax on gasoline and diesel in Sweden resulted in
15 significant reductions of CO₂ emissions in the transportation sector (Shmelev and Speck, 2018;
16 Andersson, 2019). An assessment of a variety of carbon tax schemas across various sectors in the
17 European Union shows a negative relationship between CO₂ emissions and a CO₂ tax (Hájek et al.,
18 2019). In British Columbia (Canada), the carbon tax resulted in a decrease in demand for gasoline and
19 a reduction in total GHG emissions (not exclusive to the transportation sector) estimated to be between
20 5 and 15% (Murray and Rivers, 2015; Rivers and Schaufele, 2015). Low Carbon Fuel Standards in
21 California have contributed to reducing carbon emissions in the transportation sector by approximately
22 9.85–13.28% during 1997–2014 (Huseynov and Palma, 2018).

23 The power sector typically accounts for a large portion of countries' CO₂ emissions. Market-based
24 regulation and government subsidies in China contributed to improving operational efficiency and
25 reducing emissions (Zhao et al., 2015). In addition, the implementation of ultra-low emission standards
26 also has resulted in a significant reduction in emissions from China's power plants (Tang et al., 2019).
27 Mandatory climate and energy policies, including the California Global Warming Solutions Act,
28 reduced CO₂ emissions by 2.7–25% of the average state-level annual emissions from the power sector
29 over the period 1990–2014 in the USA. Mandatory GHG registry/reporting, electric decoupling and
30 public benefit fund have been effective in further decreasing power sector emissions in the USA (Martin
31 and Saikawa, 2017). In the UK electricity sector, a carbon price floor, combined with electricity market
32 reform (competitive auctions for both firm capacity and renewable energy), displaced coal, whose share
33 fell from 46% in 1995 to 7% in 2017, halving CO₂ emissions, while renewables grew from under 4% in
34 2008 to 22% by 2017 (Grubb and Newbery, 2018). See Chapter 13 for more.

35 An alternative approach to a carbon tax is an indirect emissions tax on fuels such as an excise tax, or on
36 vehicles, based on the expected CO₂ intensity of new passenger vehicles. Vehicle purchase taxes can
37 result in a reduction in GHG emissions through reducing the CO₂ emissions intensity of vehicles, while
38 also discouraging new vehicle purchases (Aydin and Esen, 2018). For example, a vehicle tax policy in
39 Norway resulted in a reduction of average CO₂ intensity per kilometre of 7.5 gCO₂ km⁻¹ (Ciccone, 2018;
40 Steinsland et al., 2018). Despite such evidence, studies of carbon pricing find that additional policies are
41 often needed to stimulate sufficient emissions reductions in transportation (*medium confidence*)
42 (Tvinnereim and Mehling, 2018).

43 Electric vehicles (EVs) powered by clean electricity can reduce GHG emissions and such policies are
44 important for spurring adoption of such vehicles and GHG emission reductions (Kumar and Alok, 2020;
45 Thiel et al., 2020). The extent to which EV deployment can decrease emissions by replacing internal
46 combustion engine-based vehicles depends on the generation mix of the electric grid (Abdul-Manan,
47 2015; Nichols et al., 2015; Canals Casals et al., 2016; Hofmann et al., 2016; Choi et al., 2018; Teixeira

1 and Sodr , 2018), although even with current grids EVs reduce emissions in almost all cases (Knobloch
2 et al., 2020). Policy incentives for EV adoption can be an effective mechanism to increase EV sales
3 (Langbroek et al., 2016) and may include charging discounts, purchase subsidies, regulations, and
4 government leadership (*medium confidence*) (Bakker and Jacob Trip, 2013; Silvia and Krause, 2016;
5 Teixeira and Sodr , 2018; Qiu et al., 2019; Santos and Davies, 2020). The presence of charging
6 infrastructure and publicly available charging increases the adoption rate of EVs (Vergis and Chen,
7 2015; Javid et al., 2019). A comparison of EV adoption rates across 30 countries shows a positive
8 correlation between charging stations and EV market share (Sierzchula et al., 2014). A rollout of 80,000
9 DC fast chargers across the United States is estimated to have resulted in a 4% reduction in emissions
10 compared to a baseline of no additional fast chargers (Levinson and West, 2018). More recently, bans
11 on internal combustion engine vehicles have provided a much more direct approach to stimulating the
12 adoption of EVs and its supporting infrastructure; however, the efficacy of such measures depends on
13 enforcement (Pl tz et al., 2019).

14 Public transit can reduce vehicle travel and reduce GHG emissions by reducing the number of trips taken
15 by private vehicles and the length of those trips (*medium confidence*). Changes to the operation of public
16 transportation systems (such as density of bus stops, distance from stops to households, duration and
17 frequency of trip times, and lowering ridership costs) can result in a mode shift from private car trips to
18 public transit trips (Cats et al., 2017; Choi, 2018; Carroll et al., 2019). These changes in the public transit
19 system operation and network optimisation have been shown to have reduced GHG emissions in cases
20 such as San Francisco, in which the cost optimisation of the transit network was estimated to decrease
21 emissions by a factor of three (Cheng et al., 2018) and Barcelona, where the optimisation of the urban
22 bus system was estimated to reduce GHG emissions by 50% (Griswold et al., 2017). For every 1%
23 increase in investment in transit services and transit-oriented design, there is an estimated 0.16%
24 reduction in private vehicle kilometres travelled per capita (McIntosh et al., 2014).

25 Bike and car sharing programmes can reduce GHG emissions (*medium confidence*). Albeit a study of
26 eight cities in the United States with larger bike share systems and higher ridership found that their
27 potential to reduce total emissions is limited to <0.1% of total GHG emissions from the transportation
28 sectors of these cities (Kou et al., 2020). The emissions reductions effects of car-sharing programmes
29 depends on the specifics of programmes: the mode shift from public transit to car-sharing services can
30 outweigh the decreases in GHG emissions associated with decreased cars on the road (Jung and Koo,
31 2018), whereas car-sharing programmes with electric vehicle fleets may reduce GHG emissions (Luna
32 et al., 2020).

33 **2.8.4 Emission Impacts of Other Related Policies**

34 Policies other than those intended directly to mitigate GHG emissions can also influence these
35 emissions. Policies to protect the stratospheric ozone layer is a case in point. Implementing the Montreal
36 Protocol and its amendments, emissions of controlled ozone-depleting substances (ODSs) (those
37 covered by the protocol) declined to a very low level of about 1.4 GtCO₂-eq yr⁻¹ by 2010, avoiding GHG
38 emissions of an estimated 13.3–16.7 GtCO₂-eq yr⁻¹ (9.7–12.5 GtCO₂-eq yr⁻¹ when accounting for the
39 ozone depletion and hydrofluorocarbons (HFCs) offsets) (Velders et al., 2007). Yet fluorinated gases
40 (F-gases), the substances introduced to substitute ODSs are also potent GHGs. See Section 2.2 for
41 emissions data and Chapter 13 on current policies to mitigate HFCs and other F-gases. GHG
42 implications of two other categories of non-climate policies are briefly assessed in this section.

43 **2.8.4.1 Co-impacts of air quality, sector-specific and energy policies on climate mitigation**

44 Co-impacts of local or regional air pollution abatement policies for climate mitigation are widely studied
45 in the literature. Cross-border externalities of air pollution have also made these a focus of several
46 international agreements (Mitchell et al., 2020). Evaluating the effectiveness of such treaties and policies
47 is difficult because deriving causal inferences and accurate attribution requires accounting for several

1 confounding factors, and direct and indirect spillovers (Isaksen, 2020). Nevertheless, several studies
2 assess the effectiveness of such treaties and regulations (De Foy et al., 2016; Li et al., 2017a, 2017b;
3 Morgenstern, 2018; Mardones and Cornejo, 2020). However, there is little ex-post empirical analysis
4 and a greater focus on ex-ante studies in the literature.

5 At a local scale, air pollutants are often co-emitted with GHGs in combustion processes. Many air quality
6 policies and regulations focus on local pollution from specific sources that can potentially either
7 substitute or complement global GHG emissions in production and generation processes. Also, policies
8 that reduce certain air pollutants, such as SO₂, have a positive radiative forcing effect (Navarro et al.,
9 2016). The evidence on individual air pollution control regulation and policies for GHG emissions is
10 therefore mixed (*medium evidence, medium agreement*). Evidence from the USA suggests that increased
11 stringency of local pollution regulation had no statistically detectable co-benefits or costs on GHG
12 emissions (Brunel and Johnson, 2019). Evidence from China suggests that the effectiveness of policies
13 addressing local point sources differed from those of non-point sources and the co-benefits for climate
14 are mixed, though policies addressing large industrial point sources have been easier to implement and
15 have had significant impact (Huang and Wang, 2016; Xu et al., 2016; van der A et al., 2017; Dang and
16 Liao, 2019; Fang et al., 2019; Yu et al., 2019). Legislation to reduce emissions of air pollutants in Europe
17 have significantly improved air quality and health but have had an unintended warming effect on the
18 climate (Turnock et al., 2016).

19 Often, the realisation of potential co-benefits depends on the type of pollutant addressed by the specific
20 policy, and whether complementarities between local pollution and global GHG emissions are
21 considered in policy design (Rafaj et al., 2014; Li et al., 2017a) (*medium evidence, high agreement*).
22 Effective environmental regulations that also deliver co-benefits for climate mitigation require
23 integrated policies (Schmale et al., 2014; Haines et al., 2017). Uncoordinated policies can have
24 unintended consequences and even increase emissions (Holland et al., 2015). Many studies suggest that
25 policies that target both local and global environmental benefits simultaneously may be more effective
26 (Klemun et al., 2020) (*medium evidence, medium agreement*). Furthermore, air pollution policies aimed
27 at inducing structural changes, for example closure of polluting coal power plants or reducing motorised
28 miles travelled, are more likely to have potential positive spillover effects for climate mitigation, as
29 compared to policies incentivising end-of-pipe controls (Wang, 2021).

30 Other policies that typically have potential co-benefits for climate mitigation include those specific to
31 certain sectors and are discussed in Chapters 5–11. Examples of such policies include those that
32 encourage active travel modes, which have been found to have ancillary benefits for local air quality,
33 human health, and GHG emissions (Fujii et al., 2018). Policies to reduce energy use through greater
34 efficiency have also been found to have benefits for air quality and the climate (Tzeiranaki et al., 2019;
35 Bertoldi and Mosconi, 2020) (*robust evidence, medium agreement*). Important air quality and climate
36 co-benefits of renewable or nuclear energy policies have also been found (Lee et al., 2017; Apergis et
37 al., 2018; Sovacool and Monyei, 2021) (*medium evidence, medium agreement*).

38 Policies specific to other sectors such as encouraging green building design can also reduce GHG
39 emissions (Eisenstein et al., 2017). Evidence from several countries also show that replacing polluting
40 solid biomass cooking with cleaner gas-burning or electric alternatives have strong co-benefits for
41 health, air quality, and climate change (Anenberg et al., 2017; Singh et al., 2017; Tao et al., 2018) (*robust
42 evidence, high agreement*).

43 **2.8.4.2 Climate impacts of agricultural, forestry, land use, and AFOLU-related policies**

44 Policies on agriculture, forestry, and other land use (AFOLU), and AFOLU sector-related policies have
45 had a long history in many developing and developed countries. Co-impacts of these policies on the
46 climate have been only marginally studied, although their impacts might be quite important because the

1 AFOLU sector is responsible for 24% of total GHG emissions (*robust evidence, high agreement*). The
2 results of afforestation policies around the world and the contribution to CCS are also important.

3 Both private and governmental policies can have a major impact on the climate. Experience indicates
4 that “climate proofing” a policy is likely to require some stimulus, resources, and expertise from
5 agencies or organisations from outside the country. Stimulus and support for adaptation and mitigation
6 can come from the UN system and from international development institutions (FAO, 2009). These
7 findings are also valid for small/organic farmers vis-à-vis large-scale agro-industry. For example,
8 small/medium and environmentally concerned farmers in Europe are often asking for more policies and
9 regulations, and see it as necessary both from a climate perspective and to maintain competitiveness
10 relative large agro-industrial complexes. Therefore, the need for governmental support for small
11 producers in regulations encompasses all AFOLU sectors.

12 ***Forestry case: zero deforestation***

13 Forest is generally defined as land spanning more than 0.5 hectares with trees higher than 5 meters and
14 a canopy cover of more than 10%, or trees able to reach these thresholds in situ (FAO, 1998). Zero-
15 deforestation (i.e., both gross and net zero deforestation) initiatives generate results at multiple levels
16 (Meijer, 2014). Efforts to achieve zero-deforestation (and consequently emissions) are announced by
17 NGOs, companies, governments, and other stakeholder groups. NGOs engage through their
18 campaigning, but also propose tools and approaches for companies (Leijten et al., 2020). The extent to
19 which companies can actually monitor actions conducive to zero-deforestation pledges depends on their
20 position in the supply chain. Beyond the business practices of participating companies, achieving long-
21 term positive societal impacts requires upscaling from supply chains towards landscapes, with
22 engagement of all stakeholders, and in particular small producers. The various success indicators for
23 zero deforestation mirror the multiple levels at which such initiatives develop: progress towards
24 certification, improved traceability, and legality are apparent output measures, whereas direct-area
25 monitoring and site selection approaches target the business practices themselves.

26 Such efforts have led to the development of the High Carbon Stock (HCS) approach that combines
27 carbon stock values with the protection of HCS areas (including peatlands and riparian zones) and areas
28 important for the livelihoods of local communities (Rosoman et al., 2017). Long-term positive impacts,
29 however, will need to be assessed with hindsight and focus on national and global statistics. Successful
30 initiatives targeting zero deforestation at jurisdictional level would also need to improve the enforcement
31 of forest laws and regulations (EIL, 2015; Meyer and Miller, 2015).

32 Large-scale agribusiness, banks, and consumer goods companies dominate supply chain-focused zero-
33 deforestation initiatives, but only the producers, including local communities and smallholders, can
34 change the production circumstances (TFD, 2014). Producers shoulder much of the burden for meeting
35 environmental requirements of pledges. And local communities and small producers are vulnerable to
36 being cut out when supply chains reorient. The zero-deforestation pledges do not always devise
37 programmes for introducing new sourcing strategies, and governments may have an important
38 contribution to make here, particularly in safeguarding the interests of small producers.

39 Other than in Brazil and Indonesia, beyond individual supply chains, there is still little evidence on
40 positive results of zero-deforestation commitments as information available for companies to judge their
41 progress is scarce. Moreover, many zero-deforestation pledges set targets to be achieved by 2020 or
42 2030, and, consequently, many companies have not yet reported publicly on their progress. Similarly,
43 only a few governments have yet shown progress in reducing deforestation, but the New York
44 Declaration on Forests, the SDGs and the Paris Agreement were adopted relatively recently. The
45 effectiveness of private-sector zero-deforestation pledges depends on the extent to which they can be
46 supported by governmental action and foster a cooperative environment with the engagement of all
47 stakeholders. Where the pledges are coordinated with regulation, multi-stakeholder dialogues, and
48 technical and financial support, a true paradigm shift becomes possible. Many governments are still

1 building the capacity to improve overall forest governance, but implementing ambitious international
2 targets is likely to depend on technical and major financial support that has not yet been mobilised.

4 **2.9 Knowledge Gaps**

- 5 • Global GHG emissions estimates are published less frequently and with greater reporting lags
6 than, for example, CO₂ from fossil fuel and industry. Data quality and reporting frequency
7 remains an issue particularly in developing countries where the statistical infrastructure is not
8 well developed. Efforts to compile a global GHG emissions inventory by country, sector, and
9 across time that is annually updated based on the best-available inventory information, similar
10 to on-going activities for CO₂, CH₄ or N₂O, could fill this gap. Uncertainties and their
11 methodological treatment in GHG emissions estimates are still not comprehensively
12 understood.
- 13 • There is a more fundamental data gap for F-gas emissions, where data quality in global
14 inventories is poor due to considerable gaps in the underlying activity data – particularly in
15 developing countries. Comprehensive tracking of F-gas emissions would also imply the
16 inclusion of other gases not covered under the Paris Agreement such as chlorofluorocarbons,
17 hydrochlorofluorocarbons and others.
- 18 • Currently, despite advances in terms of data availability, sectoral and spatial resolution, the
19 results in consumption-based emission estimates are dependent on the database used, the level
20 of sectoral aggregation and country resolution. More fine-grained data at spatial resolution as
21 well as the product level would support to explore the mitigation options at the sub-national
22 level, companies and households.
- 23 • Consumption-based emission accounts too suffer from lack of quantification of uncertainties at
24 the subnational level and especially in data-scarce environments such as for developing
25 countries. A better understanding of drivers that caused decoupling of emissions at the national
26 and especially sub-national level are important to explore.
- 27 • Understanding how social-economic drivers modulate emission mitigation is crucial.
28 Technological improvements (e.g. improved energy or land use intensity of the economy) have
29 shown persistent pattern over the last few decades but gains have been outpaced by increases in
30 affluence (GDP per capita) and population growth, leading to continued emissions growth. The
31 key gap in knowledge therefore is how these drivers of emissions can be mitigated by demand
32 management, alternative economic models, population control and rapid technological
33 transition to different extent and in different settings. More research on decoupling and
34 sustainability transformations would help to answer these questions. Key knowledge gaps also
35 remain in role of trade, in particular, how supporting low-carbon technologies in developing
36 and exporting countries can counteract the upward-driving effect of trade, and how to achieve
37 decoupling without outsourcing emissions to others and often to less developed regions.
- 38 • Understanding of how inequality affects emissions is in a nascent stage. Less is known about
39 the causal mechanisms by which different dimensions of inequality like income, socio-
40 economic, spatial, socio-cultural-gender and ethnicity affect emissions. In particular, limited
41 knowledge exists on the linkages between dimensions of inequality other than income or wealth
42 and emissions arising from different service demands. Research gaps are apparent on how
43 inequalities in living standards relate to emissions and how changes in inequalities between
44 genders, social groups, and other marginalised communities impact emissions trends.
- 45 • Digitalisation of the economy are often quoted as providing new mitigation opportunities, but
46 knowledge and evidences are yet limited- such as understanding of the role of smart apps and
47 the potentials and influence of disruptive technologies at the demand and supply side on GHG
48 emissions.
- 49 • Despite growing evidence of technological progress across a variety of mitigation areas and the
50 availability of increasingly precise data sets, knowledge gaps remain on technological change

1 and innovation and evidence on speed of transitions to clarify what would make them fast or
2 slow. Innovation is an inherently uncertain process and there will always be imperfect ex ante
3 knowledge on technological outcomes and their effects on mitigation. The extent to which a
4 low-carbon transition can proceed faster than historical examples is crucial to aid future
5 mitigation. That depends on a better understanding of the speed of building, updating and
6 replacing infrastructure. Additionally, how and whether financing for low-carbon technology
7 investment in low and middle income countries can be delivered at low-cost and sustained over
8 time are important questions. The emerging findings that small-scale technologies learn faster
9 and are adopted more quickly needs to be tested against a broader set of cases and in particular
10 against the large dispersion in data.

- 11 • Future CO₂ emissions from existing and planned infrastructure is not well understood and
12 quantified outside the power sector. Further integration of bottom-up accounting and scenario
13 approaches from integrated assessment seems promising. Comprehensive assessments of hard-
14 to-abate residual fossil fuel emissions and their relationship to CO₂ removal activities are
15 lacking, but will be important for informing net zero emissions strategies.
- 16 • Empirical evidence of emission impacts from climate policies, including carbon pricing, is not
17 sufficient for unambiguous attribution assessment, mainly due to the limited experience with
18 climate-related policy experiments to date. More attention to the methodology for
19 comprehensive evaluation of climate policies and measures, such as effective carbon rates is
20 apparent. Key knowledge gaps also exist on ex-post evaluations of climate and non-climate
21 policies and measures for their impact on emissions, particularly at the global scale, considering
22 national circumstances and priorities.

25 **Frequently Asked Questions (FAQs)**

26 **FAQ 2.1 Are emissions still increasing or are they falling?**

27 Global greenhouse gas (GHG) emissions continued to rise and reached 59±6.6 GtCO₂-eq in 2019,
28 although the rate of growth has fallen compared to the previous decade. Still, emissions were higher
29 than at any point in human history before. Emissions were around 12% and 54% higher than in 2010
30 and 1990, respectively. Average annual GHG emissions for 2009–2019 were higher compared to the
31 periods 2000–2009 and 1990–1999, respectively. GHG emission growth slowed since 2010: while
32 average annual GHG emission growth was 2.1% between 2000 and 2010, it was only 1.3% for 2010–
33 2019. In order to stop the temperature increase, however, net emissions must be zero.

34 **FAQ 2.2 Are there countries that have reduced emissions and grown economically at the same 35 time?**

36 About 24 countries that have reduced territorial CO₂ and GHG emissions for more than 10 years.
37 Uncertainties in emission levels and changes over time prevents a precise assessment in some country
38 cases. In the short observation period of 2010–2015, 43 out of 166 countries have achieved absolute
39 decoupling of consumption-based CO₂ emissions from economic growth, which means that these
40 countries experienced GDP growth while their emissions have stabilised or declined. A group of
41 developed countries, such as some EU countries and the United States, and some developing countries,
42 such as Cuba, have successfully achieved an absolute decoupling of consumption-based CO₂ emissions
43 and GDP growth. Decoupling has been achieved at various levels of per capita income and per capita
44 emissions. Overall, the absolute reduction in annual emissions achieved by some countries has been
45 outweighed by growth in emissions elsewhere in the world.

46 **FAQ 2.3 How much time do we have to act to keep global warming below 1.5 degrees?**

47 If global CO₂ emissions continue at current rates, the remaining carbon budget for keeping warming to
48 1.5°C will likely be exhausted before 2030. Between 1850 and 2019, total cumulative CO₂ emissions

1 from the fossil fuel industry (FFI) and agriculture, forestry, and other land use (AFOLU) were 2400
2 (± 240 GtCO₂). Of these, about 410 \pm 30 GtCO₂ were added since 2010. This is about the same size as the
3 remaining carbon budget for keeping global warming to 1.5°C and between one third and half the
4 1150 \pm 220 (1350, 1700) GtCO₂ for limiting global warming below 2°C with a 67% (50%, 33%)
5 probability, respectively (Canadell et al., 2021). At current (2019) rates of emissions, it would only take
6 8 (2-15) and 25 (18-35) years to emit the equivalent amount of CO₂ for a 67th percentile 1.5°C and 2°C
7 remaining carbon budget, respectively. This highlights the dependence of 1.5°C pathways on the
8 availability of substantial CO₂ removal capacities, as discussed in chapters 3, 4, and 12, but also Section
9 2.7 of this chapter.

1 **Executive summary**

2 **Chapter 3 assesses the emissions pathways literature in order to identify their key**
3 **characteristics (both in commonalities and differences) and to understand how societal choices**
4 **may steer the system into a particular direction (*high confidence*).** More than 2000 quantitative
5 emissions pathways were submitted to the IPCC's Sixth Assessment Report (AR6) database, out of
6 which 1202 scenarios included sufficient information for assessing the associated warming consistent
7 with WGI. Five Illustrative Mitigation Pathways (IMPs) were selected, each emphasizing a different
8 scenario element as its defining feature: heavy reliance on renewables (IMP-Ren), strong emphasis on
9 energy demand reductions (IMP-LD), extensive use of CDR in the energy and the industry sectors to
10 achieve net negative emissions (IMP-Neg), mitigation in the context of broader sustainable
11 development (IMP-SP), and the implications of a less rapid and gradual strengthening of near-term
12 mitigation actions (IMP-GS). {3.2, 3.3}

13
14 **Pathways consistent with the implementation and extrapolation of countries' current policies**
15 **see GHG emissions reaching 52-60 GtCO₂-eq yr⁻¹ by 2030 and to 46-67 GtCO₂-eq yr⁻¹ by 2050,**
16 **leading to a median global warming of 2.4°C to 3.5°C by 2100 (*medium confidence*).** These
17 pathways consider policies at the time that they were developed. The Shared Socioeconomic
18 Pathways (SSPs) permit a more systematic assessment of future GHG emissions and their
19 uncertainties than was possible in AR5. The main emissions drivers include growth in population,
20 reaching 8.5-9.7 billion by 2050, and an increase in global GDP of 2.7-4.1% per year between 2015
21 and 2050. Final energy demand in the absence of any new climate policies is projected to grow to
22 around 480 to 750 EJ yr⁻¹ in 2050 (compared to around 390 EJ in 2015). (*medium confidence*) The
23 highest emissions scenarios in the literature result in global warming of >5°C by 2100, based on
24 assumptions of rapid economic growth and pervasive climate policy failures. (*high confidence*). {3.3}

25
26 **Many pathways in the literature show how to likely limit global warming compared to**
27 **preindustrial times to 2°C with no overshoot or to 1.5°C with limited overshoot. The likelihood**
28 **of limiting warming to 1.5°C with no or limited overshoot has dropped in AR6 compared to**
29 **SR1.5 because global GHG emissions have risen since the time SR1.5 was published, leading to**
30 **higher near-term emissions (2030) and higher cumulative CO₂ emissions until the time of net**
31 **zero (*medium confidence*).** Only a small number of published pathways limit global warming to
32 1.5°C without overshoot over the course of the 21st century. {3.3, Annex III.II.3}

33
34 **Cost-effective mitigation pathways assuming immediate actions to likely limit warming to 2°C**
35 **are associated with net global GHG emissions of 30-49 GtCO₂-eq yr⁻¹ by 2030 and 13-27 GtCO₂-**
36 **eq yr⁻¹ by 2050 (*medium confidence*).** This corresponds to reductions, relative to 2019 levels, of 12-
37 46% by 2030 and 52-77% by 2050. Pathways that limit global warming to below 1.5°C with no or
38 limited overshoot require a further acceleration in the pace of the transformation, with net GHG
39 emissions typically around 21-36 GtCO₂-eq yr⁻¹ by 2030 and 1-15 GtCO₂-eq yr⁻¹ by 2050; thus
40 reductions of 38–63% by 2030 and 75-98% by 2050 relative to 2019 levels. {3.3}

41 **Pathways following current NDCs¹ until 2030 reach annual emissions of 47-57 GtCO₂-eq by**
42 **2030, thereby making it impossible to limit warming to 1.5°C with no or limited overshoot and**
43 **strongly increasing the challenge to likely limit warming to 2°C (*high confidence*).** A high

FOOTNOTE ¹ Current NDCs refers to the most recent nationally determined contributions submitted to the UNFCCC as well as those publicly announced with sufficient detail on targets, but not yet submitted, up to 11 October 2021, and reflected in studies published up to 11 October 2021.

1 overshoot of 1.5°C increases the risks from climate impacts and increases the dependence on large
2 scale carbon dioxide removal from the atmosphere. A future consistent with current NDCs implies
3 higher fossil fuel deployment and lower reliance on low carbon alternatives until 2030, compared to
4 mitigation pathways with immediate action to likely limit warming to 2°C and below. To likely limit
5 warming to 2°C after following the NDCs to 2030, the pace of global GHG emission reductions
6 would need to accelerate quite rapidly from 2030 onward: to an average of 1.3-2.1 GtCO₂-eq per year
7 between 2030 and 2050, which is similar to global CO₂ emission reductions in 2020 due to the
8 COVID-19 pandemic, and around 70% faster than in immediate action pathways likely limiting
9 warming to 2°C. Accelerating emission reductions after following an NDC pathway to 2030 would be
10 particularly challenging because of the continued build-up of fossil fuel infrastructure that would be
11 expected to take place between now and 2030. {3.5, 4.2}

12 **Pathways accelerating actions compared to current NDCs that reduce annual GHG emissions to**
13 **47 (38-51) GtCO₂-eq by 2030, or 3-9 GtCO₂-eq below projected emissions from fully**
14 **implementing current NDCs reduce the mitigation challenge for likely limiting warming to 2°C**
15 **after 2030. (*medium confidence*).** The accelerated action pathways are characterized by a global, but
16 regionally differentiated, roll-out of regulatory and pricing policies. Compared to NDCs, they see less
17 fossil fuels and more low-carbon fuels until 2030, and narrow, but do not close the gap to pathways
18 assuming immediate global action using all available least-cost abatement options. All delayed or
19 accelerated action pathways likely limiting warming to below 2°C converge to a global mitigation
20 regime at some point after 2030 by putting a significant value on reducing carbon and other GHG
21 emissions in all sectors and regions. {3.5}

22 **Mitigation pathways limiting warming to 1.5°C with no or limited overshoot reach 50%**
23 **reductions of CO₂ in the 2030s, relative to 2019, then reduce emissions further to reach net zero**
24 **CO₂ emissions in the 2050s. Pathways likely limiting warming to 2°C reach 50% reductions in**
25 **the 2040s and net zero CO₂ by 2070s (*medium confidence*).** {3.3, Cross-Chapter Box 3 in Chapter
26 3}

27
28 **Peak warming in mitigation pathways is determined by the cumulative net CO₂ emissions until**
29 **the time of net zero CO₂ and the warming contribution of other GHGs and climate forcers at**
30 **that time (*high confidence*).** Cumulative net CO₂ emissions from 2020 to the time of net zero CO₂
31 are 510 (330-710) GtCO₂ in pathways that limit warming to 1.5°C with no or limited overshoot and
32 890 (640-1160) GtCO₂ in pathways likely limiting warming to 2.0°C. These estimates are consistent
33 with the assessment of remaining carbon budgets by WGI after adjusting for differences in peak
34 warming levels. {3.3, Box 3.4}

35 **Rapid reductions in non-CO₂ GHGs, particularly methane, would lower the level of peak**
36 **warming (*high confidence*).** Residual non-CO₂ emissions at the time of reaching net zero CO₂ range
37 between 4-11 GtCO₂-eq yr⁻¹ in pathways likely limiting warming to 2.0°C or below. Methane (CH₄)
38 is reduced by around 20% (1-46%) in 2030 and almost 50% (26-64%) in 2050, relative to 2019.
39 Methane emission reductions in pathways limiting warming to 1.5°C with no or limited overshoot are
40 substantially higher by 2030, 33% (19-57%), but only moderately so by 2050, 50% (33-69%).
41 Methane emissions reductions are thus attainable at relatively lower GHG prices but are at the same
42 time limited in scope in most 1.5-2°C pathways. Deeper methane emissions reductions by 2050 could
43 further constrain the peak warming. N₂O emissions are reduced too, but similar to CH₄, emission
44 reductions saturate for more stringent climate goals. In the mitigation pathways, the emissions of
45 cooling aerosols are reduced due to reduced use of fossil fuels. The overall impact on non-CO₂-related
46 warming combines these factors. {3.3}

1 **Net zero GHG emissions imply net negative CO₂ emissions at a level compensating residual non-**
2 **CO₂ emissions. Only 30% of the pathways likely limiting warming to 2°C or below reach net**
3 **zero GHG emissions in the 21st century. (*high confidence*).** In those pathways reaching net zero
4 GHGs, it is achieved around 10-20 years later than for net zero CO₂. (*medium confidence*). The
5 reported quantity of residual non-CO₂ emissions depends on accounting: the choice of GHG metric.
6 Reaching and sustaining global net zero GHG emissions, measured in terms of GWP-100, results in a
7 gradual decline of temperature. (*high confidence*) {3.3, Cross-Chapter Box 3 in Chapter 3, Cross-
8 Chapter Box 2 in Chapter 2}

9
10 **Pathways likely limiting warming to 2°C and below exhibit substantial reductions in emissions**
11 **from all sectors (*high confidence*).** Projected CO₂ emissions reductions between 2019 and 2050 in
12 1.5°C pathways with no or limited overshoot are around 77% (31-96%) for energy demand, 115% for
13 energy supply (90 to 167%), and 148% for AFOLU (94 to 387%). In pathways likely limiting
14 warming to 2°C, projected CO₂ emissions are reduced between 2019 and 2050 by around 49% for
15 energy demand, 97% for energy supply, and 136% for AFOLU. (*medium confidence*) {3.4}

16
17 **Delaying or sacrificing emissions reductions in one sector or region involves compensating**
18 **reductions in other sectors or regions if warming is to be limited (*high confidence*).** Mitigation
19 pathways show differences in the timing of decarbonization and when net zero CO₂ emissions are
20 achieved across sectors and regions. At the time of global net zero CO₂ emissions, emissions in some
21 sectors and regions are positive while others are negative; the ordering depends on the mitigation
22 options available, the cost of those options, and the policies implemented. In cost-effective mitigation
23 pathways, the energy supply sector typically reaches net zero CO₂ before the economy as a whole,
24 while the demand sectors reach net zero CO₂ later, if ever (*high confidence*). {3.4}

25
26 **Pathways likely limiting warming to 2°C and below involve substantial reductions in fossil fuel**
27 **consumption and a near elimination of the use of coal without CCS (*high confidence*).** These
28 pathways show an increase in low carbon energy, with 88% (69-97%) of primary energy coming from
29 these sources by 2100. {3.4}

30
31 **Stringent emissions reductions at the level required for 2°C and below are achieved through**
32 **increased direct electrification of buildings, transport, and industry, resulting in increased**
33 **electricity generation in all pathways (*high confidence*).** Nearly all electricity in pathways likely
34 limiting warming to 2°C or below is from low or no carbon technologies, with different shares of
35 nuclear, biomass, non-biomass renewables, and fossil CCS across pathways. {3.4}

36
37 **The measures required to likely limit warming to 2°C or below can result in large scale**
38 **transformation of the land surface (*high confidence*).** Pathways likely limiting warming to 2°C or
39 below are projected to reach net zero CO₂ emissions in the AFOLU sector between 2020s and 2070,
40 with an increase of forest cover of about 322 million ha (-67 to 890 million ha) in 2050 in pathways
41 limiting warming to 1.5°C with no or limited overshoot. Cropland area to supply biomass for
42 bioenergy (including BECCS) is around 199 (56-482) million ha in 2100 in pathways limiting
43 warming to 1.5°C with no or limited overshoot. The use of bioenergy can lead to either increased or
44 reduced emissions, depending on the scale of deployment, conversion technology, fuel displaced, and
45 how/where the biomass is produced (*high confidence*). {3.4}

46
47 **Anthropogenic land CO₂ emissions and removals in IAM pathways cannot be directly compared**
48 **with those reported in national GHG inventories (*high confidence*).** Methodologies enabling a
49 more like-for-like comparison between models' and countries' approaches would support more
50 accurate assessment of the collective progress achieved under the Paris Agreement. {3.4, 7.2.2.5}

1
2 **Pathways that likely limiting warming to 2°C or below involve some amount of CDR to**
3 **compensate for residual GHG emissions remaining after substantial direct emissions reductions**
4 **in all sectors and regions (*high confidence*).** CDR deployment in pathways serves multiple
5 purposes: accelerating the pace of emissions reductions, offsetting residual emissions, and creating the
6 option for net negative CO₂ emissions in case temperature reductions need to be achieved in the long
7 term (*high confidence*). CDR options in the pathways are mostly limited to BECCS, afforestation and
8 DACCS. CDR through some measures in AFOLU can be maintained for decades but not in the very
9 long term because these sinks will ultimately saturate (*high confidence*). {3.4}

10
11 **Mitigation pathways show reductions in energy demand relative to reference scenarios, through**
12 **a diverse set of demand-side interventions (*high confidence*).** Bottom-up and non-IAM studies
13 show significant potential for demand-side mitigation. A stronger emphasis on demand-side
14 mitigation implies less dependence on CDR and, consequently, reduced pressure on land and
15 biodiversity. {3.4, 3.7}

16
17 **Limiting warming requires shifting energy investments away from fossil-fuels and towards low-**
18 **carbon technologies (*high confidence*).** The bulk of investments are needed in medium- and low-
19 income regions. Investment needs in the electricity sector are on average 2.3 trillion USD₂₀₁₅ yr⁻¹
20 over 2023-2052 for pathways limiting temperature to 1.5°C with no or limited overshoot, and 1.7
21 trillion USD₂₀₁₅ yr⁻¹ for pathways likely limiting warming to 2°C. {3.6.1}

22
23 **Pathways likely avoiding overshoot of 2°C warming require more rapid near-term**
24 **transformations and are associated with higher up-front transition costs, but meanwhile bring**
25 **long-term gains for the economy as well as earlier benefits in avoided climate change impacts**
26 **(*high confidence*).** This conclusion is independent of the discount rate applied, though the modelled
27 cost-optimal balance of mitigation action over time does depend on the discount rate. Lower discount
28 rates favour earlier mitigation, reducing reliance on CDR and temperature overshoot. {3.6.1, 3.8}

29
30 **Mitigation pathways likely limiting warming to 2°C entail losses in global GDP with respect to**
31 **reference scenarios of between 1.3% and 2.7% in 2050; and in pathways limiting warming to**
32 **1.5°C with no or limited overshoot, losses are between 2.6% and 4.2%. Yet, these estimates do**
33 **not account for the economic benefits of avoided climate change impacts (*medium confidence*).**
34 In mitigation pathways likely limiting warming to 2°C, marginal abatement costs of carbon are about
35 90 (60-120) USD₂₀₁₅/tCO₂ in 2030 and about 210 (140-340) USD₂₀₁₅/tCO₂ in 2050; in pathways
36 that limit warming to 1.5°C with no or limited overshoot, they are about 220 (170-290)
37 USD₂₀₁₅/tCO₂ in 2030 and about 630 (430-990) USD₂₀₁₅/tCO₂ in 2050². {3.6.1}

38
39 **The global benefits of pathways likely limiting warming to 2°C outweigh global mitigation costs**
40 **over the 21st century, if aggregated economic impacts of climate change are at the moderate to**
41 **high end of the assessed range, and a weight consistent with economic theory is given to**
42 **economic impacts over the long-term. This holds true even without accounting for benefits in**
43 **other sustainable development dimensions or non-market damages from climate change**
44 **(*medium confidence*).** The aggregate global economic repercussions of mitigation pathways include
45 the macroeconomic impacts of investments in low-carbon solutions and structural changes away from
46 emitting activities, co-benefits and adverse side effects of mitigation, (avoided) climate change
47 impacts, and (reduced) adaptation costs. Existing quantifications of global aggregate economic

FOOTNOTE² Numbers in parenthesis represent the interquartile range of the scenario samples.

1 impacts show a strong dependence on socioeconomic development conditions, as these shape
2 exposure and vulnerability and adaptation opportunities and responses. (Avoided) impacts for poorer
3 households and poorer countries represent a smaller share in aggregate economic quantifications
4 expressed in GDP or monetary terms, whereas their well-being and welfare effects are comparatively
5 larger. When aggregate economic benefits from avoided climate change impacts are accounted for,
6 mitigation is a welfare-enhancing strategy. (*high confidence*) {3.6.2}

7
8 **The economic benefits on human health from air quality improvement arising from mitigation**
9 **action can be of the same order of magnitude as mitigation costs, and potentially even larger**
10 **(*medium confidence*).** {3.6.3}

11
12 **Differences between aggregate employment in mitigation pathways compared to reference**
13 **scenarios are relatively small, although there may be substantial reallocations across sectors,**
14 **with job creation in some sectors and job losses in others.** The net employment effect (and its sign)
15 depends on scenario assumptions, modelling framework, and modelled policy design. Mitigation has
16 implications for employment through multiple channels, each of which impacts geographies, sectors
17 and skill categories differently. (*medium confidence*) {3.6.4}

18
19 **The economic repercussions of mitigation vary widely across regions and households, depending**
20 **on policy design and level of international cooperation (*high confidence*).** Delayed global
21 cooperation increases policy costs across regions, especially in those that are relatively carbon
22 intensive at present (*high confidence*). Pathways with uniform carbon values show higher mitigation
23 costs in more carbon-intensive regions, in fossil-fuels exporting regions and in poorer regions (*high*
24 *confidence*). Aggregate quantifications expressed in GDP or monetary terms undervalue the economic
25 effects on households in poorer countries; the actual effects on welfare and well-being are
26 comparatively larger (*high confidence*). Mitigation at the speed and scale required to likely limit
27 warming to 2°C or below implies deep economic and structural changes, thereby raising multiple
28 types of distributional concerns across regions, income classes and sectors (*high confidence*). {3.6.1,
29 3.6.4}

30
31 **The timing of mitigation actions and their effectiveness will have significant consequences for**
32 **broader sustainable development outcomes in the longer term (*high confidence*).** Ambitious
33 mitigation can be considered a precondition for achieving the Sustainable Development Goals,
34 especially for vulnerable populations and ecosystems with little capacity to adapt to climate impacts.
35 Dimensions with anticipated co-benefits include health, especially regarding air pollution, clean
36 energy access and water availability. Dimensions with potential trade-offs include food, employment,
37 water stress, and biodiversity, which come under pressure from large-scale CDR deployment, energy
38 affordability/access, and mineral resource extraction. (*high confidence*) {3.7}

39
40 **Many of the potential trade-offs of mitigation measures for other sustainable development**
41 **outcomes depend on policy design and can thus be compensated or avoided with additional**
42 **policies and investments or through policies that integrate mitigation with other SDGs (*high***
43 ***confidence*).** Targeted SDG policies and investments, for example in the areas of healthy nutrition,
44 sustainable consumption and production, and international collaboration, can support climate change
45 mitigation policies and resolve or alleviate trade-offs. Trade-offs can be addressed by complementary
46 policies and investments, as well as through the design of cross-sectoral policies integrating
47 mitigation with the Sustainable Development Goals of health, nutrition, sustainable consumption and
48 production, equity and biodiversity. {3.7}

1 **Decent living standards, which encompass many SDG dimensions, are achievable at lower**
2 **energy use than previously thought (*high confidence*).** Mitigation strategies that focus on lower
3 demands for energy and land-based resources exhibit reduced trade-offs and negative consequences
4 for sustainable development relative to pathways involving either high emissions and climate impacts
5 or those with high consumption and emissions that are ultimately compensated by large quantities of
6 BECCS. {3.7}

7
8 **Different mitigation pathways are associated with different feasibility challenges, though**
9 **appropriate enabling conditions can reduce these challenges.** Feasibility challenges are transient
10 and concentrated in the next two to three decades (*high confidence*). They are multi-dimensional,
11 context-dependent and malleable to policy, technological and societal trends. {3.8}

12
13 **Mitigation pathways are associated with significant institutional and economic feasibility**
14 **challenges rather than technological and geophysical.** The rapid pace of technological
15 development and deployment in mitigation pathways is not incompatible with historical records.
16 Institutional capacity is rather a key limiting factor for a successful transition. Emerging economies
17 appear to have highest feasibility challenges in the short to medium term. {3.8}

18
19 **Pathways relying on a broad portfolio of mitigation strategies are more robust and resilient**
20 **(*high confidence*).** Portfolios of technological solutions reduce the feasibility risks associated with the
21 low carbon transition. {3.8}

3.1 Introduction

3.1.1 Assessment of mitigation pathways and their compatibility with long-term goals

Chapter 3 takes a long-term perspective on climate change mitigation pathways. Its focus is on the implications of long-term targets for the required short- and medium-term system changes and associated greenhouse gas (GHG) emissions. This focus dictates a more global view and on issues related to path-dependency and up-scaling of mitigation options necessary to achieve different emissions trajectories, including particularly deep mitigation pathways that require rapid and fundamental changes.

10

Stabilizing global average temperature change requires to reduce CO₂ emissions to net zero. Thus, a central cross-cutting topic within the Chapter is the timing of reaching net zero CO₂ emissions and how a “balance between anthropogenic emissions by sources and removals by sinks” could be achieved across time and space. This includes particularly the increasing body of literature since the IPCC Special Report on Global Warming of 1.5°C (SR1.5) which focuses on net zero CO₂ emissions pathways that avoid temperature overshoot and hence do not rely on net negative CO₂ emissions. The chapter conducts a systematic assessment of the associated economic costs as well as the benefits of mitigation for other societal objectives, such as the Sustainable Development Goals (SDGs). In addition, the Chapter builds on SR1.5 and introduces a new conceptual framing for the assessment of possible social, economic, technical, political, and geophysical “feasibility” concerns of alternative pathways, including the enabling conditions that would need to fall into place so that stringent climate goals become attainable.

23

The structure of the Chapter is as follows: Section 3.2 introduces different types of mitigation pathways as well as the available modelling. Section 3.3 explores different emissions trajectories given socio-economic uncertainties and consistent with different long-term climate outcomes. A central element in this section is the systematic categorization of the scenario space according to key characteristics of the mitigation pathways (including e.g., global average temperature change, socio-economic development, technology assumptions, etc.). In addition, the section introduces selected Illustrative Mitigation Pathways (IMPs) that are used across the whole report. Section 3.4 conducts a sectoral analysis of the mitigation pathways, assessing the pace and direction of systems changes across sectors. Among others, this section aims at the integration of the sectoral information across WGIII AR6 chapters through a comparative assessment of the sectoral dynamics in economy-wide systems models compared to the insights from bottom-up sectoral models (from Chapters 6-11). Section 3.5 focuses on the required timing of mitigation actions, and implication of near-term choices for the attainability of a range of long-term climate goals. After having explored the underlying systems transitions and the required timing of the mitigation actions, Section 3.6 assesses the economic implications, mitigation costs and benefits; and Section 3.7 assesses related co-benefits, synergies, and possible trade-offs for sustainable development and other societal (non-climate) objectives. Section 3.8 assumes a central role in the Chapter and introduces a multi-dimensional feasibility metric that permits the evaluation of mitigation pathways across a range of feasibility concerns. Finally, methods of the assessment and knowledge gaps are discussed in Section 3.9, followed by Frequently Asked Questions.

44

3.1.2 Linkages to other Chapters in the Report

Chapter 3 is linked to many other chapters in the report. The most important connections exist with Chapter 4 on mitigation and development pathways in the near to mid-term, with the sectoral chapters (Chapters 6-11), with the chapters dealing with cross-cutting issues (e.g., feasibility), and finally also with WGI and WGII AR6.

49

1
2 Within the overall framing of the AR6 report, Chapter 3 and Chapter 4 provide important
3 complementary views of the required systems transitions across different temporal and spatial scales.
4 While Chapter 3 focuses on the questions concerning the implications of the long-term objectives for
5 the medium-to-near-term transformations, Chapter 4 comes from the other direction, and focuses on
6 current near-term trends and policies (such as the Nationally Determined Contributions - NDCs) and
7 their consequences with regards to GHG emissions. The latter chapter naturally focuses thus much
8 more on the regional and national dimensions, and the heterogeneity of current and planned policies.
9 Bringing together the information from these two chapters enables the assessment of whether current
10 and planned actions are consistent with the required systems changes for the long-term objectives of
11 the Paris Agreement.

12
13 Important other linkages comprise the collaboration with the “sectoral” Chapters 6-11 to provide an
14 integrated cross-sectoral perspective. This information (including information also from the sectoral
15 chapters) is taken up ultimately also by Chapter 5 on demand/services and Chapter 12 for a further
16 assessment of sectoral potential and costs.

17
18 Linkages to other chapters exist also on the topic of feasibility, which are informed by the policy, the
19 sectoral and the demand chapters, the technology and finance chapters, as well as Chapter 4 on
20 national circumstances.

21
22 Close collaboration with WGI permitted the use of AR6-calibrated emulators, which assure full
23 consistency across the different working groups. Linkages to WGII concern the assessment of macro-
24 economic benefits of avoided impacts that are put into the context of mitigation costs as well as co-
25 benefits and trade-offs for sustainable development.

26 27 **3.1.3 Complementary use of large scenario ensembles and a limited set of Illustrative** 28 **Mitigation Pathways (IMPs)**

29 The assessment of mitigation pathways explores a wide scenario space from the literature within
30 which seven Illustrative Pathways (IPs) are explored. The overall process is indicated in Figure 3.5a.

31
32 For a comprehensive assessment, a large ensemble of scenarios is collected and made available
33 through an interactive [AR6 scenario database](#). The collected information is shared across the chapters
34 of AR6 and includes more than 3000 different pathways from a diverse set of studies. After an initial
35 screening and quality control, scenarios were further vetted to assess if they sufficiently represented
36 historical trends (Annex III). Subsequently, the climate consequences of each scenario were assessed
37 using the climate emulator (leading to further classification). The assessment in Chapter 3 is however
38 not limited to the scenarios from the database, and wherever necessary other literature sources are also
39 assessed in order to bring together multiple lines of evidence.

40
41 In parallel, based on the overall AR6 assessment seven illustrative pathways (IP) were defined
42 representing critical mitigation strategies discussed in the assessment. The seven pathways are
43 composed of two sets: (i) one set of five Illustrative Mitigation Pathways (IMPs) and (ii) one set of
44 two reference pathways illustrative for high emissions. The IMPs are on the one hand representative
45 of the scenario space but help in addition to communicate archetypes of distinctly different systems
46 transformations and related policy choices. Subsequently, seven scenarios were selected from the full
47 database that fitted these storylines of each IP best. For these scenarios are more strict vetting criteria
48 were applied. The selection was done by first applying specific filters based on the storyline followed
49 by a final selection (see Box 3.1 and Figure 3.5 a).

START BOX HERE**Box 3.1 Illustrative Mitigation Pathways**

The literature shows a wide range of possible emissions trajectories, depicting developments in the absence of new climate policies or showing pathways consistent with the Paris Agreement. From the literature, a set of five Illustrative Mitigation Pathways (IMPs) was selected to denote implications of choices on socio-economic development and climate policies, and the associated transformations of the main GHG emitting sectors (see Figure 3.5b). The IMPs include a set of transformative pathways that illustrates how choices may lead to distinctly different transformations that may keep temperature increase to below 2°C or 1.5°C. These pathways illustrate the implications of a focus on renewable energy such as solar and wind; reduced energy demand; extensive use of CDR in the energy and the industry sectors to achieve net negative emissions and reliance on other supply-side measures; strategies that avoid net-negative carbon emissions, and gradual strengthening. In addition, one IMP explores how climate policies consistent with keeping temperature to 1.5°C can be combined with a broader shift towards sustainable development. These IMPs are used in various chapters, exploring for instance their implications for different sectors, regions, and innovation characteristics (see Figure 3.5b).

END BOX HERE**3.2 What are mitigation pathways compatible with long-term goals?****3.2.1 Scenarios and emission pathways**

Scenarios and emission pathways are used to explore possible long-term trajectories, the effectiveness of possible mitigation strategies, and to help understand key uncertainties about the future. A **scenario** is an integrated description of a possible future of the human–environment system (Clarke et al. 2014), and could be a qualitative narrative, quantitative projection, or both. Scenarios typically capture interactions and processes driving changes in key driving forces such as population, GDP, technology, lifestyles, and policy, and the consequences on energy use, land use, and emissions. Scenarios are not predictions or forecasts. An **emission pathway** is a modelled trajectory of anthropogenic emissions (Rogelj et al. 2018a) and, therefore, a part of a scenario.

There is no unique or preferred method to develop scenarios, and future pathways can be developed from diverse methods, depending on user needs and research questions (Turnheim et al. 2015; Trutnevyte et al. 2019a; Hirt et al. 2020). The most comprehensive scenarios in the literature are qualitative narratives that are translated into quantitative pathways using models (Clarke et al. 2014; Rogelj et al. 2018a). Schematic or illustrative pathways can also be used to communicate specific features of more complex scenarios (Allen et al. 2018). Simplified models can be used to explain the mechanisms operating in more complex models (e.g., Emmerling et al. (2019)). Ultimately, a diversity of scenario and modelling approaches can lead to more robust findings (Gambhir et al. 2019; Schinko et al. 2017).

3.2.1.1 Reference scenarios

It is common to define a reference scenario (also called a baseline scenario). Depending on the research question, a reference scenario could be defined in different ways (Grant et al. 2020): 1) a hypothetical world with no climate policies or climate impacts (Kriegler et al. 2014b), 2) assuming current policies or pledged policies are implemented (Roelfsema et al. 2020), or 3) a mitigation scenario to compare sensitivity with other mitigation scenarios (Kriegler et al. 2014a; Sognaes et al. 2021).

1 No-climate-policy reference scenarios have often been to compare with mitigation scenarios (Clarke
2 et al. 2014). A no-climate-policy scenario assumes that no future climate policies are implemented,
3 beyond what is in the model calibration, effectively implying that the carbon price is zero. No-
4 climate-policy reference scenarios have a broad range depending on socioeconomic assumptions and
5 model characteristics, and consequently are important when assessing mitigation costs (Riahi et al.
6 2017; Rogelj et al. 2018b). As countries move forward with climate policies of varying stringency,
7 no-climate-policy baselines are becoming increasingly hypothetical (Hausfather and Peters 2020).
8 Studies clearly show current policies are having an effect, particularly when combined with the
9 declining costs of low carbon technologies (IEA 2020a; UNEP 2020; Roelfsema et al. 2020; Sognaes
10 et al. 2021), and, consequently, realised trajectories begin to differ from earlier no-climate-policy
11 scenarios (Burgess et al. 2020). High-end emission scenarios, such as RCP8.5 and SSP5-8.5, are
12 becoming less likely with climate policy and technology change (see Box 3.3), but high-end
13 concentration and warming levels may still be reached with the inclusion of strong carbon or climate
14 feedbacks (Pedersen et al. 2020; Hausfather and Peters 2020).

15 **3.2.1.2 Mitigation scenarios**

16 Mitigation scenarios explore different strategies to meet climate goals and are typically derived from
17 reference scenarios by adding climate or other policies. Mitigation pathways are often developed to
18 meet a predefined level of climate change, often referred to as a backcast. There are relatively few
19 IAMs that include an endogenous climate model or emulator due to the added computational
20 complexity, though exceptions do exist. In practice, models implement climate constraints by either
21 iterating carbon price assumptions (Strefler et al. 2021b) or by adopting an associated carbon budget
22 (Riahi et al. 2021). In both cases, other GHGs are typically controlled by CO₂-equivalent pricing. A
23 large part of the AR5 literature has focused on forcing pathways towards a target at the end of the
24 century (van Vuuren et al. 2007, 2011; Clarke et al. 2009; Blanford et al. 2014; Riahi et al. 2017),
25 featuring a temporary overshoot of the warming and forcing levels (Geden and Lösschel 2017). In
26 comparison, many recent studies explore mitigation strategies that limit overshoot (Johansson et al.
27 2020; Riahi et al. 2021). An increasing number of IAM studies also explore climate pathways that
28 limit adverse side-effects with respect to other societal objectives, such as food security (van Vuuren
29 et al. 2019; Riahi et al. 2021) or larger sets of sustainability objectives (Soergel et al. 2021a).

30 **3.2.2 The utility of Integrated Assessment Models**

31 Integrated Assessment Models (IAMs) are critical for understanding the implications of long-term
32 climate objectives for the required near-term transition. For doing so, an integrated systems
33 perspective including the representation of all sectors and GHGs is necessary. IAMs are used to
34 explore the response of complex systems in a formal and consistent framework. They cover broad
35 range of modelling frameworks (Keppo et al. 2021). Given the complexity of the systems under
36 investigation, IAMs necessarily make simplifying assumptions and therefore results need to be
37 interpreted in the context of these assumptions. IAMs can range from economic models that consider
38 only carbon dioxide emissions through to detailed process-based representations of the global energy
39 system, covering separate regions and sectors (such as energy, transport, and land use), all GHG
40 emissions and air pollutants, interactions with land and water, and a reduced representation of the
41 climate system. IAMs are generally driven by economics and can have a variety of characteristics
42 such as partial-, general, or non-equilibrium, myopic or perfect foresight, be based on optimization or
43 simulation, have exogenous or endogenous technological change, amongst many other characteristics.
44 IAMs take as input socioeconomic and technical variables and parameters to represent various
45 systems. There is no unique way to integrate this knowledge into a model, and due to their
46 complexity, various simplifications and omissions are made for tractability. IAMs therefore have
47 various advantages and disadvantages which need to be weighed up when interpreting IAM outcomes.
48 Annex III contains an overview of the different types of models and their key characteristics.
49

1 Most IAMs are necessarily broad as they capture long-term dynamics. IAMs are strong in showing
2 the key characteristics of emission pathways and are most suited to questions related to short- versus
3 long-term trade-offs, key interactions with non-climate objectives, long-term energy and land-use
4 characteristics, and implications of different overarching technological and policy choices (Rogelj et
5 al. 2018a; Clarke et al. 2014). While some IAMs have an high level of regional and sectoral detail, for
6 questions that require higher levels of granularity (e.g., local policy implementation) specific region
7 and sector models may be better suited. Utility of the IAM pathways increases when the quantitative
8 results are contextualized through qualitative narratives or other additional types of knowledge to
9 provide deeper insights (Geels et al. 2016a; Weyant 2017; Gambhir et al. 2019).

10 IAMs have a long history in addressing environmental problems, particularly in the IPCC assessment
11 process (van Beek et al. 2020). Many policy discussions have been guided by IAM-based
12 quantifications, such as the required emission reduction rates, net zero years, or technology
13 deployment rates required to meet certain climate outcomes. This has led to the discussion whether
14 IAM scenarios have become performative, meaning that they act upon, transform or bring into being
15 the scenarios they describe (Beck and Mahony 2017, 2018). Transparency of underlying data and
16 methods is critical for scenario users to understand what drives different scenario results (Robertson
17 2020). A number of community activities have thus focused on the provision of transparent and
18 publicly accessible databases of both input and output data (Riahi et al. 2012; Huppmann et al. 2018;
19 Krey et al. 2019; Daioglou et al. 2020) as well as the provision of open-source code, and increased
20 documentation (Annex III). Transparency is needed to reveal conditionality of results on specific
21 choices in terms of assumptions (e.g., discount rates) and model architecture. More detailed
22 explanations of underlying model dynamics would be critical to increase the understanding of what
23 drives results (Bistline et al. 2020; Butnar et al. 2020; Robertson 2020).

24 Mitigation scenarios developed for a long-term climate constraint typically focus on cost-effective
25 mitigation action towards a long-term climate goal. Results from IAM as well as sectoral models
26 depend on model structure (Mercure et al. 2019), economic assumptions (Emmerling et al. 2019),
27 technology assumptions (Pye et al. 2018), climate/emissions target formulation (Johansson et al.
28 2020), and the extent to which pre-existing market distortions are considered (Guivarch et al. 2011).
29 The vast majority of IAM pathways do not consider climate impacts (Schultes et al. 2021). Equity
30 hinges upon ethical and normative choices. As most IAM pathways follow the cost-effectiveness
31 approach, they do not make any additional equity assumptions. Notable exceptions include (Tavoni et
32 al. 2015; Pan et al. 2017; van den Berg et al. 2020; Bauer et al. 2020). Regional IAM results need thus
33 to be assessed with care, considering that emissions reductions are happening where it is most cost-
34 effective, which needs to be separated from the fact who is ultimately paying for the mitigation costs.
35 Cost-effective pathways can provide a useful benchmark, but may not reflect real-world developments
36 (Trutnevyte 2016; Calvin et al. 2014a). Different modelling frameworks may lead to different
37 outcomes (Mercure et al. 2019). Recent studies have shown that other desirable outcomes can evolve
38 with only minor deviations from cost-effective pathways (Neumann and Brown 2021; Bauer et al.
39 2020). IAM and sectoral models represent social, political, and institutional factors only in a
40 rudimentary way. This assessment is thus relying on new methods for the ex-post assessment of
41 feasibility concerns (Jewell and Cherp 2020; Brutschin et al. 2021). A literature is emerging that
42 recognises and reflects on the diversity and strengths/weaknesses of model-based scenario analysis
43 (Keppo et al. 2021).

44 The climate constraint implementation can have a meaningful impact on model results. The literature
45 so far included many temperature overshoot scenarios with heavy reliance on long-term CDR and net
46 negative CO₂ emissions to bring back temperatures after the peak (Johansson et al. 2020; Rogelj et al.
47 2019b). New approaches have been developed to avoid temperature overshoot. The new generation of
48 scenarios show that CDR is important beyond its ability to reduce temperature, but is essential also for

1 offsetting residual emissions to reach a net zero CO₂ emissions (Rogelj et al. 2019b; Johansson et al.
2 2020; Riahi et al. 2021; Strefler et al. 2021b).

3 Many factors influence the deployment of technologies in the IAMs. Since AR5, there has been
4 fervent debate on the large-scale deployment of Bioenergy with Carbon Capture and Storage
5 (BECCS) in scenarios (Geden 2015; Fuss et al. 2014; Smith et al. 2016; Anderson and Peters 2016;
6 van Vuuren et al. 2017; Galik 2020; Köberle 2019). Hence, many recent studies explore mitigation
7 pathways with limited BECCS deployment (Grubler et al. 2018; Soergel et al. 2021a; van Vuuren et
8 al. 2019; Riahi et al. 2021). While some have argued that technology diffusion in IAMs occurs too
9 rapidly (Gambhir et al. 2019), others argued that most models prefer large-scale solutions resulting in
10 a relatively slow phase-out of fossil fuels (Carton 2019). While IAMs are particularly strong on
11 supply-side representation, demand-side measures still lag in detail of representation despite progress
12 since AR5 (Grubler et al. 2018; van den Berg et al. 2019; Lovins et al. 2019; O'Neill et al. 2020b;
13 Hickel et al. 2021; Keyßer and Lenzen 2021). The discount rate has a significant impact on the
14 balance between near-term and long-term mitigation. Lower discount rates <4% (than used in IAMs)
15 may lead to more near-term emissions reductions – depending on the stringency of the target
16 (Emmerling et al. 2019; Riahi et al. 2021). Models often use simplified policy assumptions (O'Neill
17 et al. 2020b) which can affect the deployment of technologies (Sognaes et al. 2021). Uncertainty in
18 technologies can lead to more or less short-term mitigation (Grant et al. 2021; Bednar et al. 2021).
19 There is also a recognition to put more emphasis on what drives the results of different IAMs
20 (Gambhir et al. 2019) and suggestions to focus more on what is driving differences in result across
21 IAMs (Nikas et al. 2021). As noted by Weyant (2017) (p.131), “IAMs can provide very useful
22 information, but this information needs to be carefully interpreted and integrated with other
23 quantitative and qualitative inputs in the decision-making process.”

24 **3.2.3 The scenario literature and scenario databases**

25 IPCC reports have often used voluntary submissions to a scenario database in its assessments. The
26 database is an ensemble of opportunity, as there is not a well-designed statistical sampling of the
27 hypothetical model or scenario space; the literature is unlikely to cover all possible models and
28 scenarios, and not all scenarios in the literature are submitted to the database. Model inter-
29 comparisons are often the core of scenario databases assessed by the IPCC (Cointe et al. 2019; Nikas
30 et al. 2021). Single model studies may allow more detailed sensitivity analyses or address specific
31 research questions. The scenarios that are organised within the scientific community are more likely
32 to enter the assessment process via the scenario database (Cointe et al. 2019), while scenarios from
33 different communities, in the emerging literature, or not structurally consistent with the database may
34 be overlooked. Scenarios in the grey literature may not be assessed even though they may have
35 greater weight in a policy context.

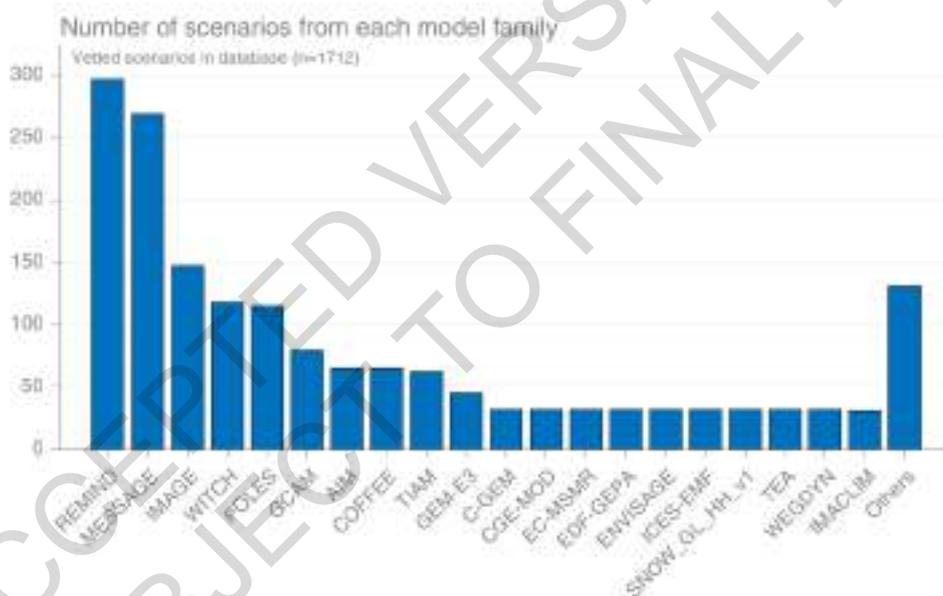

36 One notable development since IPCC AR5 is the Shared Socioeconomic Pathways (SSPs),
37 conceptually outlined in (Moss et al. 2010) and subsequently developed to support integrated climate
38 research across the IPCC Working Groups (O'Neill et al. 2014). Initially, a set of SSP narratives were
39 developed, describing worlds with different challenges to mitigation and adaptation (O'Neill et al.
40 2017a): SSP1 (sustainability), SSP2 (middle of the road), SSP3 (regional rivalry), SSP4 (inequality)
41 and SSP5 (rapid growth). The SSPs have now been quantified in terms of energy, land-use change,
42 and emission pathways (Riahi et al. 2017), for both no-climate-policy reference scenarios and
43 mitigation scenarios that follow similar radiative forcing pathways as the RCPs assessed in AR5 WGI.
44 Since then the SSPs have been successfully applied in 1000s of studies (O'Neill et al. 2020b)
45 including some critiques on the use and application of the SSP framework (Rosen 2021; Pielke and
46 Ritchie 2021). A selection of the quantified SSPs are used prominently in IPCC AR6 WGI as they
47 were the basis for most climate modelling since AR5 (O'Neill et al. 2016). Since 2014, when the first
48 set of SSP data was made available, there has been a divergence between scenario and historic trends

1 (Burgess et al. 2020). As a result, the SSPs require updating (O'Neill et al. 2020b). Most of the
 2 scenarios in the AR6 database are SSP-based and consider various updates compared to the first
 3 release (Riahi et al. 2017).

4 **3.2.4 The AR6 scenario database**

5 To facilitate this assessment, a large ensemble of scenarios has been collected and made available
 6 through an interactive WGIII AR6 scenario database. The collection of the scenario outputs is
 7 coordinated by Chapter 3 and expands upon the IPCC SR1.5 scenario explorer (Huppmann et al.
 8 2018; Rogelj et al. 2018a). A complementary database for national pathways has been established by
 9 Chapter 4. Annex III contains full details on how the scenario database was compiled.

10 The AR6 scenario database contains 3131 scenarios (see Figure 3.5a). After an initial screening and
 11 quality control, scenarios were further vetted to assess if they sufficiently represented historical trends
 12 (Annex III). Of the initial 2266 scenarios with global scope, 1686 scenarios passed the vetting process
 13 and are assessed in this Chapter. The scenarios that did not pass the vetting are still available in the
 14 database. The vetted scenarios were from over 50 different model families, or over 100 when
 15 considering all versions of the same family (Figure 3.1). The scenarios originated from over 15
 16 different model intercomparison projects, with very few scenarios originating from individual studies
 17 (Figure 3.2). Because of the uneven distribution of scenarios from different models and projects,
 18 uncorrected statistics from the database can be misleading.

19

20 **Figure 3.1 Scenario counts from each model family defined as all versions under the same model's name.**

21

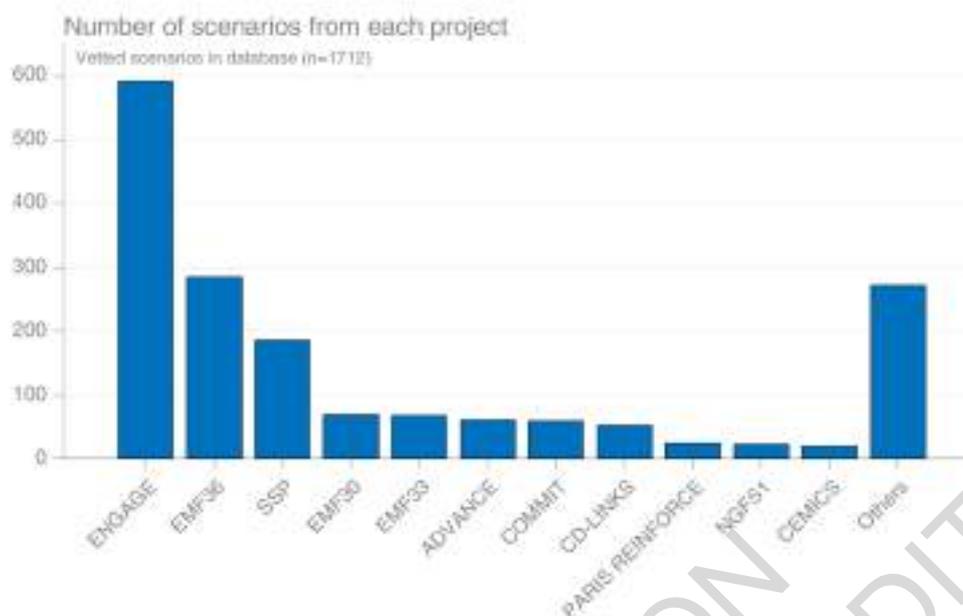

Figure 3.2 Scenario counts from each named project.

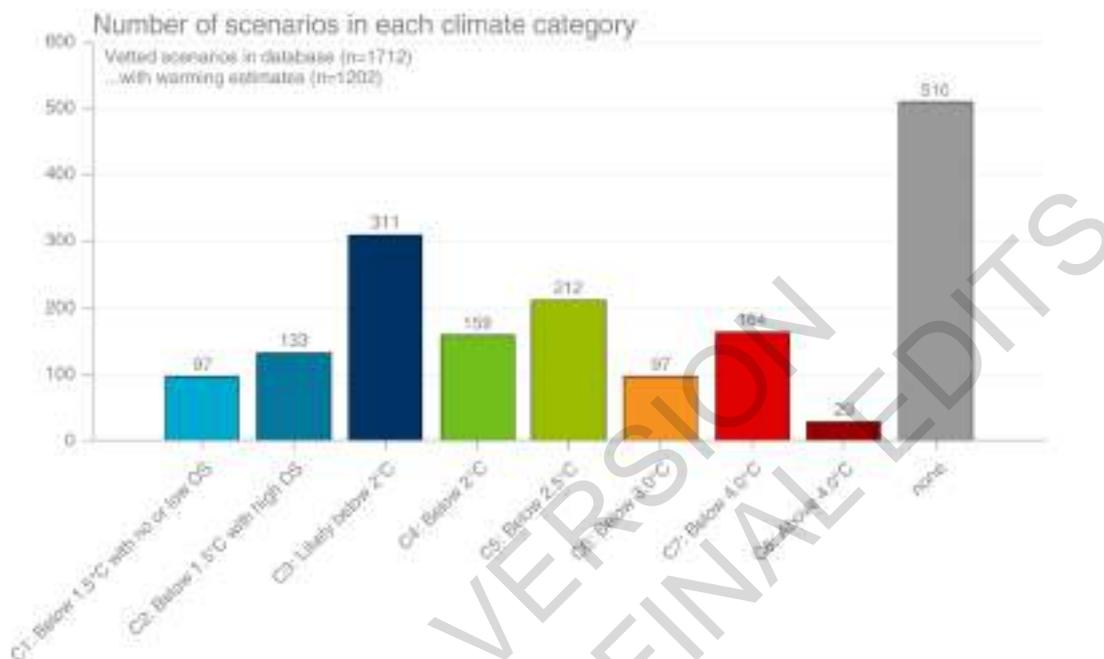

Each scenario with sufficient data is given a temperature classification using climate model emulators. Three emulators were used in the assessment: FAIR (Smith et al. 2018), CICERO-SCM (Skeie et al. 2021), MAGICC (Meinshausen et al. 2020). Only the results of MAGICC are shown in this chapter as it adequately covers the range of outcomes. The emulators are calibrated against the behaviour of complex climate models and observation data, consistent with the outcomes of AR6 WGI AR6 (WGI cross-chapter Box 7.1). The climate assessment is a three-step process of harmonization, infilling and a probabilistic climate model emulator run (Annex III.2.5.1). Warming projections until the year 2100 were derived for 1574 scenarios, of which 1202 passed vetting, with the remaining scenarios having insufficient information (Table 3.1 and Figure 3.3). For scenarios that limit warming to 2°C or below, the SR15 classification was adopted in AR6, with more disaggregation provided for higher warming levels (Table 3.1). These choices can be compared with the selection of common global warming levels (GWL) of 1.5°C, 2°C, 3°C and 4°C to classify climate change impacts in the WGII assessment.

Table 3.1 Classification of emissions scenarios into warming levels using MAGICC

Description	Subset	WGI SSP	WGIII IP	Scenarios
C1: Below 1.5°C with no or limited overshoot	<1.5°C peak warming with ≥33% chance and < 1.5°C end of century warming with >50% chance	SSP1-1.9 -	SP, LD, Ren	97
C2: Below 1.5°C with high overshoot	<1.5°C peak warming with <33% chance and < 1.5°C end of century warming with >50% chance			133
C3: Likely below 2°C	<2°C peak warming with >67% chance	SSP2-2.6	GS, Neg	311
C4: Below 2°C	<2°C peak warming with >50% chance			159
C5: Below 2.5°C	<2.5°C peak warming with >50% chance			212

C6: Below 3°C	<3°C peak warming with >50% chance	SSP2-4.5	Mod-Act	97
C7: Below 4°C	<4°C peak warming with >50% chance	SSP3-7.0	Cur-Pol	164
C8: Above 4°C	>4°C peak warming with \geq 50% chance	SSP5-8.5		29

1

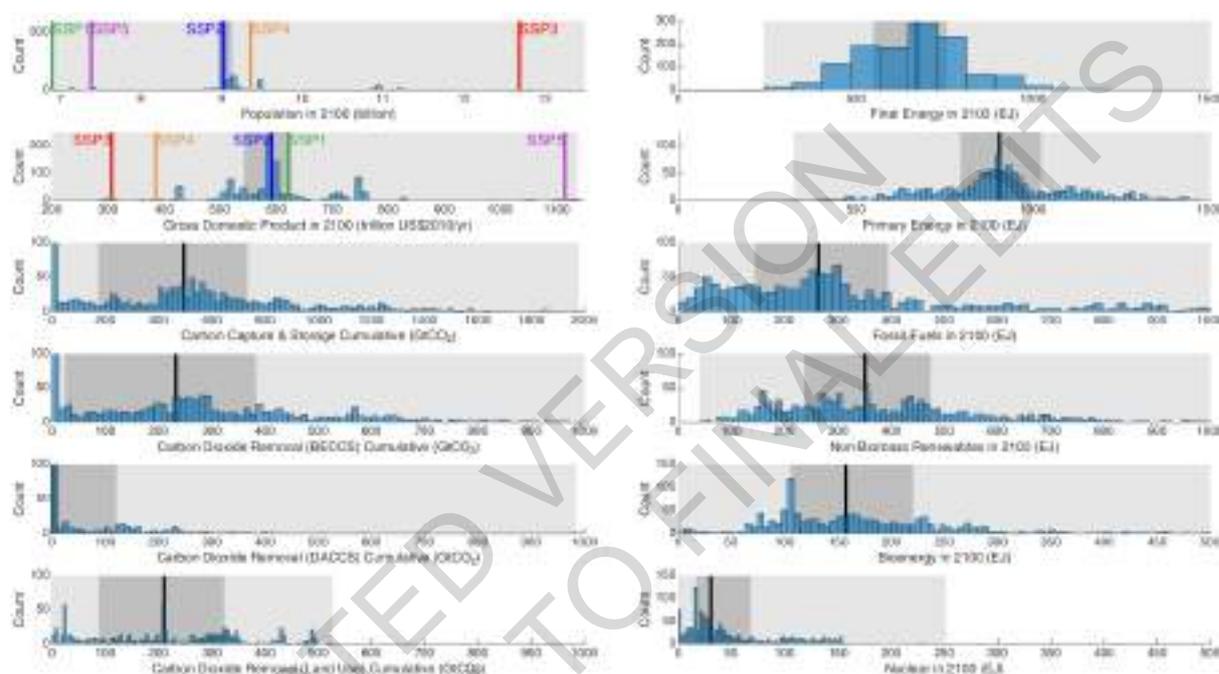

2

3 **Figure 3.3 Of the 1686 scenarios that passed vetting, 1202 had sufficient data available to be classified**
4 **according to temperature, with an uneven distribution across warming levels.**

5 In addition to the temperature classification, each scenario is assigned to one of the following policy
6 categories: (P0) diagnostic scenarios – 100 of 1686 vetted scenarios; (P1) scenarios with no globally
7 coordinated policy and either (P1a) no climate mitigation efforts – 119, (P1b) current national
8 mitigation efforts – 59, (P1c) Nationally Determined Contributions (NDCs) – 110, or (P1d) other non-
9 standard assumptions – 104; (P2) globally coordinated climate policies with immediate (i.e. before
10 2030) action – 73, (P2a) without any transfer of emission permits – 435, (P2b) with transfers – 70; or
11 (P2c) with additional policy assumptions – 55; (P3) globally coordinated climate policies with
12 delayed (i.e. from 2030 onwards or after 2030) action, preceded by (P3a) no mitigation commitment
13 or current national policies – 7, (P3b) NDCs – 376, (P3c) NDCs and additional policies – 18 and
14 (P3d) other non-standard regional assumptions – 0; (P4) Cost-Benefit Analysis (CBA) – 2. The policy
15 categories were identified using text pattern matching on the scenario metadata and calibrated on the
16 best-known scenarios from model intercomparisons, with further validation against the related
17 literature, reported emission and carbon price trajectories, and exchanges with modellers. If the
18 information available is enough to qualify a policy category number but not sufficient for a
19 subcategory, then only the number is retained (e.g., P2 instead of P2a/b/c). A suffix added after P0
20 further qualifies a diagnostic scenario as one of the other policy categories. To demonstrate the
21 diversity of the scenarios, the vetted scenarios were classified into different categories along the
22 dimensions of population, GDP, energy, and cumulative emissions (Figure 3.4). The number of
23 scenarios in each category provides some insight into the current literature, but this does not indicate a
24 higher probability of that category occurring in reality. For population, the majority of scenarios are
25 consistent with the SSP2 ‘middle of the road’ category, with very few scenarios exploring the outer

1 extremes. GDP has a slightly larger variation, but overall, most scenarios are around the SSP2
 2 socioeconomic assumptions. The level of CCS and CDR is expected to change depending on the
 3 extent of mitigation, but there remains extensive use of both CDR and CCS in scenarios. CDR is
 4 dominated by bioenergy with CCS (BECCS) and sequestration on land, with relatively few scenarios
 5 using Direct Air Capture with Carbon Storage (DACCS) and even less with Enhanced Weathering
 6 and other technologies (not shown). In terms of energy consumption, final energy has a much smaller
 7 range than primary energy as conversion losses are not included in final energy. Both mitigation and
 8 reference scenarios are shown, so there is a broad spread in different energy carriers represented in the
 9 database. Bioenergy has a number of scenarios at around 100EJ, representing a constraint used in
 10 many model intercomparisons.

11

12
13

14 **Figure 3.4 Histograms for key categories in the AR6 scenario database. Only scenarios that passed vetting**
 15 **are shown. For population and GDP, the SSP input data are also shown. The grey shading represents the**
 16 **0-100% range (light grey), 25-75% range (dark grey), and the median is a black line. The figures with**
 17 **white areas are outside of the scenario range, but the axis limits are retained to allow comparability with**
 18 **other categories. Each subfigure potentially has different x- and y-axis limits. Each figure also potentially**
 19 **contains different numbers of scenarios, depending on what was submitted to the database.**

21 3.2.5 Illustrative Mitigation Pathways

22 Successive IPCC ARs have used scenarios to illustrate key characteristics of possible climate (policy)
 23 futures. In IPCC AR5 four RCPs made the basis of climate modelling in WGI and WGII, with WGIII
 24 assessing over 1,000 scenarios spanning those RCPs (Clarke et al. 2014). Of the over 400 hundred
 25 scenarios assessed in SR15, four scenarios were selected to highlight the trade-off between short-term
 26 emission reductions and long-term deployment of BECCS (Rogelj et al. 2018a), referred to as
 27 'Illustrative Pathways'. AR6 WGI and WGII rely on the scenarios selected for CMIP6, called
 28 ScenarioMIP (O'Neill et al. 2016), to assess warming levels. IPCC AR6 WGIII uses in addition to the
 29 full set of scenarios also selected Illustrative Mitigation Pathways (IMPs).

30 In WGIII, IMPs were selected to denote the implications of different societal choices for the
 31 development of future emissions and associated transformations of main GHG emitting sectors (see
 32 Box 3.1 and Figure 3.5a). The most important function of the IMPs is to illustrate key themes that

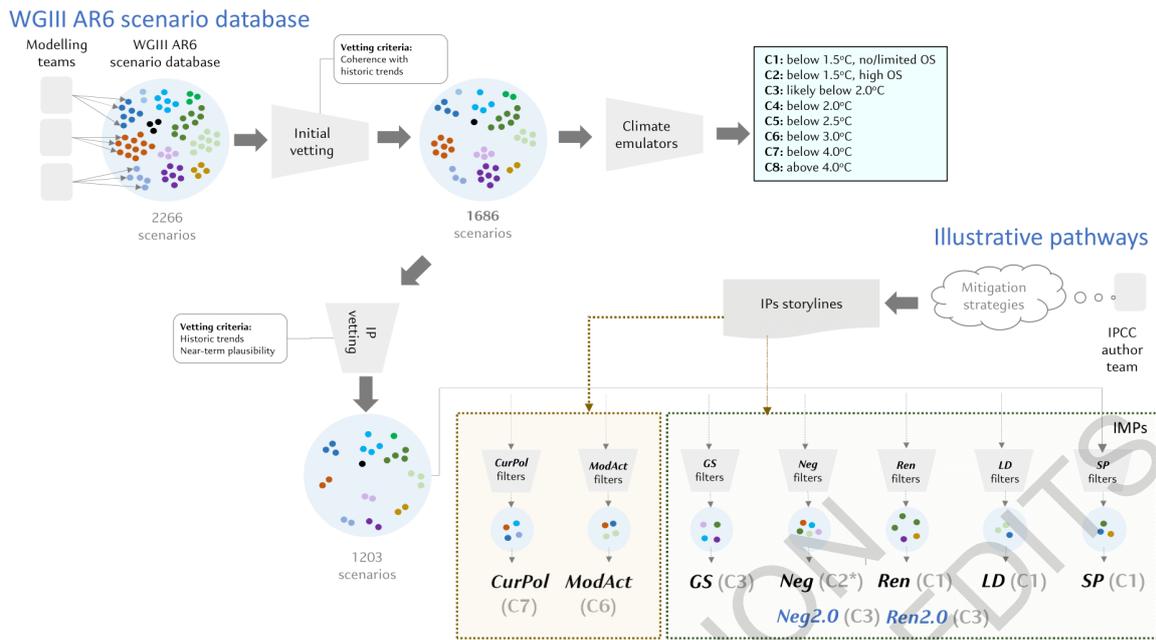

1 form a common thread in the report, both with a storyline and a quantitative illustration. The storyline
2 describes the key characteristics that define an IMP. The quantitative versions of the IMPs provide
3 numerical values that are internally consistent and comparable across chapters of the report. The
4 quantitative IMPs have been selected from the AR6 scenario database. No assessment of the
5 likelihood of each IMP has been made.

6 The selected scenarios (IPs) are divided into two sets (Figure 3.5 and Figure 3.6): two reference
7 pathways illustrative of high emissions and five Illustrative Mitigation Pathways (IMPs). The
8 narratives are explained in full in Annex III. The two reference pathways explore the consequences of
9 current policies and pledges: Current Policies (*CurPol*) and Moderate Action (*ModAct*). The *CurPol*
10 pathway explores the consequences of continuing along the path of implemented climate policies in
11 2020 and only a gradual strengthening after that. The scenario illustrates the outcomes of many
12 scenarios in the literature that project the outcomes of current policies. The *ModAct* pathway explores
13 the impact of implementing the Nationally Determined Contributions as formulated in 2020 and some
14 further strengthening after that. In line with current literature, these two reference pathways lead to an
15 increase in global mean temperature of more than 2°C (see Section 3.3).

16 The Illustrative Mitigation Pathways properly explore different pathways consistent with meeting the
17 long-term temperature goals of the Paris Agreement. They represent five different pathways that
18 emerge from the overall assessment. The IMPs consist of pathways with: gradual strengthening of
19 current policies (*GS*), extensive use of net negative emissions (*Neg*), renewables (*Ren*), low demand
20 (*LD*), and shifting pathways (*SP*). Each of these pathways can be implemented with different levels
21 of ambition. In the IMP framework, *GS* is consistent with staying likely below 2°C (C3), *Neg* shows a
22 strategy that also stays likely below 2°C level but returns to nearly 1.5°C by the end of the century
23 (hence indicated as C2*). The other variants that can limit warming to 1.5°C (C1) were selected. In
24 addition to these IMPs, sensitivity cases that explore alternative warming levels (C3) for *Neg* and *Ren*
25 are assessed (*Neg-2.0* and *Ren-2.0*).

Figure 3.5 Panel A: Process for creating the AR6 scenario database and selecting the illustrative (mitigation) pathways. The compiled scenarios in the AR6 scenarios database were vetted for consistency with historical statistics and subsequently a temperature classification was added using climate model emulators. The illustrative (mitigation) pathways were selected from the full set of pathways based on storylines of critical mitigation strategies that emerged from the assessment. **Panel B: An overview of the Illustrative Pathways selected for use in IPCC AR6 WGIII, consisting of pathways illustrative of higher emissions, Current Policies (CurPol) and Moderate Action (ModAct), and Illustrative Mitigation Pathways (IMPs): gradual strengthening of current policies (GS), extensive use of net negative emissions (Neg), renewables (Ren), low demand (LD), and shifting pathways (SP).**

1

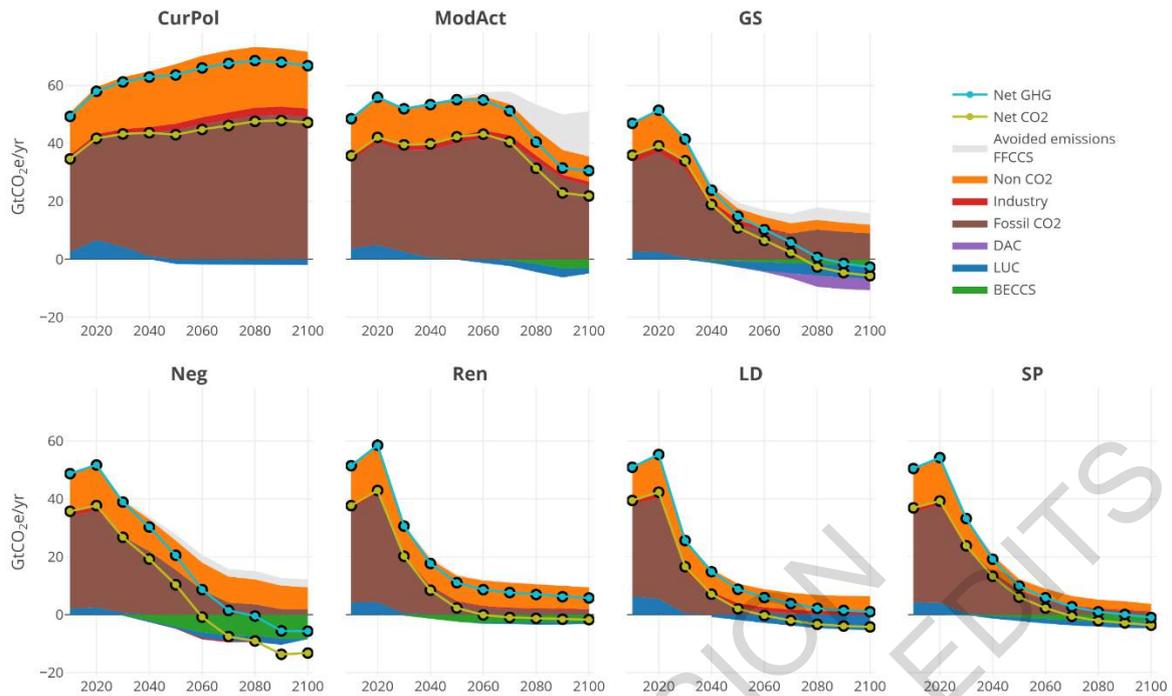

2

3

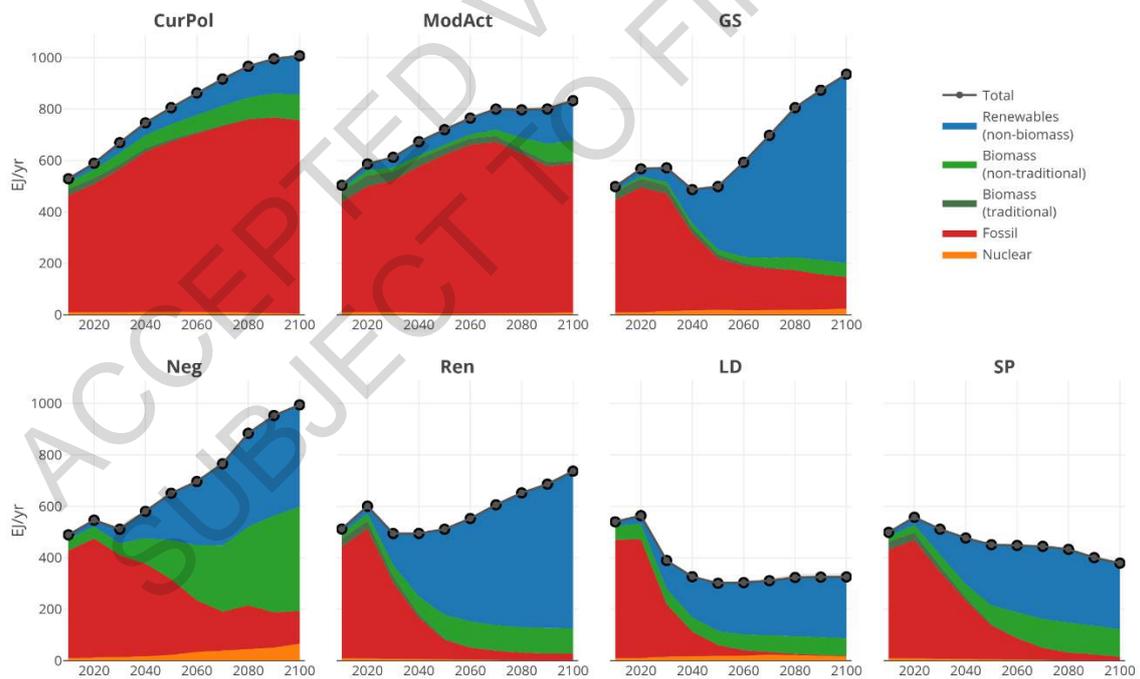

Figure 3.6 Overview of the net CO₂ emissions and Kyoto GHG emissions for each IMP

4 The IMPs are selected to have different mitigation strategies, which can be illustrated looking at the
 5 energy system and emission pathways (Figure 3.7 and Figure 3.8). The mitigation strategies show the
 6 different options in emission reduction (Figure 3.7). Each panel shows the key characteristics leading
 7 to total GHG emissions, consisting of residual (gross) emissions (fossil CO₂ emissions, CO₂ emissions
 8 from industrial processes, and non-CO₂ emissions) and removals (net land-use change, bioenergy with
 9 carbon capture and storage, and direct air carbon capture and storage), in addition to avoided
 10 emissions through the use of carbon capture and storage on fossil fuels. The *Neg* and *GS* scenarios
 11 were shown to illustrate scenarios with a significant role of CDR. The energy supply (Figure 3.8)
 12 shows the phase-out of fossil fuels in the *LD*, *Ren* and *SP* cases, but a less substantial decrease in the
 13 *Neg* case. The *GS* case needs to make up its slow start by 1) rapid reductions mid-century and 2)
 14 massive reliance on net negative emissions by the end of the century. The *CurPol* and *ModAct* cases
 15 both result in relatively high emissions, showing a slight increase and stabilization compared to
 16 current emissions, respectively.

3.3 Emission pathways, including socio-economic, carbon budget and climate responses uncertainties

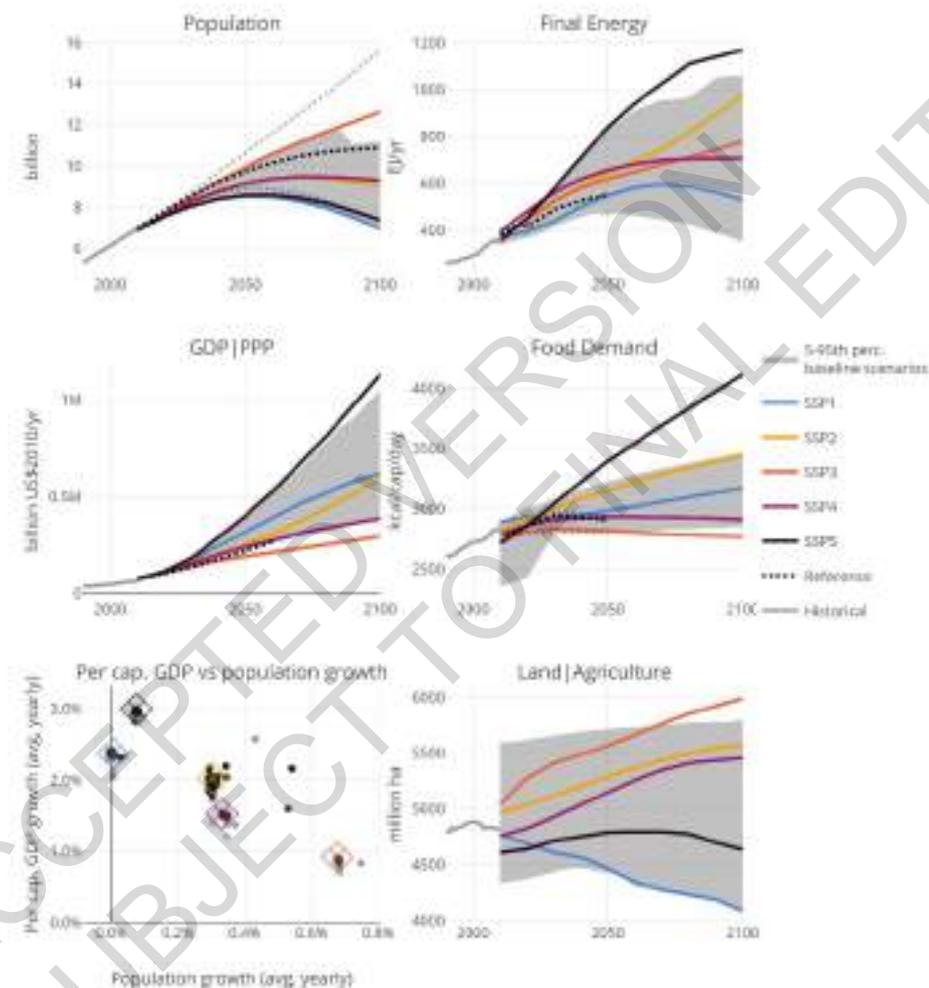

3.3.1 Socio-economic drivers of emissions scenarios

Greenhouse gas emissions mainly originate from the use and transformation of energy, agriculture, land use (change) and industrial activities. The future development of these sources is influenced by trends in socio-economic development, including population, economic activity, technology, politics, lifestyles, and climate policy. Trends for these factors are not independent, and scenarios provide a consistent outlook for these factors together (see Section 3.2). Marangoni et al. (2017) show that in projections, assumptions influencing energy intensity (e.g., structural change, lifestyle and efficiency) and economic growth are the most important determinants of future CO₂ emissions from energy combustion. Other critical factors include technology assumptions, preferences, resource assumptions and policy (van Vuuren et al. 2008). As many of the factors are represented differently in specific models, the model itself is also an important factor – providing a reason for the importance of model diversity (Sognaes et al. 2021). For land use, Stehfest et al. (2019) show that assumptions on population growth are more dominant given that variations in per capita consumption of food are smaller than for energy. Here, we only provide a brief overview of some key drivers. We focus first on so-called reference scenarios (without stringent climate policy) and look at mitigation scenarios in detail later. We use the SSPs to discuss trends in more detail. The SSPs were published in 2017, and by now, some elements will have to be updated (O'Neill et al. 2020b). Still, the ranges represent the full literature relatively well.

Historically, population and GDP have been growing over time. Scenario studies agree that further global population growth is likely up to 2050, leading to a range of possible outcomes of around 8.5-11 billion people (see Figure 3.9). After 2050, projections show a much wider range. If fertility drops below replacement levels, a decline in the global population is possible (as illustrated by SSP1 and SSP5). This typically includes scenarios with rapid development and investment in education. However, median projections mostly show a stabilisation of the world population (e.g., SSP2), while high-end projections show a continued growth (e.g., SSP3). The UN Population Prospects include considerably higher values for both the medium projection and the high end of the range than the SSP scenarios (KC and Lutz 2017; UN 2019). The most recent median UN projection reaches almost 11 billion people in 2100. The key differences are in Africa and China: here, the population projections are strongly influenced by the rate of fertility change (faster drop in SSPs). Underlying, the UN approach is more based on current demographic trends while the SSPs assume a broader range of factors (including education) driving future fertility.

Economic growth is even more uncertain than the population projections (Figure 3.9). The average growth rate of GDP was about 2.8% per year (constant USD) in the 1990-2019 period (The World Bank 2021). In 2020, the Covid-19 crisis resulted in a considerable drop in GDP (estimated around 4-5%) (IMF 2021). After a recovery period, most economic projections assume growth rates to converge back to previous projections, although at a lower level (IMF 2021; OECD 2021) (see also Box 3.2). In the long-term, assumptions on future growth relate to political stability, the role of the progress of the technology frontier and the degree to which countries can catch up (Johansson et al. 2013). The SSP scenarios cover an extensive range, with low per capita growth in SSP3 and SSP4 (mostly in developing countries) and rapid growth in SSP1 and SSP5. At the same, however, also scenarios outside the range have some plausibility – including the option of economic decline (Kallis et al. 2012) or much faster economic development (Christensen et al. 2018). The OECD long-term projection is at the global level reasonably consistent with SSP2. Equally important economic parameters include income distribution (inequity) and the type of growth (structural change, i.e., services vs manufacturing industries). Some projections (like SSP1) show a considerable convergence of income levels within and across countries, while in other projections, this does not occur (e.g., SSP3). Most scenarios reflect the suggested inverse relationship between the assumed growth rate for income and population growth (Figure 3.9e). SSP1 and SSP5 represent examples of scenarios with relatively low population increase and relatively high-income increase over the century. SSP3

1 represents an example of the opposite – while SSP2 and SSP4 are placed more in the middle. Nearly
 2 all scenarios assessed here do not account for climate impacts on growth (mostly for methodological
 3 reasons). As discussed in Section 3.5 these impacts can be considerable. An emerging area of
 4 literature emphasises the possibility of stabilisation (or even decline) of income levels in developed
 5 countries, arguing that such a trend would be preferred or even needed for environmental reasons
 6 (Anderson and Larkin 2013; Kallis et al. 2020; Hickel and Kallis 2020; Keyßer and Lenzen 2021;
 7 Hickel et al. 2021) (see also Chapter 5). Such scenarios are not common among IAM outcomes, that
 8 are more commonly based on the idea that decarbonisation can be combined with economic growth
 9 by a combination of technology, lifestyle and structural economic changes. Still, such scenarios could
 10 result in a dramatic reduction of energy and resource consumption (see further).

11 **Figure 3.9 Trends in key scenarios characteristics and driving forces as included in the SSP scenarios**
 12 **(showing 5-95th percentiles of the reference scenarios as included in the database in grey shading).**
 13 **Reference (dotted lines) refers to UN low, medium and high population scenario (UN 2019), OECD Long-**
 14 **term economic growth scenario (OECD 2021), the scenarios from IEA’s World Energy Outlook (IEA**
 15 **2019), and the scenarios in the FAO assessment (FAO 2018)**
 16

17 Scenarios show a range of possible energy projections. In the absence of climate policy, most
 18 scenarios project the final energy demand to continue to grow to around 650-800 EJ yr⁻¹ in 2100
 19 (based on the scenario database). Some projections show a very high energy demand up to 1000 EJ yr⁻¹
 20 (comparable to SSP5). The scenario of the IEA lies within the SSP range but near the SSP1
 21 projection. However, it should be noted that the IEA scenario includes current policies (most
 22 reference scenarios do not) and many scenarios published before 2021 did not account for the Covid-
 23 19 crisis. Several researchers discuss the possibility of decoupling material and energy demand from

1 economic growth in the literature, mainly in developed countries (Kemp-Benedict 2018) (decoupling
2 here refers to either a much slower increase in demand or even a decrease). In the scenario literature,
3 this is reflected by scenarios with very low demand for final energy based on increased energy
4 efficiency and less energy-intensive lifestyles (e.g., SSP1 and the LED scenario) (Grubler et al. 2018;
5 van Vuuren et al. 2018). While these studies show the feasibility of such pathways, their energy
6 efficiency improvement rates are considerably above the historic range of around 2% (Haberl et al.
7 2020).

8
9 (Vrontisi et al. 2018; Roelfsema et al. 2020; Sognaes et al. 2021)(IEA 2021a; Höhne et al.
10 2021)(Jeffery et al. 2018; Gütschow et al. 2018)(Giarola et al. 2021)(Sognaes et al. 2021)(Höhne et
11 al. 2021)(Höhne et al. 2021)These scenarios also show clear differences in food consumption and the
12 amount of land used for agriculture. Food demand in terms of per capita caloric intake is projected to
13 increase in most scenarios. However, it should be noted that there are large differences in dietary
14 composition across the scenarios (from more meat-intensive in scenarios like SSP5 to a decrease in
15 meat consumptions in other scenarios such as SSP1). Land use projections also depend on assumed
16 changes in yield and the population scenarios. Typically, changes in land use are less drastic than
17 some other parameters (in fact, the 5-95th database range is almost stable). Agriculture land is
18 projected to increase in SSP3, SSP2, and SSP4 – more-or-less stable in SSP5 and is projected to
19 decline in SSP1.

20 21 **3.3.2 Emission pathways and temperature outcomes**

22 23 **3.3.2.1 Overall mitigation profiles and temperature consequences**

24
25 Figure 3.10 shows the GHG and CO₂ emission trajectories for different temperature categories as
26 defined in Section 3.2 (the temperature levels are calculated using simple climate models, consistent
27 with the outcomes of the recent WGI assessment, Cross-Chapter Box 7.1). It should be noted that
28 most scenarios currently in the literature do not account for an impact of Covid-19 (see Box 3.2). The
29 higher categories (C6 and C7) mostly included scenarios with no or modest climate policy. Because
30 of the progression of climate policy, it is becoming more common that reference scenarios incorporate
31 implemented climate policies. Modelling studies typically implement current or pledged policies up
32 until 2030 (Vrontisi et al. 2018; Roelfsema et al. 2020; Sognaes et al. 2021) with some studies
33 focusing also on the policy development in the long term (IEA 2021a; Höhne et al. 2021). (Jeffery et
34 al. 2018; Gütschow et al. 2018)Based on the assessment by Chapter 4, reference pathways consistent
35 with the implementation and extrapolation of current policies are associated with increased GHG
36 emissions from 59 (53-65) GtCO₂-eq yr⁻¹ in 2019 to 52-60 GtCO₂-eq yr⁻¹ by 2030 and to 46-67
37 GtCO₂-eq yr⁻¹ by 2050 (see Figure 3.6). Pathways with these near-term emissions characteristics, lead
38 to a median global warming of 2.4°C to 3.5°C by 2100 (see also further in this section). These
39 pathways consider policies at the time that they were developed. A recent model comparison that
40 harmonised socioeconomic, technological, and policy assumptions (Giarola et al. 2021) found a 2.2-
41 2.9°C median temperature rise in 2100 for current and stated policies, with the results sensitive to the
42 model used and the method of implementing policies (Sognaes et al. 2021). Scenario inference and
43 construction methods using similar policy assumptions leads to a median range of 2.9-3.2°C in 2100
44 for current policies and 2.4-2.9°C in 2100 for 2030 pledges (Höhne et al. 2021). The median spread of
45 1°C across these studies (2.2-3.2°C) indicates the deep uncertainties involved with modelling
46 temperature outcomes of 2030 policies through to 2100. (Höhne et al. 2021)

47
48 The lower categories include increasingly stringent assumed climate policies. For all scenario
49 categories, except the highest category, emissions peak in the 21st century. For the lowest categories,
50 the emissions peak is mostly before 2030. In fact, for scenarios in the category that avoids
51 temperature overshoot for the 1.5°C scenario (C1 category), GHG emissions are reduced already to
52 almost zero around the middle of the century. Typically, CO₂ emissions reach net zero about 10-20
53 years before total GHG emissions reach net zero. The main reason is that scenarios reduce non-CO₂
54 greenhouse gas emissions less than CO₂ due to a limited mitigation potential (see 3.3.2.2). The figure
55 also shows that many scenarios in the literature with a temperature outcome below 2 °C show net

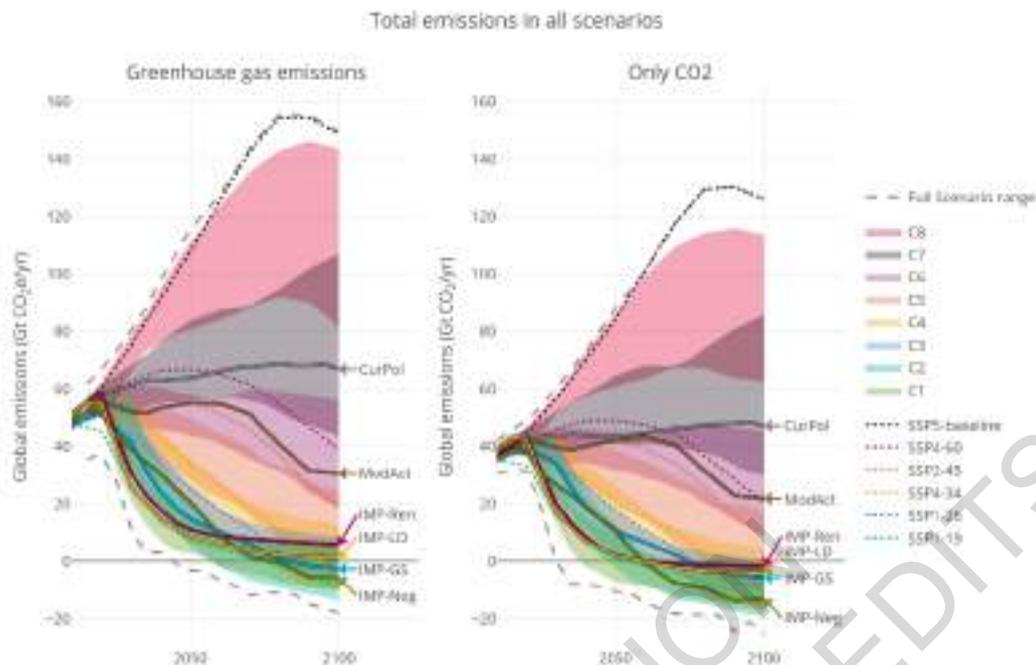

1 negative emissions. There are, however, also exceptions in which more immediate emission
2 reductions limits the need for CDR. The IMPs illustrate alternative pathways to reach the C1-C3
3 temperature levels.
4

5 **START BOX HERE**

6 **Box 3.2 Impact of Covid-19 on long-term emissions**

7
8
9 The reduction in CO₂ emissions of the Covid-19 pandemic in 2020 was estimated to be about 6% (see
10 section 4.2.2.4 and Table S4.2) lower than 2019 levels (BP 2021, Crippa et al. 2021, IEA 2021, Le
11 Quéré et al. 2021; Friedlingstein et al. 2020; Forster et al. 2020; Liu et al. 2020c). Near-real-time
12 monitoring estimates show a rebound in emissions levels, meaning 2021 emissions levels are
13 expected to be higher than 2020 (Le Quéré et al. 2021). The longer-term effects are uncertain but so
14 far do not indicate a clear structural change for climate policy related to the pandemic. The increase in
15 renewable shares in 2020 could stimulate a further transition, but slow economic growth can also slow
16 down (renewable) energy investments. Also, lifestyle changes during the crisis can still develop in
17 different directions (working from home, but maybe also living further away from work). Without a
18 major intervention, most long-term scenarios project that emission will start to follow a similar
19 pathway as earlier projections (although at a reduced level) (IEA 2020b; Kikstra et al. 2021a;
20 Rochedo et al. 2021). If emissions reductions are limited to only a short time, the adjustment of
21 pathways will lead to negligible outcomes in the order of 0.01K (Forster et al. 2020; Jones et al.
22 2021). At the same time, however, the large amount of investments pledged in the recovery packages
23 could provide a unique opportunity to determine the long-term development of infrastructure, energy
24 systems and land use (Hepburn et al. 2020; Pianta et al. 2021; Andrijevic et al. 2020b). Near-term
25 alternative recovery pathways have been shown to have the potential to influence carbon price
26 pathways, and energy investments and electrification requirements under stringent mitigation targets
27 (Kikstra et al. 2021a; Rochedo et al. 2021; Bertram et al. 2021; Pollitt et al. 2021; Shan et al. 2021).
28 Most studies suggest a noticeable reduction in 2030 emissions. However, much further reductions
29 would be needed to reach the emission levels consistent with mitigation scenarios that would likely
30 stay below 2°C or lower (see Chapter 4). At the moment, the share of investments in greenhouse gas
31 reduction is relatively small in most recovery packages, and no structural shifts for climate policies
32 are observed linked to the pandemic. Finally, most of the scenarios analysed in this Chapter do not
33 include the 2020 emissions reduction related to the Covid-19 pandemic. The effect of the pandemic
34 on the pathways will likely be very small. The assessment of climate mitigation pathways in this
35 chapter should be interpreted as being almost exclusively based on the assumption of a fast recovery
36 with limited persistent effects on emissions or structural changes.

7 **Box 3.3 The likelihood of high-end emission scenarios**

8
9 At the time the Representative Concentration Pathways (RCPs) were published, they included 3
10 scenarios that could represent emission developments in the absence of climate policy: RCP4.5, RCP6
11 and RCP8.5, described as, respectively, low, medium and high-end scenarios in the absence of strong
12 climate policy (van Vuuren et al. 2011). RCP8.5 was described as representative of the top 5%
13 scenarios in the literature. The SSPs-based set of scenarios covered the RCP forcing levels adding a
14 new low scenario (at 1.9 W/m²). Hausfather and Peters (2020) pointed out that since 2011, the rapid
15 development of renewable energy technologies and emerging climate policy have made it
16 considerably less likely that emissions could end up as high as RCP8.5. Still, emission trends in
17 developing countries track RCP8.5 Pedersen et al. (2020), and high land-use emissions could imply
18 that emissions would continue to do so in the future, even at the global scale (Schwalm et al. 2020).
19 Other factors resulting in high emissions include higher population or economic growth as included in
20 the SSPs (see subsection 3.3.1) or rapid development of new energy services. Climate projections of
21 RCP8.5 can also result from strong feedbacks of climate change on (natural) emission sources and
22 high climate sensitivity (see WGI Chapter 7), and therefore their median climate impacts might also
23 materialise while following a lower emission path (e.g., Hausfather and Betts (2020)). The discussion
24 also relates to a more fundamental discussion on assigning likelihoods to scenarios, which is
25 extremely difficult given the deep uncertainty and direct relationship with human choice. However, it
26 would help to appreciate certain projections (e.g., Ho et al. (2019)). All-in-all, this means that high-
27 end scenarios have become considerably less likely since AR5 but cannot be ruled out. It is important
28 to realize that RCP8.5 and SSP5-8.5 do not represent a typical ‘business-as-usual projection but are
29 only useful as high-end, high-risk scenarios. Reference emission scenarios (without additional climate
30 policy) typically end up in C5-C7 categories included in this assessment.

3 **Figure 3.11: Global mean temperature outcome of the ensemble of scenarios included in the climate**
4 **categories C1-C7 (based on RCM calibrated to the WGI assessment, both in terms of future and historic**
5 **warming). The left panel shows the ranges of scenario uncertainty (shaded area) with the P50 RCM**
6 **probability (line). The right panel shows the P5 to P95 range of RCM climate uncertainty (C1-C7 is**
7 **explained in Table 3.1) and the P50 (line) and P66 (dashed line).**
8

9 Figure 3.11 shows the possible consequences of the different scenario categories for global mean
10 temperature calculated using a reduced complexity model calibrated to the IPCC WGI assessment
11 (see Annex III and WGI report). For the C5-C7 categories (containing most of the reference and
12 current policy scenarios), the global mean temperature is expected to increase throughout the century
13 (and further increase will happen after 2100 for C6 and C7). While warming would likely be in the
14 range from 2.2-3.8 °C – warming above 5°C cannot be excluded. The highest emissions scenarios in
15 the literature combine assumptions about rapid long-term economic growth and pervasive climate
16 policy failures, leading to a reversal of some recent trends (see box 3.3). For the categories C1-C4, a
17 peak in global mean temperature is reached mid-century for most scenarios in the database, followed
18 by a small (C3/C4) or more considerable decline (C1/C2). There is a clear distinction between the
19 scenarios with no or limited overshoot (typically <0.1 °C, C1) compared to those with high overshoot
20 (C2): in emissions, the C1 category is characterised by steep early reductions and a relatively small
21 contribution of net negative emissions (like *LD* and *Ren*) (Figure 3.10). In addition to the temperature
22 caused by the range of scenarios in each category (main panel), also climate uncertainties contribute
23 to a range of temperature outcomes (including uncertainties regarding the carbon cycle, climate
24 sensitivity, and the rate of change, see WGI). The bars on the right of Figure 3.11 show the
25 uncertainty range for each category (combining scenario and uncertainty). While the C1 category
26 more likely than not leads to warming below 1.5 °C by the end of the century, even with such a
27 scenario, warming above 2°C cannot be excluded (95th percentile). The uncertainty range for the
28 highest emission categories (C7) implies that these scenarios could lead to a warming above 6°C.
29

30 3.3.2.2 *The role of carbon dioxide and other greenhouse gases*

31 The trajectory of future CO₂ emissions plays a critical role in mitigation, given CO₂ long-term impact
32 and dominance in total greenhouse gas forcing. As shown in Figure 3.12, CO₂ dominates total
33 greenhouse gas emissions in the high emissions scenarios but is also reduced most, going from
34 scenarios in the highest to lower categories. In C4 and below, most scenarios exhibit net negative CO₂
35 emissions in the second half of the century compensating for some of the residual emissions of non-
36 CO₂ gases as well as reducing overall warming from an intermediate peak. Still, early emission

1 reductions and further reductions in non-CO₂ emissions can also lead to scenarios without net
 2 negative emissions in 2100, even in C1 and C3 (shown for the 85-95th percentile). In C1, avoidance of
 3 significant overshoot implies that immediate gross reductions are more relevant than long-term net
 4 negative emissions (explaining the lower number than in C2) but carbon dioxide removal is still
 5 playing a role in compensating for remaining positive emissions in hard-to-abate sectors.

6

7 **Figure 3.12 Upper left: The role of CO₂ and other greenhouse gases. Emission in CO₂-eq in 2100 (using**
 8 **AR6 GWP-100) (other = halogenated gases) and upper right: Cumulative CO₂ emissions in the 2020-2100**
 9 **period. The lower left and right panel show the development of CH₄ and N₂O emissions over time.**

10 **Energy emissions include the contribution of BECCS. For both energy and AFOLU sectors, the positive**
 11 **and negative values represent the cumulated annual balances. In both panels, the three bars per scenario**
 12 **category represent the lowest 5-15th percentile, the average value and the highest 5-15th percentile. These**
 13 **illustrate the range of scenarios in each category. The definition of C1-C7 can be found in Table 3.1**

14 CH₄ and N₂O emissions are also reduced from C7 to C1, but this mostly occurs between C7 and C5.
 15 The main reason is the characteristics of abatement potential: technical measures can significantly
 16 reduce CH₄ and N₂O emissions at relatively low costs to about 50% of the current levels (e.g., by
 17 reducing CH₄ leaks from fossil fuel production and transport, reducing landfill emissions gazing, land
 18 management and introducing measure related to manure management, see also Chapter 7 and 11).

19 However, technical potential estimates becomes exhausted even if the stringency of mitigation is
 20 increased (Harmsen et al. 2019a,b; Höglund-Isaksson et al. 2020). Therefore, further reduction may
 21 come from changes in activity levels, such as switching to a less meat-intensive diet reducing
 22 livestock (Stehfest et al. 2009; Willett et al. 2019; Ivanova et al. 2020) (see also Chapter 7). Other
 23 non-CO₂ GHG emissions (halogenated gases) are reduced to low levels for scenarios below 2.5°C.
 24

1 Short-lived climate forcers (SLCFs) also play an important role in climate change, certainly for short-
2 term changes (see Figure SPM.2, WGI) (Shindell et al. 2012). These forcers consist of 1) substances
3 contributing to warming, such as methane, black carbon and tropospheric ozone and 2) substances
4 contributing to cooling (other aerosols, such as related to sulphur emissions). Most SLCFs are also air
5 pollutants, and reducing their emissions provides additional co-benefits (Shindell et al. 2017a,b;
6 Hanaoka and Masui 2020). In the case of the first group, emission reduction thus leads to both air
7 pollution and climate benefits. For the second, group there is a possible trade-off (Shindell and Smith
8 2019; Lund et al. 2020). As aerosol emissions are mostly associated with fossil fuel combustion, the
9 benefits of reducing CO₂ could, in the short term, be reduced as a result of lower aerosol cooling.
10 There has been an active discussion on the exact climate contribution of SLCF focused policies in the
11 literature. This discussion partly emerged from different assumptions on possible reductions in the
12 absence of ambitious climate policy and the uncertain global climate benefit from aerosol (black
13 carbon) (Rogelj et al. 2014). The latter is now assessed to be smaller than originally thought (Smith et
14 al. 2020b; Takemura and Suzuki 2019) (see also WGI Chapter 6, Section 6.4). Reducing SLCF
15 emissions is critical to meet long-term climate goals and might help reduce the rate of climate change
16 in the short term. Deep SLCF emission reductions also increase the remaining carbon budget for a
17 specific temperature goal (Rogelj et al. 2015a; Reisinger et al. 2021) (see Box 3.4). A more detailed
18 discussion can be found in WGI Chapter 5 and 6.

19
20 For accounting of emissions and the substitution of different gases as part of a mitigation strategy,
21 typically, emission metrics are used to compare the climate impact of different gases. Most policies
22 currently use Global Warming Potentials with a 100-year time horizon as this is also mandated for
23 emissions reporting in the Paris Rulebook (for a wider discussion of GHG metrics, see Box 2.2 in
24 Chapter 2 and WGI, Chapter 7, Section 7.6). Alternative metrics have also been proposed, such as
25 those using a shorter or longer time horizon or those that focus directly on the consequences of
26 reaching a certain temperature target (Global Temperature Change Potential, GTP), allowing a more
27 direct comparison with cumulative CO₂ emissions (Allen et al. 2016; Lynch et al. 2020) or focusing
28 on damages (Global Damage Potential) (an overview is given in Chapter 2, and Cross-Chapter Box
29 3). Depending on the metric, the value attributed to reducing short-lived forcers like methane can be
30 lower in the near term (e.g., in the case of GTP) or higher (GWP with short reference period). For
31 most metrics, however, the impact on mitigation strategies is relatively small, among others, due to
32 the marginal abatement cost curve of methane (low costs for low to medium mitigation levels;
33 expensive for high levels). The timing of reductions across different gases impacts warming and the
34 co-benefits (Harmsen et al. 2016; Cain et al. 2019). Nearly all scenarios in the literature use GWP-100
35 in cost-optimisation, reflecting the existing policy approach; the use of GWP-100 deviates from cost-
36 optimal mitigation pathways by at most a few percent for temperature goals of likely below 2°C and
37 lower (see Box 2.2 in Chapter 2).

38 *Cumulative CO₂ emissions and temperature goals*

39 The dominating role of CO₂ and its long lifetime in the atmosphere and some critical characteristics of
40 the earth system implies that there is a strong relationship between cumulative CO₂ emissions and
41 temperature outcomes (MacDougall and Friedlingstein 2015; Meinshausen et al. 2009; Allen et al.
42 2009; Matthews et al. 2009). This is illustrated in Figure 3.13 that plots the cumulative CO₂ emissions
43 against the projected outcome for global mean temperature, both until a temperature peak and full
44 century. The deviations from in linear relationship in Figure 3.13 are mostly caused by different non-
45 CO₂ emission and forcing levels (see also Rogelj et al. (2015b)). This means that reducing non-CO₂
46 emissions can play an important role in limiting peak warming: the smaller the residual non-CO₂
47 warming, the larger the carbon budget. This impact on carbon budgets can be substantial for stringent
48 warming limits. For 1.5°C pathways, variations in non-CO₂ warming across different emission
49 scenarios have been found to vary the remaining carbon budget by approximately 220 GtCO₂ (see
50 WGI Chapter 5, Subsection 5.5.2.2). In addition to reaching net zero CO₂ emissions, a strong
51 reduction in methane emissions is the most critical component in non-CO₂ mitigation to keep the Paris
52 climate goals in reach (van Vuuren et al. 2018; Collins et al. 2018) (see also WGI, Chapter 5, 6 and
53 7). It should be noted that the temperature categories (C1-C7) generally aligned with the horizontal
54 axis, except for the end-of-century values for C1 and C2 that coincide.

START BOX HERE**Box 3.4 Consistency of remaining carbon budgets in the WGI assessment and cumulative CO₂ emissions in WGIII mitigation pathways****Introduction**

The WGI assessment has shown that the increase in global mean temperature has a near-linear relationship with cumulative CO₂ emissions (Chapter 5, Section 5.5, Box 5.3). Consistently, WGI has confirmed that net zero CO₂ emissions are required to halt CO₂-induced warming. This permits the estimation of carbon budgets consistent with specific temperature goals. In Chapter 3, we present the temperature outcomes and cumulative CO₂ emissions associated with different warming levels for around 1200 scenarios published in the literature and which were classified according to different warming levels (see Section 3.2 and Annex III, Part II.2.5). In this box, we discuss the consistency of the assessments presented here and in IPCC WGI. The box summarises how the remaining carbon budgets assessed by WGI relate to the remaining cumulative CO₂ emissions until the time of net zero CO₂ emissions in mitigation pathways (Table 3.2, Table SPM1) assessed by WGIII.

In its assessment, WGI uses a framework in which the various components of the remaining carbon budget are informed by various lines of evidence and assessed climate system characteristics. WGIII, instead, uses around 1200 emission scenarios with estimated warming levels that cover the scenario range presented in WGI but also contain many more intermediate projections with varying emission profiles and a combination of CO₂ emissions and other greenhouse gases. In order to assess their climate outcomes, climate model emulators are used. The emulators are reduced complexity climate models that are provided by WGI, and which are calibrated to the WGI assessment of future warming for various purposes (a detailed description of the use of climate model emulators in the WGI and WGIII assessments can be found in Cross-chapter Box 7.1 in the WGI report, with the connection of WGI and WGII discussed in Annex III.2.5.1).

Remaining carbon budgets estimated by WGI

WGI estimated the remaining carbon budgets from their assessment of (i) the transient climate response to cumulative emissions of carbon dioxide (TCRE), and estimates of (ii) the historical human-induced warming, (iii) the temperature change after reaching net zero CO₂ emissions, (iv) the contribution of future non-CO₂ warming (derived from the emissions scenarios assessed in the Special Report on 1.5°C Warming using WGI-calibrated emulators), and (v) the earth system feedbacks (WGI Chapter 5.5, Box 5.2). For a given warming level, WGI assessed the remaining carbon budget from the beginning of 2020 onwards. These are 650 / 500 / 400 GtCO₂ for limiting warming to 1.5°C with 33% / 50% / 67% chance and 1350 / 1150 GtCO₂ for limiting warming to 2°C with 50% / 67% chance. The estimates are subject to considerable uncertainty related to historical warming, future non-CO₂ forcing, and poorly quantified climate feedbacks. For instance, variation in non-CO₂ emissions across scenarios are estimated to either increase or decrease the remaining carbon budget estimates by 220 GtCO₂. The estimates of the remaining carbon budget assume that non-CO₂ emissions are reduced consistently with the tight temperature targets for which the budgets are estimated.

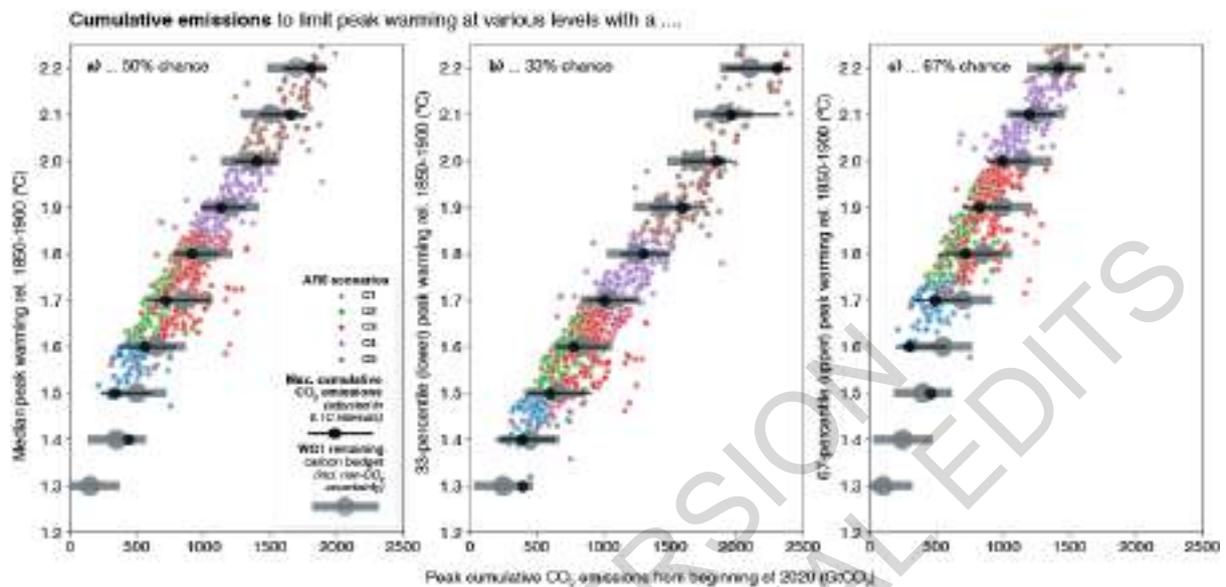

Cumulative CO₂ emissions until net zero estimated by WGIII

WGIII provides estimates of cumulative net CO₂ emissions (from 2020 inclusive) until the time of reaching net zero CO₂ emissions (henceforth called “peak cumulative CO₂ emissions”) and until the end of the century for eight temperature classes that span a range of warming levels. The numbers can be found in Table 3.2 (330-710 GtCO₂ for C1; 540-930 for C2 and 640-1160 for C3).

Comparing the WGI remaining carbon budgets and remaining cumulative CO₂ emissions of the WGIII scenarios

A comparison between WGI and WGIII findings requires recognising that, unlike in WGI, cumulative emissions in WGIII are not provided for a specific peak warming threshold or level but are instead provided for a set of scenarios in a category, representing a specific range of peak temperature

1 outcomes (for instance the C4 category contains scenarios with a median peak warming anywhere
 2 between approximately 1.8°C and up to 2°C). When accounting for this difference, the WGI and
 3 WGIII findings are very consistent for temperature levels below 2°C. Figure 1 compares the peak
 4 temperatures and associated cumulative CO₂ emissions (i.e., peak cumulative CO₂ emissions) for the
 5 WGIII scenarios to the remaining carbon budgets assessed by WGI. This shows only minor
 6 differences between the WGI and WGIII approaches.
 7

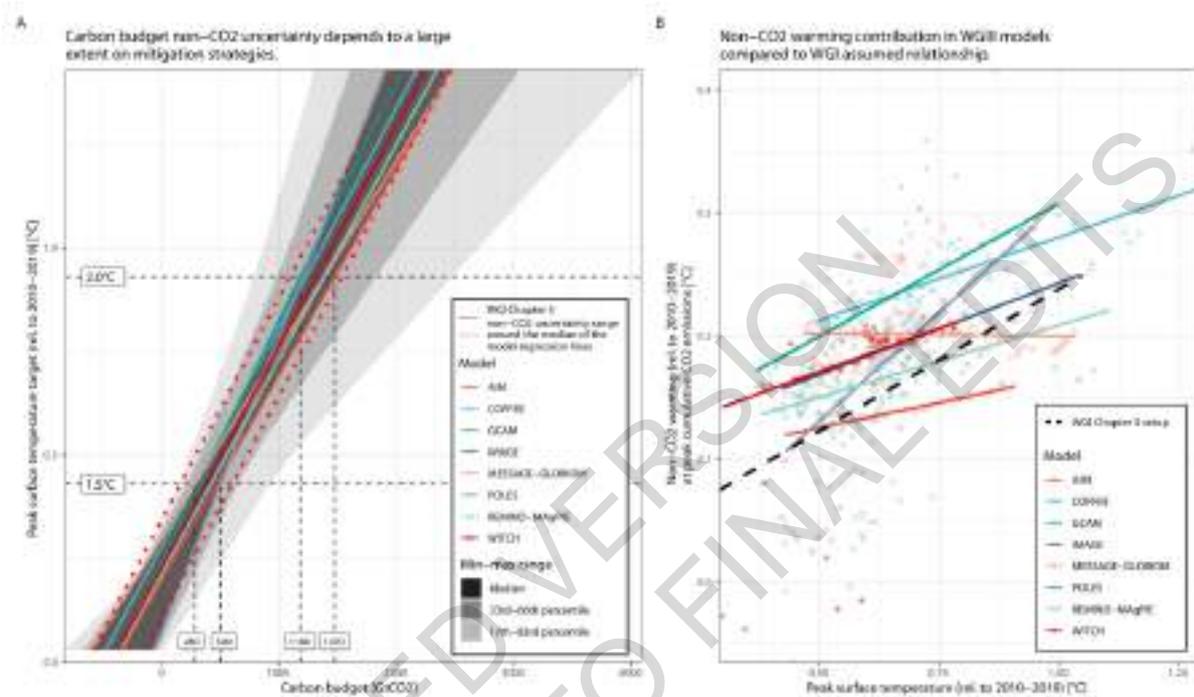

8
 9
 10 **Box 3.4 Figure 1: Cumulative CO₂ emissions from AR6 scenario categories (coloured dots), adjusted for**
 11 **distinct 0.1°C warming levels (black bars) in comparison to the WGI remaining carbon budgets (grey**
 12 **bars). The cumulative carbon emissions for the AR6 scenarios are shown for the median peak warming**
 13 **(panel a), the 33rd-percentile peak warming (panel b) and the upper 67th-percentile peak warming (panel**
 14 **c) calculated with the WGI-calibrated emulator MAGICC7 (IPCC AR6 WGI, Cross-Chapter Box 7.1).**
 15 **The adjustment to the nearest 0.1°C intervals is made using WGI TCRE (at the relevant percentile, e.g.,**
 16 **the 67th-percentile TCRE is used to adjust the 67th-percentile peak warming), with the 5% to 95% range**
 17 **of adjusted scenarios provided by the black bar. The WGI remaining carbon budget is shown, including**
 18 **the WGI estimate of at least a ±220 GtCO₂ uncertainty due to non-CO₂ emissions variations across**
 19 **scenarios (grey bars). For median peak warming (panel a) projections below 2°C relative to 1850-1900,**
 20 **the WGIII assessment of cumulative carbon emissions tends to be slightly smaller than the remaining**
 21 **carbon budgets provided by WGI but well within the uncertainties. Note that only a few scenarios in**
 22 **WGIII limit warming to below 1.5°C with a 50% chance, thus statistics for that specific threshold have**
 23 **low confidence.**

24
 25 After correcting for the categorisation, some (small) differences between the WGI and WGIII
 26 numbers arise from remaining differences between the outcomes of the climate emulators and their
 27 set-up (see Cross-Chapter Box 7.1 in IPCC WGI AR6) and the differences in the underlying
 28 scenarios. Moreover, the WGI assessment estimated the non-CO₂ warming at the time of net zero CO₂
 29 emissions based on a relationship derived from the SR1.5 scenario database with historical emission
 30 estimates as in Meinshausen et al. (2020) (WGI chapter 5). The WGIII assessment uses the same
 31 climate emulator with improved historical emissions estimates (Nicholls et al. 2021) (WGI Cross-
 32 Chapter Box 7.1). Annex III.2.5.1 further explores the effects of these factors on the relationship
 33 between non-CO₂ warming at peak cumulative CO₂ and peak surface temperature.
 34

35 Estimates of the remaining carbon budgets thus vary with the assumed level of non-CO₂ emissions,
 36 which are a function of policies and technology development. The linear relationship used in the WGI
 37 assessment between peak temperature and the warming as a result of non-CO₂ emissions (based on
 38 the SR1.5 data) is shown in the right panel of Figure 2 (dashed line). In the WG3 approach, the non-
 39 CO₂ warming for each single scenario is based on the individual scenario characteristics. This shown

1 in the same figure by plotting the outcomes of scenario outcomes of a range models (dots). The lines
 2 show the fitted data for individual models, emphasizing the clear differences across models and the
 3 relationship with peak warming (policy level). In some scenarios stringent non-CO₂ emission
 4 reductions provide an option to reach more stringent climate goals with the same carbon budget. This
 5 is especially the case for scenarios with a very low non-CO₂ warming, for instance as a result of
 6 methane reductions through diet change. The left panel shows how these differences impact estimates
 7 of the remaining carbon budget. While the WGIII AR6 scenario database includes a broad range of
 8 non-CO₂ emission projections the overall range is still very consistent with the WGI relationship and
 9 the estimated uncertainty with a ± 220 GtCO₂ range (see also panel B of Figure II.2 in Annex III.2.5).
 10

11
 12 **Box 3.4 Figure 2: Panel A) Differences in regressions of the relationship between peak surface**
 13 **temperature and associated cumulative CO₂ emissions from 2020 derived from scenarios of eight**
 14 **integrated assessment model frameworks. The coloured lines show the regression at median for scenarios**
 15 **of the 8 modelling frameworks, each with more than 20 scenarios in the database and a detailed land-use**
 16 **representation. The red dotted lines indicate the non-CO₂ uncertainty range of WGI Chapter 5 (± 220**
 17 **GtCO₂), here visualised around the median of the 8 model framework lines. Carbon budgets from 2020**
 18 **until 1.5C (0.43K above 2010-2019 levels) and 2.0C (0.93K above 2010-2019 levels) are shown for**
 19 **minimum and maximum model estimates at the median, rounded to the nearest 10GtCO₂. Panel B)**
 20 **Shows the relationship between the estimated non-CO₂ warming in mitigation scenarios that reach net**
 21 **zero and the associated peak surface temperature outcomes. The coloured lines show the regression at**
 22 **median for scenarios of the 8 modelling frameworks with more than 20 scenarios in the database and a**
 23 **detailed land-use representation. The black dashed line indicates the non-CO₂ relationship based on the**
 24 **scenarios and climate emulator setup as was assessed in WGI Chapter 5.**

25 Overall, the slight differences between the cumulative emissions in WGIII and the carbon budget in
 26 WGI are because the non-CO₂ warming in the WGIII AR6 scenarios is slightly lower than in the
 27 SR1.5 scenarios that are used for the budget estimates in WGI (Annex III.2.5.1). In addition,
 28 improved consistency with Cross-Chapter Box 7.1 in WGI results in a non-CO₂ induced temperature
 29 difference of about ~ 0.05 K between the assessments. Re-calculating the remaining carbon budget
 30 using the WGI methodology combined with the full WGIII AR6 scenario database results in a
 31 reduction of the estimated remaining 1.5C carbon budget by about 100 GtCO₂ (-20%), and a reduction
 32 of ~ 40 GtCO₂ (-3%) for 2C. Accounting also for the categorisation effect, the difference between the
 33 WGI and WGIII estimates is found to be small and well within the uncertainty range (Figure 1). This
 34 means that the cumulative CO₂ emissions presented in WGIII and the WGI carbon budgets are highly
 35 consistent.

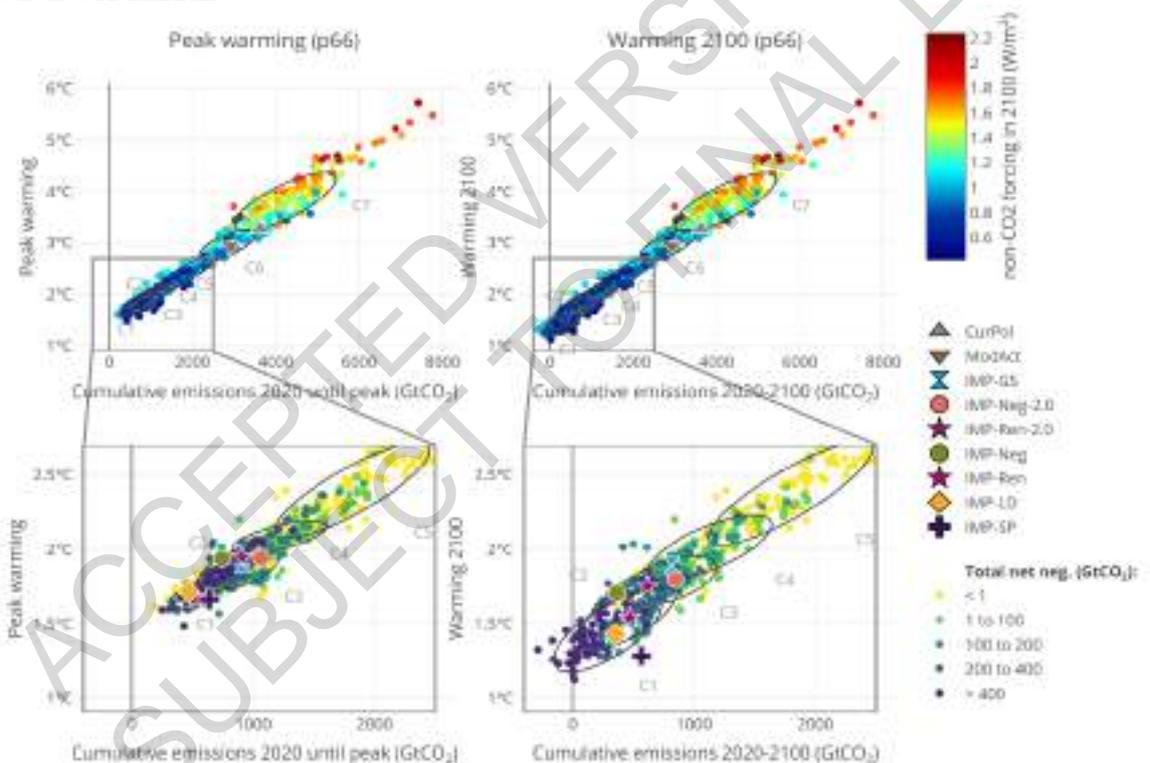

1 A detailed comparison of the impact of different assessment steps, i.e., the new emulators, scenarios,
2 and harmonisation methods, has been made and is presented in Annex III.

3 *Policy implications*

4 The concept of a finite carbon budget means that the world needs to get to net zero CO₂, no matter
5 whether global warming is limited to 1.5°C or well below 2°C (or any other level). Moreover,
6 exceeding the remaining carbon budget will have consequences by overshooting temperature levels.
7 Still, the relationship between the timing of net zero and temperature targets is a flexible one, as
8 discussed further in Cross-Chapter Box 3. It should be noted that national level inventory as used by
9 UNFCCC for the land use, land-use change and forestry sector are different from the overall concept
10 of anthropogenic emissions employed by IPCC WG1. For emissions estimates based on these
11 inventories, the remaining carbon budgets must be correspondingly reduced by approximately 15%,
12 depending on the scenarios (Grassi et al., 2021) (see also Chapter 7).

13
14
15 One of the uncertainties of the remaining carbon budget is the level of non-CO₂ emissions which is a
16 function of policies and technology development. This represents a point of leverage for policies
17 rather than an inherent geophysical uncertainty. Stringent non-CO₂ emission reductions hence can
18 provide – to some degree – an option to reach more stringent climate goals with the same carbon
19 budget.

20 **END BOX HERE**

22
23 **Figure 3.13: The near-linear relationship between cumulative CO₂ emissions and temperature. The left**
24 **panel shows cumulative emissions until net zero emission is reached. The right panel shows cumulative**
25 **emissions until the end of the century, plotted against peak and end-of-century temperature, respectively.**
26 **Both are shown as a function of non-CO₂ forcing and cumulative net negative CO₂ emissions. Position**
27 **temperature categories (circles) and IPs are also indicated, including two 2°C sensitivity cases for *Neg***
28 **(*Neg-2.0*) and *Ren* (*Ren-2.0*).**

29 The near-linear relationship implies that cumulative CO₂ emissions are critically important for climate
30 outcomes (Collins et al. 2013). The maximum temperature increase is a direct function of the
31 cumulative emissions until net zero CO₂ emissions is reached (the emission budget) (Figure 3.13, left
32 side). The end-of-century temperature correlates well with cumulative emissions across the century

1 (right panel). For long-term climate goals, positive emissions in the first half of the century can be
2 offset by net removal of CO₂ from the atmosphere (net negative emissions) at the cost of a temporary
3 overshoot of the target (Tokarska et al. 2019). The bottom panels of Figure 3.13 show the contribution
4 of net negative CO₂ emissions.

5
6 Focusing on cumulative emissions, the right-hand panel of Figure 3.12 shows that for high-end
7 scenarios (C6-C7), most emissions originate from fossil fuels, with a smaller contribution from net
8 deforestation. For C5 and lower, there is also a negative contribution to emissions from both AFOLU
9 emissions and energy systems. For the energy systems, these negative emissions originate from bio-
10 energy-and-carbon-capture-and-storage (BECCS), while for AFOLU, they originate from re- and
11 afforestation. For C3-C5, reforestation has a larger CDR contribution than BECCS, mostly due to
12 considerably lower costs (Rochedo et al. 2018). For C1 and C2, the tight carbon budgets imply in
13 many scenarios more CDR use (Riahi et al. 2021). Please note that net negative emissions are not so
14 relevant for peak temperature targets, and thus the C1 category, but CDR can still be used to offset the
15 remaining positive emissions (Riahi et al. 2021). While positive CO₂ emissions from fossil fuels are
16 significantly reduced, inertia and hard-to-abate sectors imply that in many C1-C3 scenarios, around
17 800-1000 GtCO₂ of net positive cumulative CO₂ emissions remain. This is consistent with literature
18 estimates that current infrastructure is associated with 650 GtCO₂ (best estimate) if operated until the
19 end of its lifetime (Tong et al. 2019). These numbers are considerably above the estimated carbon
20 budgets for 1.5 °C estimated in WGI, hence explaining CDR reliance (either to offset emissions
21 immediately or later in time).

22
23 Creating net negative emissions can thus be an important part of a mitigation strategy to offset
24 remaining emissions or compensate for emissions earlier in time. As indicated above, there are
25 different ways to potentially achieve this, including re- and afforestation and BECCS (as often
26 covered in IAMs) but also soil carbon enhancement, direct air carbon capture and storage (DACCS)
27 and ocean alkalization (see Chapter 12). Except for reforestation, these options have not been tested
28 at large scale and often require more R&D. Moreover, the reliance on CDR in scenarios has been
29 discussed given possible consequences of land use related to biodiversity loss and food security
30 (BECCS and afforestation), the reliance on uncertain storage potentials (BECCS and DACCS), water
31 use (BECCS), energy use (DACCS), the risks of possible temperature overshoot and the
32 consequences for meeting sustainable development goals (Venton 2016; Peters and Geden 2017;
33 Smith et al. 2016; van Vuuren et al. 2017; Anderson and Peters 2016; Honegger et al. 2021). In the
34 case of BECCS, it should be noted that bio-energy typically is associated with early-on positive CO₂
35 emissions and net-negative effects are only achieved in time (carbon debt), and its potential is limited
36 (Cherubini et al. 2013; Hanssen et al. 2020) (most IAMs have only a very limited representation of
37 these time dynamics). Several scenarios have therefore explored how reliance on net negative CO₂
38 emissions can be reduced or even avoided by alternative emission strategies (Grubler et al. 2018; van
39 Vuuren et al. 2018) or early reductions by more stringent emission reduction in the short-term (Rogelj
40 et al. 2019b; Riahi et al. 2021). A more in-depth discussion of land-based mitigation options can be
41 found in Chapter 7. It needs to be emphasized that even in strategies with net negative CO₂ emissions,
42 the emission reduction via more conventional mitigation measures (efficiency improvement,
43 decarbonisation of energy supply) is much larger than the CDR contribution (Tsutsui et al. 2020).

44 45 **3.3.2.3 The timing of net zero emissions**

46
47 In addition to the constraints on change in global mean temperature, the Paris Agreement also calls for
48 reaching a balance of sources and sinks of GHG emissions (Art. 4). Different interpretations of the
49 concept related to balance have been published (Rogelj et al. 2015c; Fuglestedt et al. 2018). Key
50 concepts include that of net zero CO₂ emissions (anthropogenic CO₂ sources and sinks equal zero)
51 and net zero greenhouse gas emission (see also Annex I Glossary and Box 3.3). The same notion can
52 be used for all GHG emissions, but here ranges also depend on the use of equivalence metrics
53 (Chapter 2, Box 2.2). Moreover, it should be noted that while reaching net zero CO₂ emissions
54 typically coincides with the peak in temperature increase; net zero GHG emissions (based on GWP-
55 100) implies a decrease in global temperature (Riahi et al. 2021) and net zero GHG emission typically

1 requires negative CO₂ emissions to compensate for the remaining emissions from other GHGs. Many
2 countries have started to formulate climate policy in the year that net zero emissions (either CO₂ or all
3 greenhouse gases) are reached – although, at the moment, formulations are often still vague (Rogelj et
4 al. 2021). There has been increased attention on the timing of net zero emissions in the scientific
5 literature and ways to achieve it.

6
7 Figure 3.14 shows that there is a relationship between the temperature target, the cumulative CO₂
8 emissions budget, and the net zero year for CO₂ emissions (left) and the sum of greenhouse gases
9 (right) for the scenarios published in the literature. In other words, the temperature targets from the
10 Paris Agreement can, to some degree, be translated into a net zero emission year (Tanaka and O'Neill
11 2018). There is, however, a considerable spread. In addition to the factors influencing the emission
12 budget (see WGI and section 3.3.2.2), this is influenced by the emission trajectory until net zero is
13 reached, decisions related to temperature overshoot and non-CO₂ emissions (especially for the
14 moment CO₂ reaches net zero emissions). Scenarios with limited or no net negative emissions and
15 rapid near-term emission reductions can allow small positive emissions (e.g., in hard-to-abate-
16 sectors). They may therefore have a later year that net zero CO₂ emissions are achieved. High
17 emissions in the short-term, in contrast, require an early net zero year.

18
19 For the scenarios in the C1 category (warming below 1.5°C (50% probability) with limited
20 overshoot), the net zero year for CO₂ emissions is typically around 2035-2070. For scenarios in C3
21 (likely limiting warming to below 2°C), CO₂ emissions reach net zero around 2060-2100. Similarly,
22 also the years for net zero GHG emissions can be calculated (see right graph). The GHG net zero
23 emissions year is typically around 10-20 years later than the carbon neutrality. Residual non-CO₂
24 emissions at the time of reaching net zero CO₂ range between 4-11 GtCO₂-eq in pathways that *likely*
25 limit warming to 2.0°C or below. In pathways likely limiting warming to 2°C, methane is reduced by
26 around 20% (1-46%) in 2030 and almost 50% (26-64%) in 2050, and in pathways limiting warming to
27 1.5°C with no or limited overshoot by around 33% (19-57) in 2030 and a similar 50% (33-69%) in
28 2050. Emissions reduction potentials assumed in the pathways become largely exhausted when
29 limiting warming to below 2°C. N₂O emissions are reduced too, but similar to CH₄, emission
30 reductions saturate for stringent climate goals. In the mitigation pathways, the emissions of cooling
31 aerosols are reduced due to reduced use of fossil fuels. The overall impact on non-CO₂-related
32 warming combines these factors.

33 In cost-optimal scenarios, regions will mostly achieve net zero emissions as a function of options for
34 emission reduction, CDR, and expected baseline emission growth (van Soest et al. 2021b). This
35 typically implies relatively early net zero emission years in scenarios for the Latin America region and
36 relatively late net zero years for Asia and Africa (and average values for OECD countries). However,
37 an allocation based on equity principles (such as responsibility, capability and equality) might result
38 in different carbon neutrality years, based on the principles applied – with often earlier net zero years
39 for the OECD (Fyson et al. 2020; van Soest et al. 2021b). Therefore, the emission trajectory until net
40 zero emissions is a critical determinant of future warming (see Section 3.5). The more CO₂ is emitted
41 until 2030, the less CO₂ can be emitted after that to stay below a warming limit (Riahi et al. 2015). As
42 discussed before, also non-CO₂ forcing plays a key role in the short term.

5 This cross-chapter box surveys scientific, technical and policy aspects of net zero carbon dioxide
6 (CO₂) and net zero greenhouse gas (GHG) emissions, with a focus on timing, the relationship with
7 warming levels, and sectoral and regional characteristics of net zero emissions. Assessment of net
8 zero GHG emissions additionally requires consideration of non-CO₂ gases and choice of GHG
9 emission metrics used to aggregate emissions and removals of different GHGs (Cross-Chapter Box 2
10 in Chapter 2; Cross-Chapter Box 7 in Chapter 10). The following considers net zero CO₂ and GHG
11 emissions globally, followed by regional and sectoral dimensions.

12 *Net zero CO₂*

14 **Reaching net zero CO₂ emissions globally is necessary for limiting global warming to any level.**
15 At the point of net zero CO₂, the amount of CO₂ human activity is putting into the atmosphere equals
16 the amount of CO₂ human activity is removing from the atmosphere (see Glossary). Reaching and
17 sustaining net zero CO₂ emissions globally stabilizes CO₂-induced warming. Reaching net zero CO₂
18 emissions and then moving to net negative CO₂ emissions globally leads to a peak and decline in
19 CO₂-induced warming (WGI AR6 Chapter 5.5, 5.6).

20 **Limiting warming to 1.5°C or likely to 2°C requires deep, rapid, and sustained reductions of**
21 **other greenhouse gases including methane alongside rapid reductions of CO₂ emissions to net**
22 **zero.** This ensures that the warming contributions from non-CO₂ forcing agents as well as from CO₂
23 emissions are both limited at low levels. WGI estimated remaining carbon budgets until the time of
24 reaching net zero CO₂ emissions for a range of warming limits, taking into account historical CO₂
25 emissions and projections of the warming from non-CO₂ forcing agents (WGI AR6 Chapter 5.5,
26 Cross-chapter box 3).

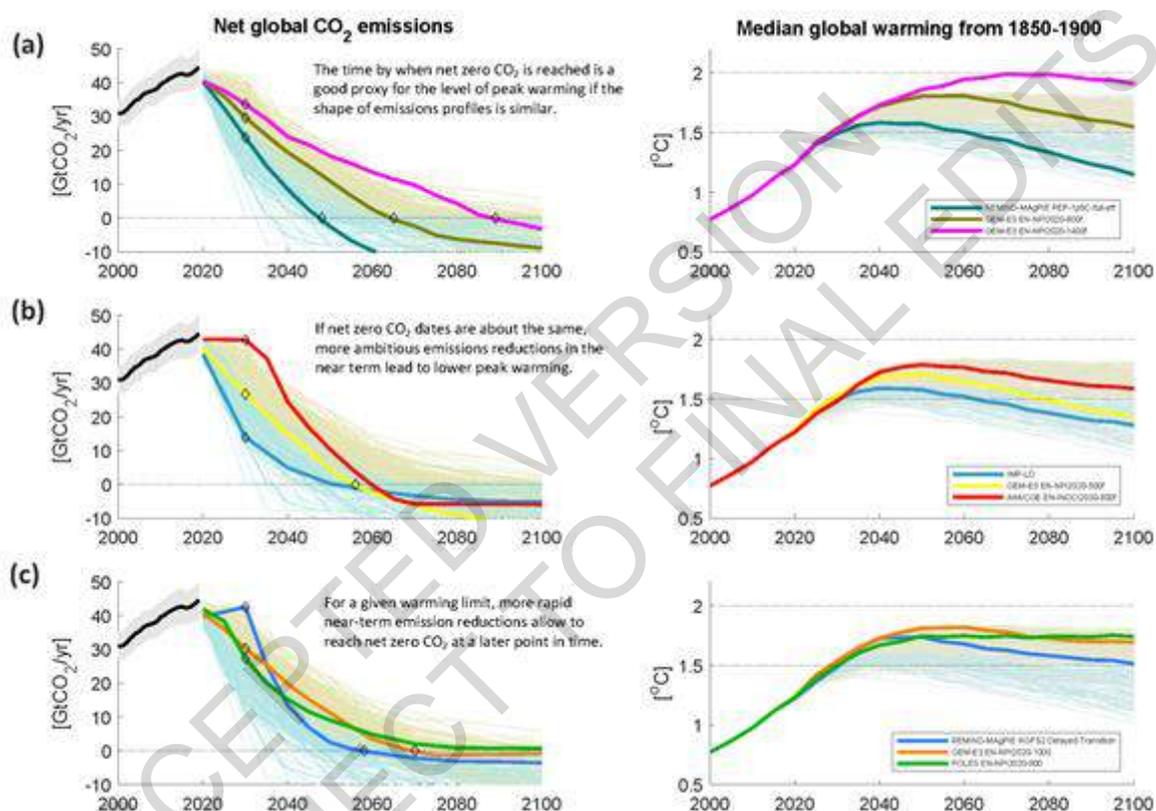

27 **The earlier global net zero CO₂ emissions are reached, the lower the cumulative net amount of**
28 **CO₂ emissions and human-induced global warming, all else being equal** (Figure 1a in this Box).
29 For a given net zero date, a variation in the shape of the CO₂ emissions profile can lead to a variation
30 in the cumulative net amount of CO₂ emissions until the time of net zero CO₂ and as a result to
31 different peak warming levels. For example, cumulative net CO₂ emissions until the time of reaching
32 net zero CO₂ will be smaller, and peak warming lower, if emissions are reduced steeply and then more
33 slowly compared to reducing emissions slowly and then more steeply (Figure 1b in this Box).

34 **Net zero CO₂ emissions are reached between 2050-2055 (2035-2070) in global emissions**
35 **pathways limiting warming to 1.5°C with no or limited overshoot, and between 2070-2075**
36 **(2060-...) in pathways likely limiting warming to 2°C as reported in the AR6 scenario database**
37 **(median five-year interval and 5th-95th percentile ranges)³.** The variation of non-CO₂ emissions in 1.5-
38 2°C pathways varies the available remaining carbon budget which can move the time of reaching net
39 zero CO₂ in these pathways forward or backward⁴. The shape of the CO₂ emissions reduction profile

FOOTNOTE ³ A small fraction of pathways in the AR6 scenarios database that likely limit warming to 2°C (9%) or are as likely as not to limit warming to 2°C (14%) do not reach net-zero CO₂ emissions during the 21st century. This is not inconsistent with the fundamental scientific requirement to reach net-zero CO₂ emissions for a stable climate, but reflects that in some pathways, concurrent reductions in non-CO₂ emissions temporarily compensate for on-going warming from CO₂ emissions. These would have to reach net-zero CO₂ emissions eventually after 2100 to maintain these warming limits. For the two classes of pathways, the 95th percentile cannot be deduced from the scenario database as more than 5% of them do not reach net zero CO₂ by 2100.

FOOTNOTE ⁴ WGI Chapter 5.5 estimates a variation of the remaining carbon budget by ± 220 GtCO₂ due to variations of the non-CO₂ warming contribution in 1.5-2°C pathways. This translates to a shift of the timing of

1 also affects the time of reaching net zero CO₂ (Figure 1c in this Box). Global emission pathways that
 2 more than halve CO₂ emissions from 2020 to 2030 can follow this rapid reduction by a more gradual
 3 decline towards net zero CO₂ and still limit warming to 1.5°C with no or limited overshoot, reaching
 4 the point of net zero after 2050. The literature since SR1.5 included a larger fraction of such pathways
 5 than were available at the time of SR1.5. This is the primary reason for the small backward shift in the
 6 median estimate of reaching global net zero CO₂ emissions in 1.5°C pathways collected in the AR6
 7 scenario database compared to SR1.5. This does not mean that the world is assessed to have more
 8 time to rapidly reduce current emissions levels compared to SR1.5. The assessment of emissions
 9 reductions by 2030 and 2040 in pathways limiting warming to 1.5°C with no or limited overshoot has
 10 not changed substantially. It only means that the exact timing of reaching net zero CO₂ after a steep
 11 decline of CO₂ emissions until 2030 and 2040 can show some variation, and the SR1.5 median value
 12 of 2050 is still close to the middle of the current range (Figure 1c in this Box).

13

14 **Cross-Chapter Box 3 Figure 1: Selected global CO₂ emissions trajectories with similar shape and**
 15 **different net zero CO₂ date (Panel a), different shape and similar net zero CO₂ date (Panel b), and similar**
 16 **peak warming, but varying shapes and net zero CO₂ dates (Panel c). Funnels show pathways limiting**
 17 **warming to 1.5°C with no or limited overshoot (light blue) and likely limiting warming to 2°C (beige).**
 18 **Historic CO₂ emissions from Chapter 2.2 (EDGAR v6).**

19 **Pathways coinciding with emissions levels projected from the implementation of current NDCs**
 20 **would result in substantially (>0.1°C) exceeding 1.5°C. They would have to reach net zero CO₂**

net zero CO₂ by about ±10 years, assuming global CO₂ emissions decrease linearly from current levels of around 40 GtCO₂ to net zero.

1 **around 5-10 years later⁵ than in pathways with no or limited overshoot in order to reach the net**
2 **negative emissions that would then be required to return warming to 1.5°C by 2100.** Those high
3 overshoot pathways have higher transient warming and higher reliance on net-negative CO₂ emissions
4 towards the end of the 21st century. As they need to reach net zero CO₂ only a few years later, with
5 2030 CO₂ emission levels being around twice as high, they imply post-2030 CO₂ emissions reduction
6 rates that are almost double that of pathways limiting warming to 1.5°C with no or limited overshoot
7 (Section 3.5).

8 **Pathways following emissions levels projected from the implementation of current NDCs until**
9 **2030 would have to reach net zero CO₂ around 10 years earlier⁶ than cost-effective pathways to**
10 **likely limit warming to 2°C.** While cost-effective pathways take around 50-55 years to reach net
11 zero CO₂ emissions, those pathways would only have 35-40 years left for transitioning to net zero
12 CO₂ from 2030 onwards, close to the transition times that 1.5°C pathways are faced with today.
13 Current CO₂ emissions and 2030 emission levels projected under the current NDCs are in a similar
14 range. (3.5, 4.2)

15 *Net zero GHG emissions*

16 **The amount of CO₂-equivalent emissions and the point when net zero GHG emissions are**
17 **reached in multi-GHG emissions pathways depends on the choice of GHG emissions metric.**
18 Various GHG emission metrics are available for this purpose⁷. GWP100 is the most commonly used
19 metric for reporting CO₂-equivalent emissions and is required for emissions reporting under the
20 Rulebook of the Paris Agreement. (Cross-Chapter Box 2 in Chapter 2, Annex II section 9, Annex I)

21 **For most choices of GHG emissions metric, reaching net zero GHG emissions requires net**
22 **negative CO₂ emissions in order to balance residual CH₄, N₂O and F-gas emissions.** Under
23 foreseen technology developments, some CH₄, N₂O and F-gas emissions from, e.g., agriculture and
24 industry will remain over the course of this century. Net negative CO₂ emissions will therefore be
25 needed to balance these remaining non-CO₂ GHG emissions to obtain net zero GHG emissions at a
26 point in time after net zero CO₂ has been reached in emissions pathways. Both the amount of net
27 negative CO₂ emissions and the time lag to reaching net zero GHG depend on the choice of GHG
28 emission metric.

29 **Reaching net zero GHG emissions globally in terms of GWP100 leads to a reduction in global**
30 **warming from an earlier peak.** This is due to net negative CO₂ emissions balancing the GWP100-
31 equivalent emissions of short lived GHG emissions, which by themselves do not contribute to further
32 warming if sufficiently declining (Fuglestad et al. 2018; Rogelj et al. 2021). Hence, 1.5-2°C

FOOTNOTE ⁵ Pathways following emissions levels of current NDCs to 2030 and then returning median warming to below 1.5°C in 2100 reach net zero during 2055-2060 (2045-2070) (median five year interval and 5th-95th percentile range).

FOOTNOTE ⁶ Pathways that follow emission levels projected from the implementation of current NDCs until 2030 and that still likely limit warming to 2°C reach net zero CO₂ emissions during 2065 - 2070 (2060 - ...) compared with 2075 - 2080 (2060 - ...) in cost-effective pathways acting immediately to likely limit warming to 2°C (median five year interval and 5th-95th percentile range). See Footnote 1 for the lack of 95th percentile. (Chapter 3.3 Table 3.1.)

FOOTNOTE ⁷ Defining net zero GHG emissions for a basket of greenhouse gases (GHGs) relies on a metric to convert GHG emissions including methane (CH₄), nitrous oxide (N₂O), fluorinated gases (F-gases), and potentially other gases, to CO₂-equivalent emissions. The choice of metric ranges from Global Warming Potentials (GWPs) and Global Temperature change Potentials (GTP) to economically-oriented metrics. All metrics have advantages and disadvantages depending on the context in which they are used (Cross-Chapter Box 2 in Chapter 2).

1 emissions pathways in the AR6 scenario database that reach global net zero GHG emissions in the
2 second half of the century show warming being halted at some peak value followed by a gradual
3 decline towards the end of the century (WGI Chapter 1 Box 1.4).

4 **Global net zero GHG emissions measured in terms of GWP100 are reached between 2095-2100**
5 **(2055 - ...)⁸ in emission pathways limiting warming to 1.5°C with no or limited overshoot**
6 (median and 5th-95th percentile). Around 50% of pathways limiting warming to 1.5°C with no or
7 limited overshoot and 70% of pathways limiting likely warming to 2°C do not reach net zero GHG
8 emissions in terms of GWP100 before 2100. These pathways tend to show less reduction in warming
9 after the peak than pathways that reach net zero GHG emissions. For the subset of pathways that
10 reach net zero GHG emissions before 2100, including 90% of pathways that return warming to 1.5°C
11 by 2100 after a high (>0.1°C) overshoot, the time lag between reaching net zero CO₂ and net zero
12 GHG is 11-14 (6-40) years and the amount of net negative CO₂ emissions deployed to balance non-
13 CO₂ emissions at the time of net zero is -6 to -7 (-10 to -4) GtCO₂ (range of medians and lowest 5th
14 to highest 95 percentile across the four scenario classes that limit median warming to 2°C or lower).
15 (section 3.3, Table 3.1)

16 *Sectoral and regional aspects of net zero*

17 **The timing of net zero CO₂ or GHG emissions may differ across regions and sectors. Achieving**
18 **net zero emissions globally implies that some sectors and regions must reach net zero CO₂ or**
19 **GHG ahead of the time of global net zero CO₂ or GHG if others reach it later.** Similarly, some
20 sectors and regions would need to achieve net negative CO₂ or GHG emissions to compensate for
21 continued emissions by other sectors and regions after the global net zero year. Differences in the
22 timing to reach net zero emissions between sectors and regions depend on multiple factors, including
23 the potential of countries and sectors to reduce GHG emissions and undertake carbon dioxide
24 removal, the associated costs, and the availability of policy mechanisms to balance emissions and
25 removals between sectors and countries (Fyson et al. 2020; Strefler et al. 2021a; van Soest et al.
26 2021b). A lack of such mechanisms could lead to higher global costs to reach net zero emissions
27 globally, but less interdependencies and institutional needs (Fajardy and Mac Dowell 2020). Sectors
28 will reach net zero CO₂ and GHG emissions at different times if they are aiming for such targets with
29 sector-specific policies or as part of an economy-wide net zero emissions strategy integrating
30 emissions reductions and removals across sectors. In the latter case, sectors with large potential for
31 achieving net-negative emissions would go beyond net zero to balance residual emissions from
32 sectors with low potential which in turn would take more time compared to the case of sector-specific
33 action. Global pathways project global AFOLU emissions to reach global net zero CO₂ the earliest,
34 around 2030-2035 in pathways likely to limit warming to 2°C and below, by rapid reduction of
35 deforestation and enhancing carbon sinks on land, although net zero GHG emissions from global
36 AFOLU are typically reached 30 years later, if at all. The ability of global AFOLU CO₂ emissions to
37 reach net zero as early as in the 2030s in modelled pathways hinges on optimistic assumptions about
38 the ability to establish global cost-effective mechanisms to balance emissions reductions and removals
39 across regions and sectors. These assumptions have been challenged in the literature and the Special
40 Report on Climate Change and Land (IPCC SRCCL).

41 **The adoption and implementation of net zero CO₂ or GHG emission targets by countries and**
42 **regions also depends on equity and capacity criteria.** The Paris Agreement recognizes that peaking
43 of emissions will occur later in developing countries (Article 4.1). Just transitions to net zero CO₂ or
44 GHG could be expected to follow multiple pathways, in different contexts. Regions may decide about
45 net zero pathways based on their consideration of potential for rapid transition to low-carbon
46 development pathways, the capacity to design and implement those changes, and perceptions of
47 equity within and across countries. Cost-effective pathways from global models have been shown to

FOOTNOTE ⁸ The 95th percentile cannot be deduced from the scenario database as more than 5% of pathways do not reach net zero GHG by 2100 (Chapter 3.3 Table 3.1.), hence denoted by -...

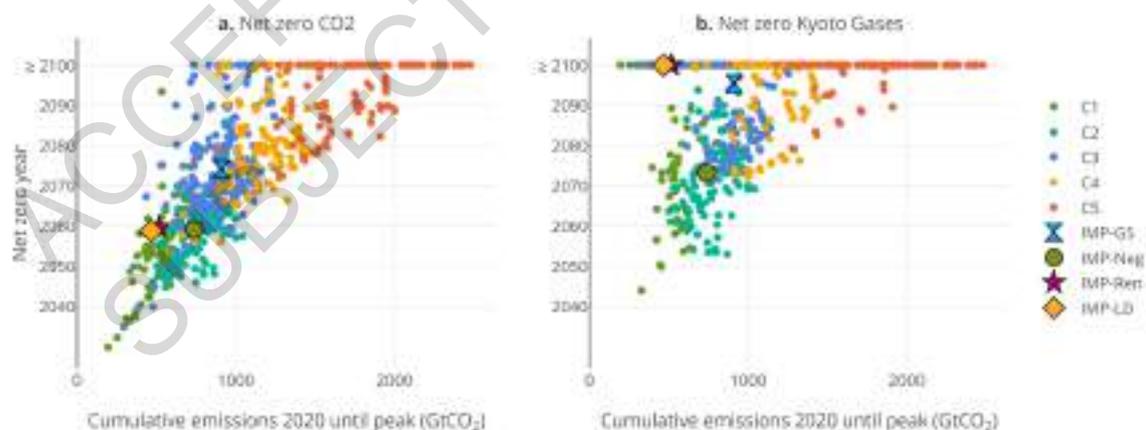

1 distribute the mitigation effort unevenly and inequitably in the absence of financial support
 2 mechanisms and capacity building (Budolfson et al. 2021), and hence would require additional
 3 measures to become aligned with equity considerations (Fyson et al. 2020; van Soest et al. 2021b).
 4 Formulation of net zero pathways by countries will benefit from clarity on scope, roadmaps and
 5 fairness (Rogelj et al. 2021; Smith 2021). Achieving net zero emission targets relies on policies,
 6 institutions and milestones against which to track progress. Milestones can include emissions levels,
 7 as well as markers of technological diffusion.

8 **The accounting of anthropogenic carbon dioxide removal on land matters for the evaluation of**
 9 **net zero CO₂ and net zero GHG strategies.** Due to the use of different approaches between national
 10 inventories and global models, the current net CO₂ emissions are lower by 5.5 GtCO₂, and cumulative
 11 net CO₂ emissions in modelled 1.5-2°C pathways would be lower by 104-170 GtCO₂, if carbon
 12 dioxide removals on land are accounted based on national GHG inventories. National GHG
 13 inventories typically consider a much larger area of managed forest than global models, and on this
 14 area additionally consider the fluxes due to human-induced global environmental change (indirect
 15 effects) to be anthropogenic, while global models consider these fluxes to be natural. Both approaches
 16 capture the same land fluxes, only the accounting of anthropogenic vs. natural emission is different.
 17 Methods to convert estimates from global models to the accounting scheme of national GHG
 18 inventories will improve the use of emission pathways from global models as benchmarks against
 19 which collective progress is assessed. (7.2.2.5, Cross-Chapter Box 3 in this chapter)

20 **Net zero CO₂ and carbon neutrality have different meanings in this assessment, as is the case for**
 21 **net zero GHG and GHG neutrality. They apply to different boundaries in the emissions and**
 22 **removals being considered.** Net zero (GHG or CO₂) refers to emissions and removals under the
 23 direct control or territorial responsibility of the reporting entity. In contrast, (GHG or carbon)
 24 neutrality includes anthropogenic emissions and anthropogenic removals within and also those
 25 beyond the direct control or territorial responsibility of the reporting entity. At the global scale, net
 26 zero CO₂ and carbon neutrality are equivalent, as is the case for net zero GHG and GHG neutrality.
 27 The term “climate neutrality” is not used in this assessment because the concept of climate neutrality
 28 is diffuse, used differently by different communities, and not readily quantified.

33

34

Figure 3.14: Net zero year for CO₂ and all GHGs (based on AR6 GWP-100) as a function of remaining carbon budget and temperature outcomes (not that stabilize (near) zero are also included in determining the net zero year)

35

36

37

38

Table 3.2 summarizes the key characteristics for all temperature categories in terms of cumulative CO₂ emissions, near-term emission reductions, and the years of peak emission and net zero CO₂ and GHG emissions. The table shows again that many pathways in the literature likely limit global warming to 2°C or limit warming to 1.5°C with limited overshoot compared to preindustrial levels.

1 Cumulative net CO₂ emissions from the year 2020 until the time of net zero CO₂ in pathways that
2 limit warming to 1.5°C with no or limited overshoot are 510 (330-710) GtCO₂ and in pathways *likely*
3 to limit warming to below 2.0°C 890 (640-1160) GtCO₂ (see also Cross-Chapter Box 3 in this
4 chapter). Mitigation pathways *likely* to limit global warming to 2°C compared to pre-industrial levels
5 are associated with net global GHG emissions of 40 (32–55) GtCO₂-eq yr⁻¹ by 2030 and 20 (13-26)
6 GtCO₂-eq yr⁻¹ in 2050. These correspond to GHG emissions reductions of 21 (1-42) % by 2030, and
7 64 (53-77) % by 2050 relative to 2019 emission levels. Pathways that limit global warming to below
8 1.5°C with no or limited overshoot require a further acceleration in the pace of the transformation,
9 with GHG emissions reductions of 43 (34–60) % by 2030 and 84 (74–98) % in 2050 relative to
10 modelled 2019 emission levels. The likelihood of limiting warming to below 1.5°C with no or limited
11 overshoot of the most stringent mitigation pathways in the literature (C1) has declined since SR1.5.
12 This is because emissions have risen since 2010 by about 9 GtCO₂ yr⁻¹, resulting in relatively higher
13 near-term emissions of the AR6 pathways by 2030 and slightly later dates for reaching net zero CO₂
14 emissions compared to SR1.5

15
16 Given the larger contribution of scenarios in the literature that aim to reduce net-negative emissions,
17 emission reductions are somewhat larger in the short-term compared to similar categories in the IPCC
18 SR1.5. At the same time, the year of net zero emissions is somewhat later (but only if these rapid,
19 short-term emission reductions are achieved). The scenarios in the literature in C1-C3 show a peak in
20 global emissions before 2025. Not achieving this requires a more rapid reduction after 2025 to still
21 meet the Paris goals (see Section 3.5).
22

- 4 C3 scenarios are sub-categorized according to policy ambition and consistent with Figure SPM 6. Hence the subtotals of C3a & C3b do not match the total of C3 scenarios, as there are C3 scenarios with policy categorizations not covered by C3a and C3b.
- 5 Percentage GHG reduction ranges shown here compare 2019 estimates from historical emissions assessed in Chapter 2 (58 Gt CO₂) to the harmonized and infilled projections from the models. Negative values (e.g., in C7, C8) represent an increase in emissions.
- 6 Gross, % reductions and emissions milestones are based on model data for CO₂ & GHG emissions, which has been harmonized to 2015 values. See also Footnote 6.
- 7 Percentiles reported across all pathways in that category including pathways that do not reach net zero before 2100 (fraction in square brackets). If the fraction of pathways that reach net zero before 2100 (one minus fraction in square brackets) is lower than the fraction of pathways covered by a percentile (e.g., 0.95 for the 95th percentile), the percentile is not defined and denoted with "...".
- 8 For cases where models do not report all GHGs, missing GHG species are infilled and calculated as Kyoto basket with AR6 GWP-100 CO₂-equivalent factors. For each scenario, a minimum of native reporting of CO₂, CH₄, and N₂O emissions to 2100 was required for the assessment of the climate response and assignment to a climate category. Emissions scenarios without climate assessment are not included in the ranges. See Annex III.
- 9 For better comparability with the WGI assessment of the remaining carbon budget, the cumulative CO₂ emissions of the pathways are harmonized to the 2015 CO₂ emissions levels used in the WGI assessment and are calculated for the future starting on 1 January 2020.
- 10 Temperature change (Global Surface Air Temperature - GSAT) for category (at peak and in 2100), based on the median warming for each scenario assessed using the probabilistic climate model emulators.
- 11 Probability of staying below the temperature thresholds for the scenarios in each category, taking into consideration the range of uncertainty from the climate model emulators consistent with the WGI AR6 assessment. The probabilities refer to the probability at peak temperature. Note that in the case of temperature overshoot (E.g., category C2 and some scenarios in C1), the probabilities at the end of the century are higher than the probability at peak temperature.

1 3.3.2.4 *Mitigation strategies*

2 Detailed sectoral implications are discussed in Section 3.4 and Chapters 5-11 (see also Table 3.3). The
3 stringency of climate policy has clear implications for mitigation action (Figure 3.15). There are a
4 number of important commonalities of pathways likely limiting warming to 2C and below: for
5 instance, they all rely on significant improvement of energy efficiency, rapid decarbonisation of
6 supply and, many of them, CDR (in energy supply or AFOLU), either in terms of net negative
7 emissions or to compensate residual emissions. Still, there are also important differences and the
8 (IMPs) show how different choices can steer the system into alternative directions with different
9 combinations of response options. For decarbonisation of energy supply many options exist, including
10 CCS, nuclear power, and renewables (see Chapter 6). In the majority of the scenarios reaching low
11 greenhouse targets, a considerable amount of CCS is applied (panel d). The share of renewables is
12 around 30-70% in the scenarios reaching a global average temperature change of likely below 2°C and
13 clearly above 40% for scenarios reaching 1.5°C (panel c). Scenarios have been published with 100%
14 renewable energy systems even at a global scale, partly reflecting the rapid progress made for these
15 technologies in the last decade (Breyer and Jefferson 2020; Creutzig et al. 2017; Jacobson et al. 2018).
16 These scenarios do not show in the graph due to a lack of information from non-energy sources. There
17 is a debate in the literature on whether it is possible to achieve a 100% renewable energy system by
18 2050 (Brook et al. 2018). This critically depends on assumptions made on future system integration,
19 system flexibility, storage options, consequences for material demand and the ability to supply high-
20 temperature functions and specific mobility functions with renewable energy. The range of studies
21 published showing 100% renewable energy systems show that it is possible to design such systems in
22 the context of energy system models (Lehtveer and Hedenus 2015a,b; Hong et al. 2014a,b; Zappa et
23 al. 2019; Pfenninger and Keirstead 2015; Sepulveda et al. 2018; IEA 2021b) (see also Box 6.6 in
24 Chapter 6 on 100% renewables in net zero CO₂ systems). Panel e and f, finally, show the contribution
25 of CDR – both in terms of net negative emissions and gross CDR. The contribution of total CDR
26 obviously exceeds the net negative emissions. It should be noted that while a majority of scenarios
27 relies on net negative emissions to reach stringent mitigation goals – this is not the case for all of
28 them.

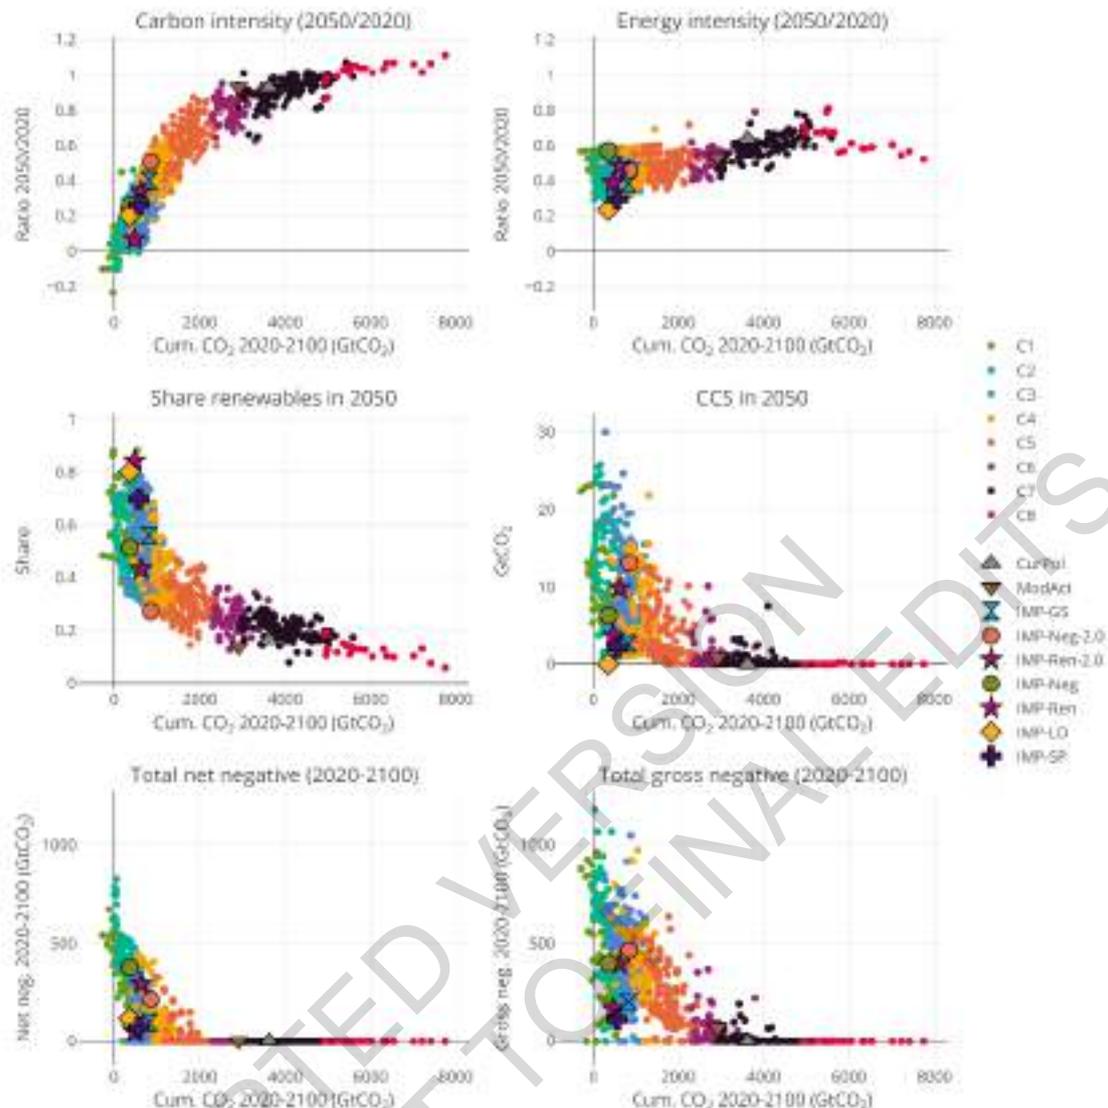

Figure 3.15: Characteristics of scenarios as a function of the remaining carbon budget (mean decarbonisation rate is shown as the average reduction in the period 2010-2050 divided by 2010 emissions). The categories C1-C7 are explained in Table 3.1

1
2
3
4
5

6 The spread shown in Figure 3.15 implies different mitigation strategies that could all lead to
7 emissions levels consistent with the Paris Agreement (and reach zero emissions). The IMPs illustrate
8 some options for different decarbonization pathways with heavy reliance on renewables (**Ren**), strong
9 emphasis on energy demand reductions (**LD**), wide-spread deployment of CDR methods coupled with
10 CCS (BECCS and DACCS) (**Neg**), mitigation in the context of sustainable development (**SP**) (Figure
11 3.16). For example, in some scenarios, a small part of the energy system is still based on fossil fuels in
12 2100 (**Neg**), while in others, fossil fuels are almost or completely phased out (**Ren**). Nevertheless, in
13 all scenarios, fossil fuel use is greatly reduced and unabated coal use is completely phased out by
14 2050. Also, nuclear power can be part of a mitigation strategy (however, the literature only includes
15 some scenarios with high-nuclear contributions, such as Berger et al. (2017)). This is explored further
16 in Section 3.5. The different strategies are also clearly apparent in the way they scenarios reach net
17 zero emissions. While **GS** and **Neg** rely significantly on BECCS and DACCS, their use is far more
18 restricted in the other IMPs. Consistently, in these IMPs also residual emissions are also significantly
19 lower.

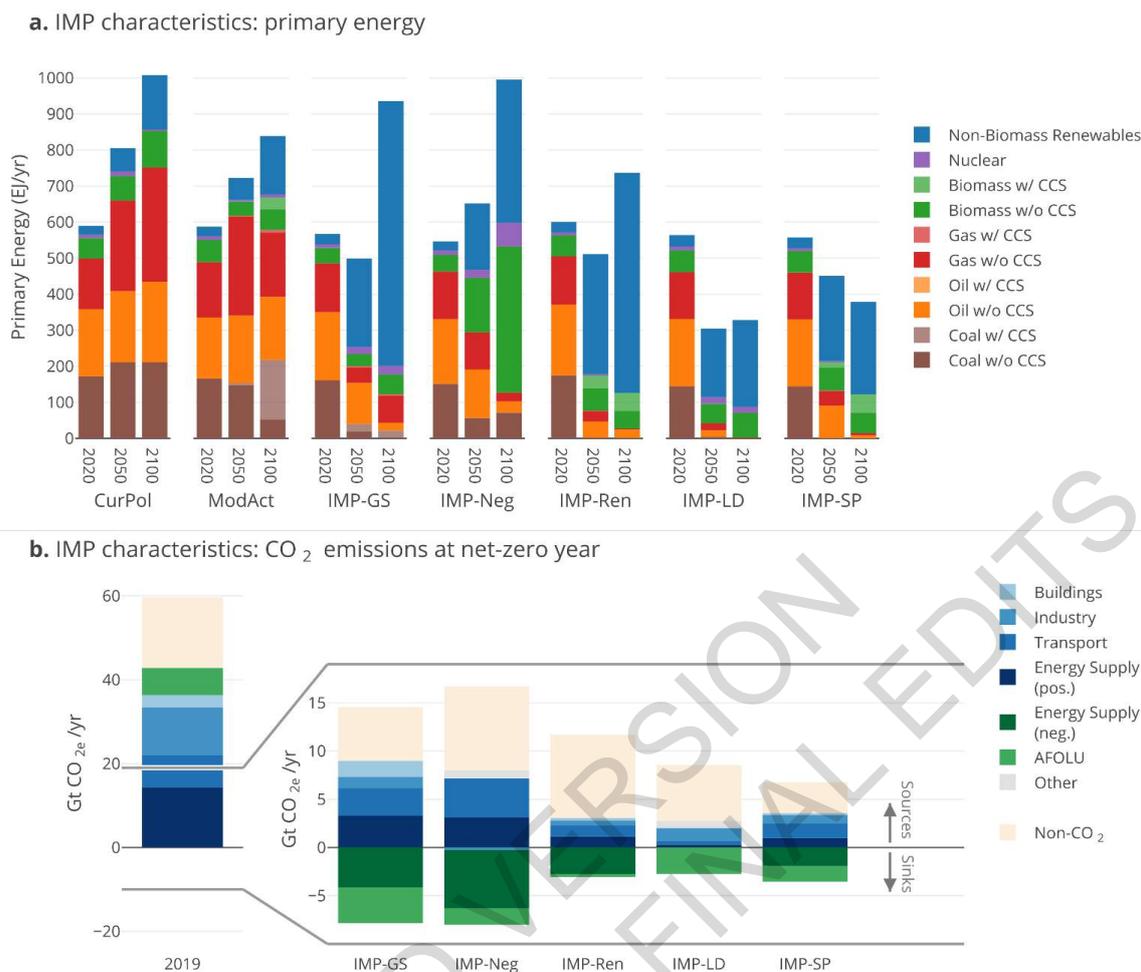

Figure 3.16: Primary energy use and net emissions at net zero year for the different IMPS

Mitigation pathways also have a regional dimension. In 2010, about 40% of emissions originated from the Developed Countries and Eastern Europe and west-central Asia regions. According to the projections shown in

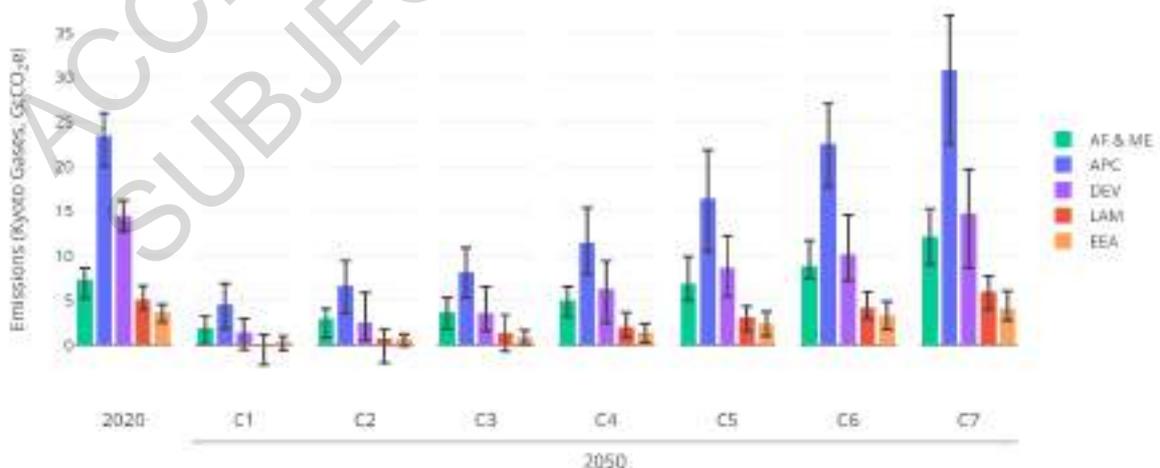

Figure 3.17, the share of the latter regions will further increase to about 70% by 2050. In the scenarios in the literature, emissions are typically almost equally reduced across the regions.

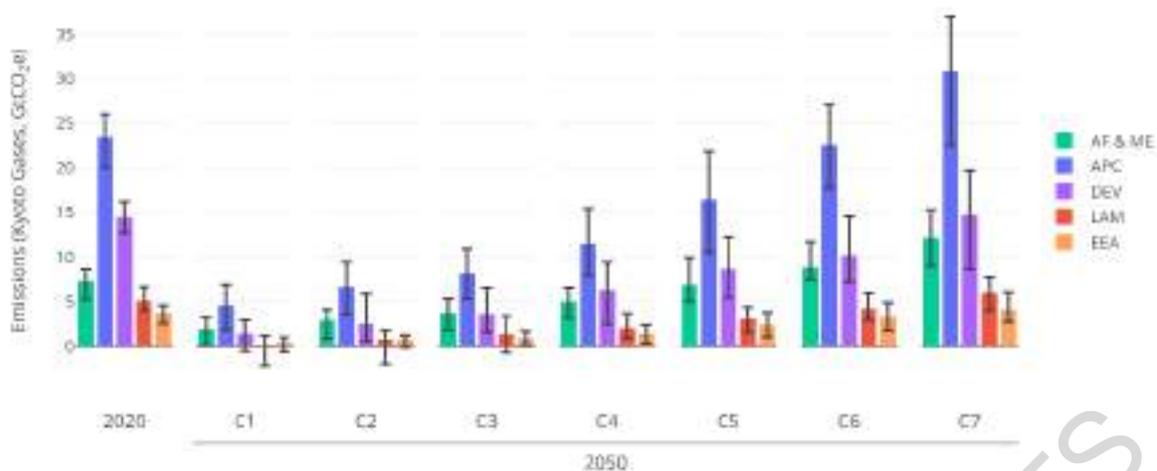

Figure 3.17⁹: Emissions by region (including 5-95th percentile range)

3.3.3 Climate impacts on mitigation potential

At the moment, climate change impact on mitigation potential is hardly considered in model-based scenarios. While a detailed overview of climate impacts is provided in IPCC WGII and Section 3.6 discusses the economic consequences, here we concentrate on the implications for mitigation potential. Climate change directly impacts the carbon budget via all kinds of feedbacks – which is included in the ranges provided for the carbon budget (e.g., 300-900 GtCO₂ for 17th-83rd percentile for not exceeding 1.5 °C; see Chapter 5 IPCC, 2021). Climate change, however, alters the production and consumption of energy (see also Chapter 6.5). An overview of the literature is provided by Yalew et al. (2020). In terms of supply, impacts could influence the cooling capacity of thermal plants, the potential and predictability of renewable energy, and energy infrastructure (Cronin et al. 2018a; van Vliet et al. 2016; Turner et al. 2017; Lucena et al. 2018; Gernaat et al. 2021; Yalew et al. 2020). Although the outcomes of these studies differ, they seem to suggest that although impacts might be relatively small at the global scale, they could be substantial at the regional scale (increasing or decreasing potential). Climate change can also impact energy demand, with rising temperatures resulting in decreases in heating demand and increases in cooling demand (Isaac and van Vuuren 2009; Zhou et al. 2014; Labriet et al. 2015; McFarland et al. 2015; Auffhammer et al. 2017; Clarke et al. 2018; van Ruijven et al. 2019; Yalew et al. 2020). As expected, the increase in cooling demand dominates the impact in warm regions and decreases in heating demand in cold regions (Clarke et al. 2018; Zhou et al. 2014; Isaac and van Vuuren 2009). Globally, most studies show a net increase in energy demand at the end of the century due to climate impacts (van Ruijven et al. 2019; Isaac and van Vuuren 2009; Clarke et al. 2018); however, one study shows a net decrease (Labriet et al. 2015). Only a few studies quantify the combined impacts of climate change on energy supply and energy demand (Emodi et al. 2019; Steinberg et al. 2020; McFarland et al. 2015; Mima and Criqui 2015). These studies show increases in electricity generation in the USA (McFarland et al. 2015; Steinberg et al. 2020) and increases in CO₂ emissions in Australia (Emodi et al. 2019) or the USA (McFarland et al. 2015).

Climate change can impact the potential for AFOLU mitigation action by altering terrestrial carbon uptake, crop yields and bioenergy potential (see also Chapter 7). Carbon sequestration in forests may be positively or adversely affected by climate change and CO₂ fertilization. On the one hand, elevated CO₂ levels and higher temperatures could enhance tree growth rates, carbon sequestration, and timber and biomass production (Beach et al. 2015; Kim et al. 2017; Anderegg et al. 2020). On the other hand,

FOOTNOTE⁹ The countries and areas classification in this figure deviate from the standard classification scheme adopted by WGIII as set out in Annex II, section 1.

1 climate change could lead to greater frequency and intensity of disturbance events in forests, such as
 2 fires, prolonged droughts, storms, pests and diseases (Kim et al. 2017; Anderegg et al. 2020). The
 3 impact of climate change on crop yields could also indirectly impact the availability of land for
 4 mitigation and AFOLU emissions (Meijl et al. 2018; Calvin et al. 2013; Kyle et al. 2014; Bajželj and
 5 Richards 2014; Beach et al. 2015). The impact is, however, uncertain, as discussed in WGII Chapter
 6 5. A few studies estimate the effect of climate impacts on AFOLU on mitigation, finding increases in
 7 carbon prices or mitigation costs by 1-6% in most scenarios (Calvin et al. 2013; Kyle et al. 2014).

8
 9 In summary, a limited number of studies quantify the impact of climate on emissions pathways. The
 10 most important impact in energy systems might be through the impact on demand, although climate
 11 change could also impact renewable mitigation potential –certainly at the local and regional scale.
 12 Climate change might be more important for land-use related mitigation measures, including
 13 afforestation, bioenergy and nature-based solutions. The net effect of changes in climate and CO₂
 14 fertilization are uncertain but could be substantial (see also Chapter 7).

16 3.4 Integrating sectoral analysis into systems transformations

17 This section describes the role of sectors in long-term emissions pathways (see Table 3.3). We discuss
 18 both sectoral aspects of IAM pathways and some insights from sectoral studies. Sectoral studies
 19 typically include more detail and additional mitigation options compared to IAMs. However, sectoral
 20 studies miss potential feedbacks and cross-sectoral linkages that are captured by IAMs. Additionally,
 21 since IAMs include all emissions sources, these models can be used to identify pathways to a
 22 particular climate goals. In such pathways, emissions are balanced across sectors typically based on
 23 relative marginal abatement costs; as a result, some sectors are sources and some are sinks at the time
 24 of net zero CO₂ emissions. For these reasons, the mitigation observed in each sector in an IAM may
 25 differ from the potential in sectoral studies. Given the strengths and limitations of each type of model,
 26 IAMs and sectoral models are complementary, providing different perspectives.

27
 28 **Table 3.3: Section 3.4 structure, definitions, and relevant chapters**

Section	Sector	What is included	Relevant chapter(s)
3.4.1	Cross-sector	Supply and demand, bioenergy, timing of net zero CO ₂ , other interactions among sectors	Chapter 5, 12
3.4.2	Energy supply	Energy resources, transformation (e.g., electricity generation, refineries, etc.)	Chapter 6
3.4.3	Buildings ¹	Residential and commercial buildings, other non-specified ²	Chapter 9
3.4.4	Transportation ¹	Road, rail, aviation, and shipping	Chapter 10
3.4.5	Industry ¹	Industrial energy use and industrial processes	Chapter 11
3.4.6	AFOLU	Agriculture, forestry, and other land use	Chapter 7
3.4.7	Other CDR	CDR options not included in individual sectors (e.g., direct air carbon capture and sequestration, enhanced weathering)	Chapter 12

29 ¹ Direct energy use and direct emissions only; emissions do not include those associated with energy
 30 production

31 ² Other non-specified fuel use, including military. Some models report this category in the buildings
 32 sector, while others report it in the “Other” sector

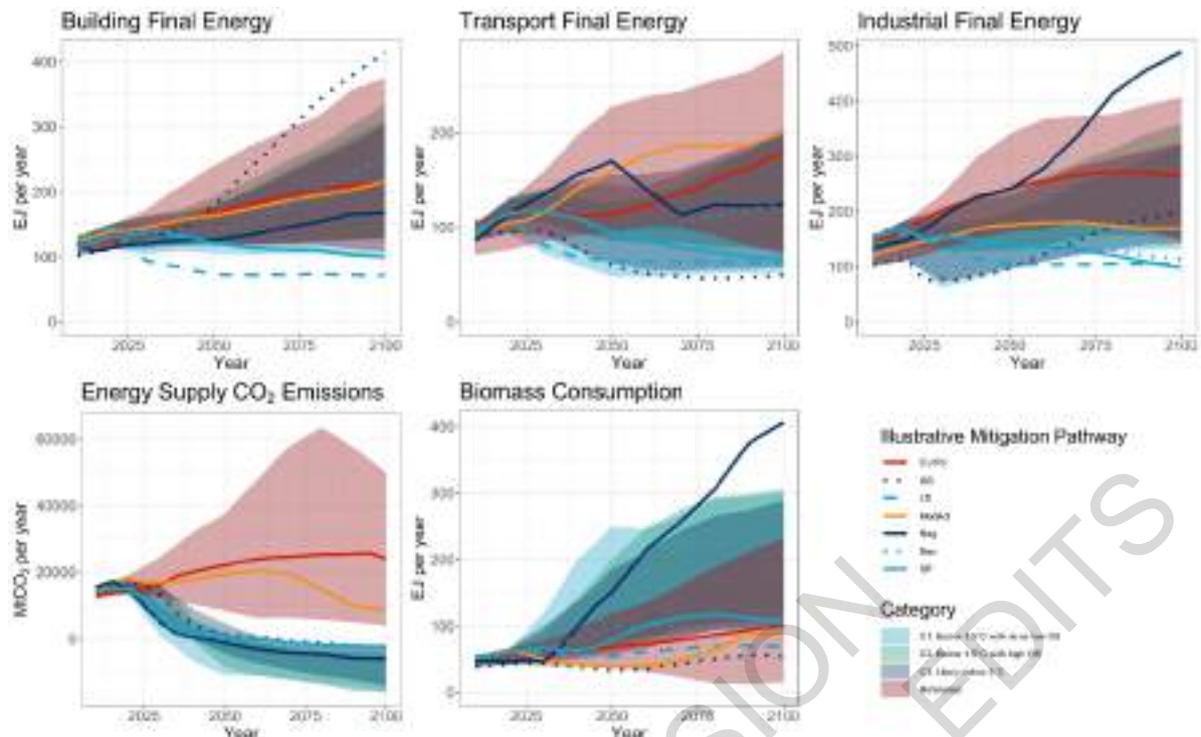

1 3.4.1 Cross-sector linkages

2 3.4.1.1 Demand and supply strategies

3 Most IAM pathways rely heavily on supply-side mitigation strategies, including fuel switching,
4 decarbonization of fuels, and CDR (Creutzig et al. 2016; Bertram et al. 2018; Rogelj et al. 2018b;
5 Mundaca et al. 2019). For demand-side mitigation, IAMs incorporate changes in energy efficiency,
6 but many other demand-side options (e.g., behaviour and lifestyle changes) are often excluded from
7 models (van Sluisveld et al. 2015; Creutzig et al. 2016; Wilson et al. 2019; van den Berg et al. 2019).
8 In addition, this mitigation is typically price-driven and limited in magnitude (Yeh et al. 2017;
9 Sharmina et al. 2020; Luderer et al. 2018; Wachsmuth and Duscha 2019). In contrast, bottom-up
10 modelling studies show considerable potential for demand-side mitigation (Yeh et al. 2017;
11 Wachsmuth and Duscha 2019; Creutzig et al. 2016; Mundaca et al. 2019) (see also Chapter 5), which
12 can slow emissions growth and/or reduce emissions (Samadi et al. 2017; Creutzig et al. 2016).

13
14 A small number of mitigation pathways include stringent demand-side mitigation, including changes
15 in thermostat set points (van Vuuren et al. 2018; van Sluisveld et al. 2016), more efficient or smarter
16 appliances (Grubler et al. 2018; Napp et al. 2019; van Sluisveld et al. 2016), increased recycling or
17 reduced industrial goods (van de Ven et al. 2018; Liu et al. 2018; van Sluisveld et al. 2016; Grubler et
18 al. 2018; Napp et al. 2019), telework and travel avoidance (van de Ven et al. 2018; Grubler et al.
19 2018), shifts to public transit (van Vuuren et al. 2018; van Sluisveld et al. 2016; Grubler et al. 2018),
20 reductions in food waste (van de Ven et al. 2018) and less meat intensive diets (van de Ven et al.
21 2018; van Vuuren et al. 2018; Liu et al. 2018). These pathways show reduced dependence on CDR
22 and reduced pressure on land (van de Ven et al. 2018; van Vuuren et al. 2018; Grubler et al. 2018;
23 Rogelj et al. 2018a) (Chapter 5.3.3). However, the representation of these demand-side mitigation
24 options in IAMs is limited, with most models excluding the costs of such changes (van Sluisveld et al.
25 2016), using stylised assumptions to represent them (van den Berg et al. 2019), and excluding
26 rebound effects (Brockway et al. 2021; Krey et al. 2019). Furthermore, there are questions about the
27 achievability of such pathways, including whether the behavioural changes included are feasible
28 (Azevedo et al. 2021) and the extent to which development and demand can be decoupled (Semieniuk
29 et al. 2021; Steckel et al. 2013; Keyßer and Lenzen 2021; Brockway et al. 2021).

30
31 Figure 3.18: Indicators of demand and supply-side mitigation in the Illustrative Pathways (lines) and
32 the 5-95% range of Reference, 1.5°C and 2°C scenarios (shaded areas). shows indicators of supply-
33 and demand-side mitigation in the IMPs, as well as the range across the database. Two of these IMPs
34 (*SP*, *LD*) show strong reductions in energy demand, resulting in less reliance on bioenergy and
35 limited CDR from energy supply. In contrast, *Neg* has higher energy demand, depending more on
36 bioenergy and net negative CO₂ emissions from energy supply.
37

1
2 **Figure 3.18: Indicators of demand and supply-side mitigation in the Illustrative Pathways (lines) and the**
3 **5-95% range of Reference, 1.5°C and 2°C scenarios (shaded areas).**

4 **3.4.1.2 Sectoral emissions strategies and the timing of net zero**

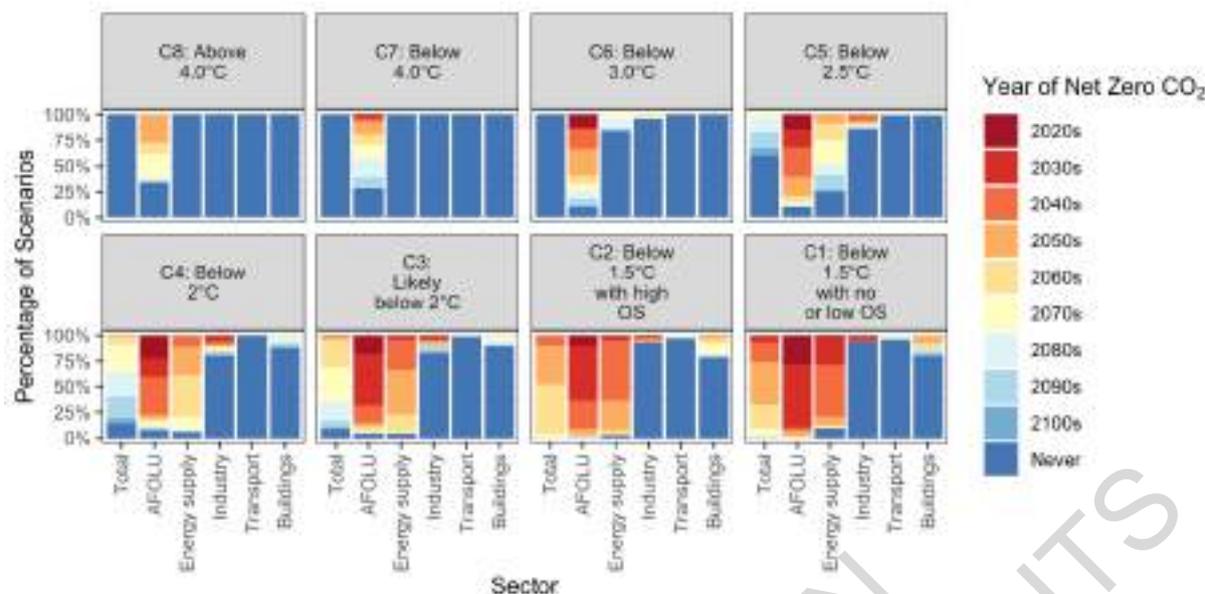

5 Mitigation pathways show differences in the timing of decarbonization (Figure 3.20) and the timing of
6 net zero (Figure 3.19) across sectors and regions (*high confidence*); the timing in a given sector
7 depends on the cost of abatement in it, the availability of CDR options, the scenario design, near-term
8 emissions levels, and the amount of non-CO₂ abatement (Yeh et al. 2017; Emmerling et al. 2019;
9 Rogelj et al. 2019a,b; Johansson et al. 2020; van Soest et al. 2021b; Ou et al. 2021; Azevedo et al.
10 2021) (Cross-Chapter Box 3 in this chapter). However, delaying emissions reductions, or more
11 limited emissions reductions in one sector or region, involves compensating reductions in other
12 sectors or regions if warming is to be limited (*high confidence*) (Rochedo et al. 2018; Price and Keppo
13 2017; Grubler et al. 2018; van Soest et al. 2021b).

1 **Table 3.4: Energy, emissions and CDR characteristics of the pathways by climate category for 2030, 2050, 2100.** Source: AR6 scenarios database

Pathway (2030-2100)	Global Mean Surface Air Temperature Change	Low carbon share of Primary Energy (%) ^{3,4}	CO ₂ intensity of Primary Energy Index 2020 = 100			Final energy demand [EJ/yr] 2020 = 478 (387-590)			Final energy intensity of GDP Index 2020 = 100			Electricity share in final energy (%) 2020 = 28 (19-35)			CO ₂ intensity of electricity [g CO ₂ -e/kWh] 2020 = 589 (498-688)			Non-energy GHG emissions [Gt CO ₂ -e] 2020 = 16 (15-17)			Final CCS (2100) [Gt CO ₂] 2020 = 0 (0-0)				CDR (2100) [Gt CO ₂] 2020 = 0 (0-0)

Footnotes

- 0 Values in the table refer to the 50th and (5th-95th) percentile values.
- 1 Category definitions consider at peak warming and warming at the end-of-century (2100).
 C1: Below 1.5°C in 2100 with a greater than 50% probability and a peak warming higher than 1.5°C with less than 67% probability.
 C2: Below 1.5°C in 2100 with a greater than 50% probability but peak warming higher than 1.5°C with greater than or equal to 67% probability.
 C3: Likely below 2 °C throughout the century with greater than 67% probability.
 C4, C5, C6, C7: Below 2 °C, 2.5 °C, 3 °C and 4 °C throughout the century, respectively, with greater than 50% probability.
 C8: Peak warming above 4 °C with greater than or equal to 50% probability.
- 2 The warming profile of *Neg* peaks around 2060 and declines thereafter to below 1.5°C (50% likelihood) shortly after 2100. Whilst technically classified as a C3, it strongly exhibits the characteristics of C2 high overshoot scenarios.
- 3 Primary Energy as calculated in 'Direct Equivalent' terms according to IPCC reporting conventions.
- 4 Low carbon energy here defined to include: renewables (including biomass, solar, wind, hydro, geothermal, ocean); fossil fuels when used with CCS; and, nuclear power.

1
 2 **Figure 3.19: Decade in which sectoral CO₂ emissions first reach net negative values. Each panel is a**
 3 **different temperature level. The colours indicate the decade in which CO₂ emissions go negative; the y-**
 4 **axis indicates the share of scenarios achieving net zero in that decade. Only scenarios that pass the vetting**
 5 **criteria are included (see Section 3.2). Scenarios achieving net zero prior to 2020 are excluded.**

6 At the time of net zero global CO₂ emissions, emissions in some sectors are positive and some
 7 negative. In cost-effective mitigation pathways, the energy supply sector typically reaches net zero
 8 CO₂ before the economy as a whole, while the demand sectors reach net zero CO₂ later, if at all
 9 (Pietzcker et al. 2014; Price and Keppo 2017; Luderer et al. 2018; Rogelj et al. 2018a,b; Méjean et al.
 10 2019; Azevedo et al. 2021) (Chapter 6.7). CO₂ emissions from transport, industry, and buildings are
 11 positive, and non-CO₂ GHG emissions are also positive at the time of global net zero CO₂ emissions
 12 (Figure 3.20).

 15 **Figure 3.20: Greenhouse gas emissions, including CO₂ emissions by sector and total non-CO₂ GHGs in**
 16 **2050 (top left), 2100 (top middle), year of global net zero CO₂ (top right), cumulative CO₂ emissions from**

1 **2020-2100 (bottom left), and cumulative CO₂ emissions from 2020 until the year of net zero CO₂ for**
 2 **scenarios that limit warming to below 2°C. Scenarios are grouped by their temperature category.**
 3 **“Industry” includes CO₂ emissions associated with industrial energy use only; sectors shown in this figure**
 4 **do not necessarily sum to total CO₂. In this, and other figures in Section 3.4, unless stated otherwise, only**
 5 **scenarios that pass the vetting criteria are included (see Section 3.2). Boxes indicate the interquartile**
 6 **range, the median is shown with a horizontal black line, while vertical lines show the 5 to 95% interval.**

7 So, while pathways indicate some flexibility in emissions reductions across sectors, all pathways
 8 involve substantial CO₂ emissions reductions in all sectors and regions (*high confidence*) (Rogelj et al.
 9 2018a,b; Luderer et al. 2018; Méjean et al. 2019; Azevedo et al. 2021). Projected CO₂ emissions
 10 reductions between 2019 and 2050 in 1.5°C pathways with no or limited overshoot are around 77%
 11 for energy demand, with a 5-95% range of 31 to 96%,¹⁰ 115% for energy supply (90 to 167%), and
 12 148% for AFOLU (94 to 387%). In likely 2°C pathways, projected CO₂ emissions are reduced
 13 between 2019 and 2050 by around 49% for energy demand, 97% for energy supply, and 136% for
 14 AFOLU (see also 3.4.2-3.4.6). Almost 75% of GHG reductions at the time of net zero GHG are from
 15 the energy system, 13% are from AFOLU CO₂, and 13% from non-CO₂ (Figure 3.21). These
 16 reductions are achieved through a variety of sectoral strategies, illustrated in Figure 3.21 (right panel),
 17 and described in Sections 3.4.2 to 3.4.7; the primary strategies include declines in fossil energy,
 18 increases in low carbon energy use, and CDR to address residual emissions.

19

20

21 **Figure 3.21: Left panel: Greenhouse gas emissions reductions from 2019 by sector at the year of net zero**
 22 **GHG for all scenarios that reach net zero GHG. Emissions reductions by sector for direct (demand) and**
 23 **indirect (upstream supply) are shown as the percent of total GHG reductions.**

24 **Right panel: key indicators in 2050 for the IMPs. Definitions of significant and very significant are**
 25 **defined relative to 2019 and vary between indicators, as follows: fossil energy (significant >10%, very**
 26 **significant >50%), renewables (>150 EJ yr⁻¹, >200 EJ yr⁻¹), bioenergy (>100%, >200%), BECCS (>2.0**
 27 **GtCO₂ yr⁻¹, >3.5 GtCO₂ yr⁻¹), AFOLU (>100% decline, >130%), energy crops (>150 million ha, >400),**
 28 **forest (>5% increase, >15%).**

29

30 In the context of mitigation pathways, only a few studies have examined solar radiation modification
 31 (SRM), typically focusing on Stratospheric Aerosol Injection (Emmerling and Tavoni 2018a,b;
 32 Arino et al. 2016; Belaia et al. 2021; Rickels et al. 2020; Heutel et al. 2018; Helweggen et al. 2019).
 33 These studies find that substantial mitigation is required to limit warming to a given level, even if

FOOTNOTE ¹⁰ Unless otherwise specified, the values in parentheses in Section 3.4 from this point forward indicate the 5-95% range.

1 SRM is available (Moreno-Cruz and Smulders 2017; Emmerling and Tavoni 2018b; Belaia et al.
2 2021). SRM may reduce some climate impacts, reduce peak temperatures, lower mitigation costs, and
3 extend the time available to achieve mitigation; however, SRM does not address ocean acidification
4 and may involve risks to crop yields, economies, human health, or ecosystems (WGII Chapter 16;
5 WGI TS; WGI Ch 5; SR1.5 SPM; Cross-Working Group Box 4 in Chapter 14). There also are
6 significant uncertainties surrounding SRM, including uncertainties on the costs and risks, which can
7 substantially alter the amount of SRM used in modelled pathways (Tavoni et al. 2017; NASEM 2021;
8 Heutel et al. 2018; Helwegen et al. 2019; IPCC 2018). Furthermore, the degree of international
9 cooperation can influence the amount of SRM deployed in scenarios, with uncoordinated action
10 resulting in larger SRM deployment and consequently larger risks/impacts from SRM (Emmerling
11 and Tavoni 2018a). Bridging research and governance involves consideration of the full range of
12 societal choices and ramifications (Sugiyama et al. 2018). More information on SRM, including the
13 caveats, risks, uncertainties, and governance issues is found in WGI Chapter 4, WGIII Chapter 14,
14 and Cross-Working Group Box 4 in Chapter 14).

15 16 **3.4.1.3 Linkages among sectors**

17 Mitigation in one sector can be dependent upon mitigation in another sector, or may involve trade-offs
18 between sectors. Mitigation in energy demand often includes electrification (Luderer et al. 2018;
19 Pietzcker et al. 2014; Sharmina et al. 2020; DeAngelo et al. 2021), however such pathways only result
20 in reduced emissions *if* the electricity sector is decarbonized (Zhang and Fujimori 2020) (see also
21 Chapter 12). Relatedly, the mitigation potential of some sectors (e.g., transportation) depends on the
22 decarbonization of liquid fuels, e.g., through biofuels (Wise et al. 2017; Pietzcker et al. 2014;
23 Sharmina et al. 2020); Chapter 12). In other cases, mitigation in one sector results in reduced
24 emissions in another sector. For example, increased recycling can reduce primary resource extraction;
25 planting trees or green roofs in urban areas can reduce the energy demand associated with space
26 cooling (Chapter 12).

27
28 Mitigation in one sector can also result in additional emissions in another. One example is
29 electrification of end use which can result in increased emissions from energy supply. However, one
30 comparatively well-researched example of this linkage is bioenergy. An increase in demand for
31 bioenergy within the energy system has the potential to influence emissions in the AFOLU sector
32 through the intensification of land and forest management and/or via land use change (Smith et al.
33 2019; Daioglou et al. 2019; Smith et al. 2020a; IPCC 2019a). The effect of bioenergy and BECCS on
34 mitigation depends on a variety of factors in modelled pathways. In the energy system, the emissions
35 mitigation depends on the scale of deployment, the conversion technology, and the fuel displaced
36 (Calvin et al. 2021). Limiting or excluding bioenergy and/or BECCS increases mitigation cost and
37 may limit the ability of a model to reach a low warming level (Edmonds et al. 2013; Calvin et al.
38 2014b; Muratori et al. 2020; Luderer et al. 2018). In AFOLU, bioenergy can increase or decrease
39 terrestrial carbon stocks and carbon sequestration, depending on the scale, biomass feedstock, land
40 management practices, and prior land use (Calvin et al. 2014c; Wise et al. 2015; Smith et al. 2019,
41 2020a; IPCC 2019a; Calvin et al. 2021).

42
43 Pathways with very high biomass production for energy use typically include very high carbon prices
44 in the energy system (Popp et al. 2017; Rogelj et al. 2018b), little or no land policy (Calvin et al.
45 2014b), a high discount rate (Emmerling et al. 2019), and limited non-BECCS CDR options (e.g.,
46 afforestation, DACCS) (Fuhrman et al. 2020; Realmonte et al. 2019; Chen and Tavoni 2013;
47 Marcucci et al. 2017; Calvin et al. 2014b). Higher levels of bioenergy consumption are likely to
48 involve trade-offs with mitigation in other sectors, notably in construction (i.e., wood for material and
49 structural products) and AFOLU (carbon stocks and future carbon sequestration), as well as trade-offs
50 with sustainability (Section 3.7) and feasibility concerns (Section 3.8). Not all of these trade-offs are

1 fully represented in all IAMs. Based on sectoral studies, the technical potential for bioenergy, when
2 constraints for food security and environmental considerations are included, are 5-50 and 50-250 EJ
3 yr⁻¹ in 2050 for residues and dedicated biomass production systems, respectively (Chapter 7).
4 Bioenergy deployment in IAMs is within the range of these potentials, with between 75 and 248 EJ
5 yr⁻¹ in 2050 in pathways that limit warming to 1.5°C with no or limited overshoot. Finally, IAMs do
6 not include all potential feedstock and management practices, and have limited representation of
7 institutions, governance, and local context (Butnar et al. 2020; Brown et al. 2019; Calvin et al. 2021).

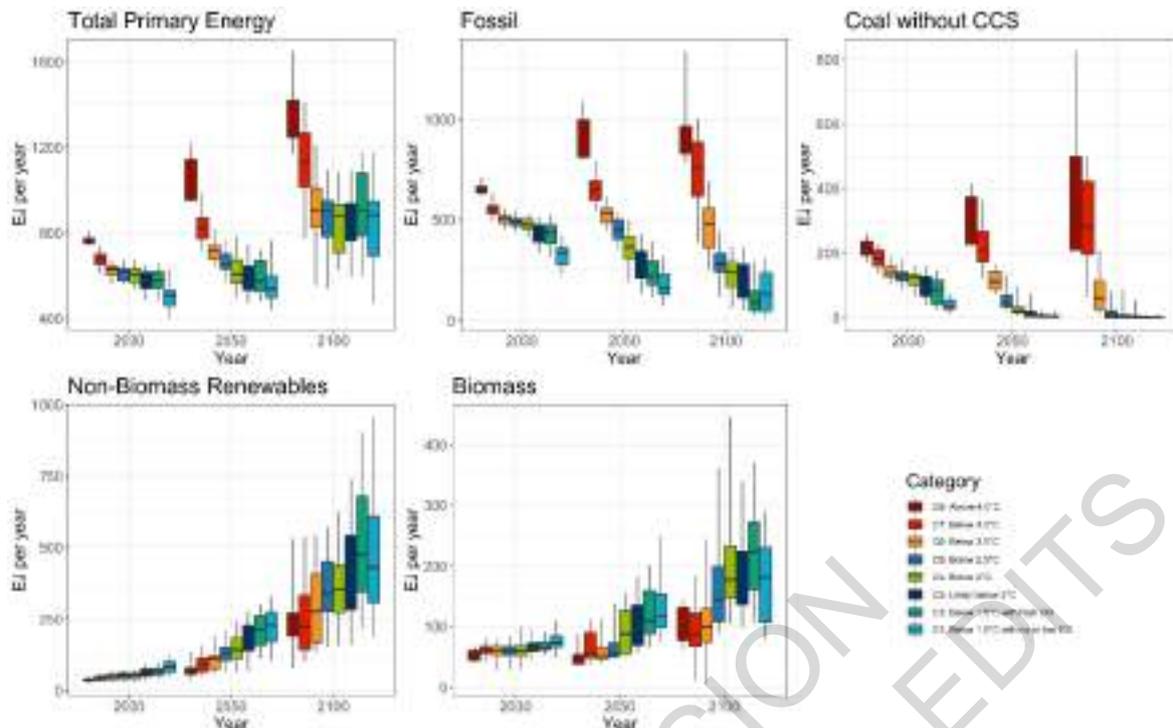

8 The inclusion of CDR options, like BECCS, can affect the timing of emissions mitigation in IAM
9 scenarios, i.e., delays in mitigations actions are compensated by net negative emissions in the second
10 half of the century. However, studies with limited net negative emissions in the long-term require very
11 rapid declines in emissions in the near-term (van Vuuren et al. 2017). Especially in forest-based
12 systems, increased harvesting of forests can perturb the carbon balance of forestry systems, increasing
13 emissions for some period; the duration of this period of increased emissions, preceding net emissions
14 reductions, can be very variable (Mitchell et al. 2012; Lamers and Junginger 2013; Röder et al. 2019;
15 Hanssen et al. 2020; Cowie et al. 2021). However, the factors contributing to differences in recovery
16 time are known (Zanchi et al. 2012; Laganière et al. 2017; Mitchell et al. 2012; Lamers and Junginger
17 2013; Röder et al. 2019). Some studies that consider market-mediated effects find that an increased
18 demand for biomass from forests can provide incentives to maintain existing forests and potentially to
19 expand forest areas, providing additional carbon sequestration as well as additional biomass (Kim et al.
20 2018; Dwivedi et al. 2014; Baker et al. 2019; Favero et al. 2020). However, these responses are
21 uncertain and likely to vary geographically.

22 23 **3.4.2 Energy supply**

24 Without mitigation, energy consumption and supply emissions continue to rise (*high confidence*)
25 (Riahi et al. 2017; Bauer et al. 2017; Kriegler et al. 2016; Mcjeon et al. 2021) (see also Chapter 6.7).
26 While the share of renewable energy continues to grow in reference scenarios, fossil fuel accounts for
27 the largest share of primary energy (Riahi et al. 2017; Bauer et al. 2017; Price and Keppo 2017).

28 In scenarios likely to limit warming to 2°C and below, transition of the energy supply sector to a low
29 or no carbon system is rapid (Rogelj et al. 2016, 2018b; Luderer et al. 2018; Grubler et al. 2018; van
30 Vuuren et al. 2018). CO₂ emissions from energy supply reach net zero around 2041 (2033 to 2057) in
31 pathways limiting warming to below 1.5°C with no or limited overshoot and around 2053 (2040 to
32 2066) in pathways likely to limit warming to 2°C. Emissions reductions continue, with emissions
33 reaching -7.1 GtCO₂ per year (-15 to -2.3 GtCO₂ per year) in 2100 in all pathways likely to limit
34 warming to 2°C and below.

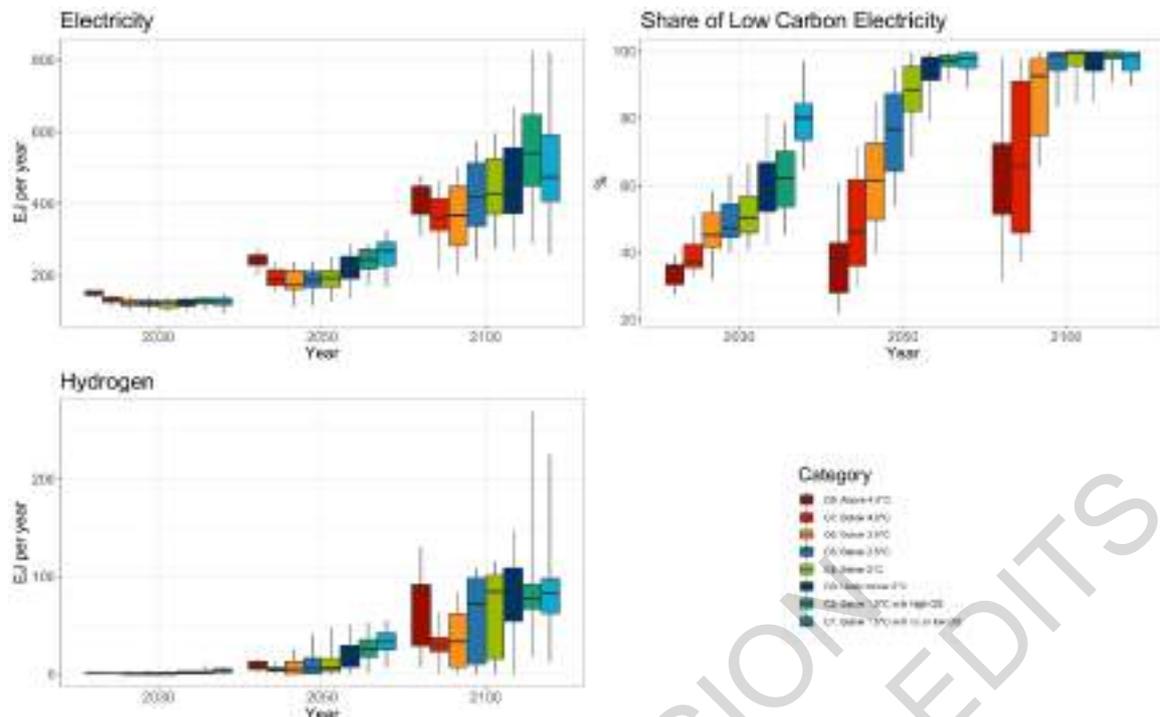

35 All pathways likely to limit warming to 2°C and below show substantial reductions in fossil fuel
36 consumption and a near elimination of the use of coal without CCS (*high confidence*) (Welsby et al.
37 2021; Bauer et al. 2017; van Vuuren et al. 2018; Rogelj et al. 2018a,b; Grubler et al. 2018; Luderer et
38 al. 2018; Azevedo et al. 2021; Mcjeon et al. 2021) (Figure 3.22). In these pathways, the use of coal,
39 gas and oil is reduced by 90, 25, and 41%, respectively, between 2019 and 2050 and 91, 39, and 78%
40 between 2019 and 2100; coal without CCS is further reduced to 99% below its 2019 levels in 2100.
41 These pathways show an increase in low carbon energy, with 88% (69-97%) of primary energy from
42 low carbon sources in 2100, with different combinations of low carbon fuels (e.g., non-biomass
43 renewables, biomass, nuclear, and CCS) (Rogelj et al. 2018a,b; van Vuuren et al. 2018) (Chapter 6.7,
44 Section 3.4.1). Across all pathways likely to limit warming to 2°C and below, non-biomass
45 renewables account for 52% (24 to 77%) of primary energy in 2100 (Pietzcker et al. 2017; Creutzig et
46 al. 2017; Rogelj et al. 2018b); Figure 3.22, Chapter 6). There are some studies analysing the potential
47 for 100% renewable energy systems (Hansen et al. 2019); however, there are a range of issues around
48 such systems (see Chapter 6.6, Box 6.6).

1

2 **Figure 3.22 Primary energy consumption across scenarios: total primary energy (top left), fossil fuels (top**
 3 **middle), coal without CCS (top right), non-biomass renewables (bottom left), and biomass (bottom**
 4 **middle). Scenarios are grouped by their temperature category. Primary energy is reported in direct**
 5 **equivalent, where one unit of nuclear or non-biomass renewable energy output is reported as one unit of**
 6 **primary energy. Not all subcategories of primary energy are shown.**

7 Stringent emissions reductions at the level required to limit warming to 2°C or 1.5°C are achieved
 8 through increased electrification of end-use, resulting in increased electricity generation in all
 9 pathways (*high confidence*) (Figure 3.23) (Rogelj et al. 2018a; Azevedo et al. 2021). Nearly all
 10 electricity in pathways likely to limit warming to 2°C and below is from low or no carbon fuels
 11 (Rogelj et al. 2018a; Azevedo et al. 2021), with different shares of nuclear, biomass, non-biomass
 12 renewables, and fossil CCS across pathways. Low emissions scenarios also show increases in
 13 hydrogen use (Figure 3.23).

1

2

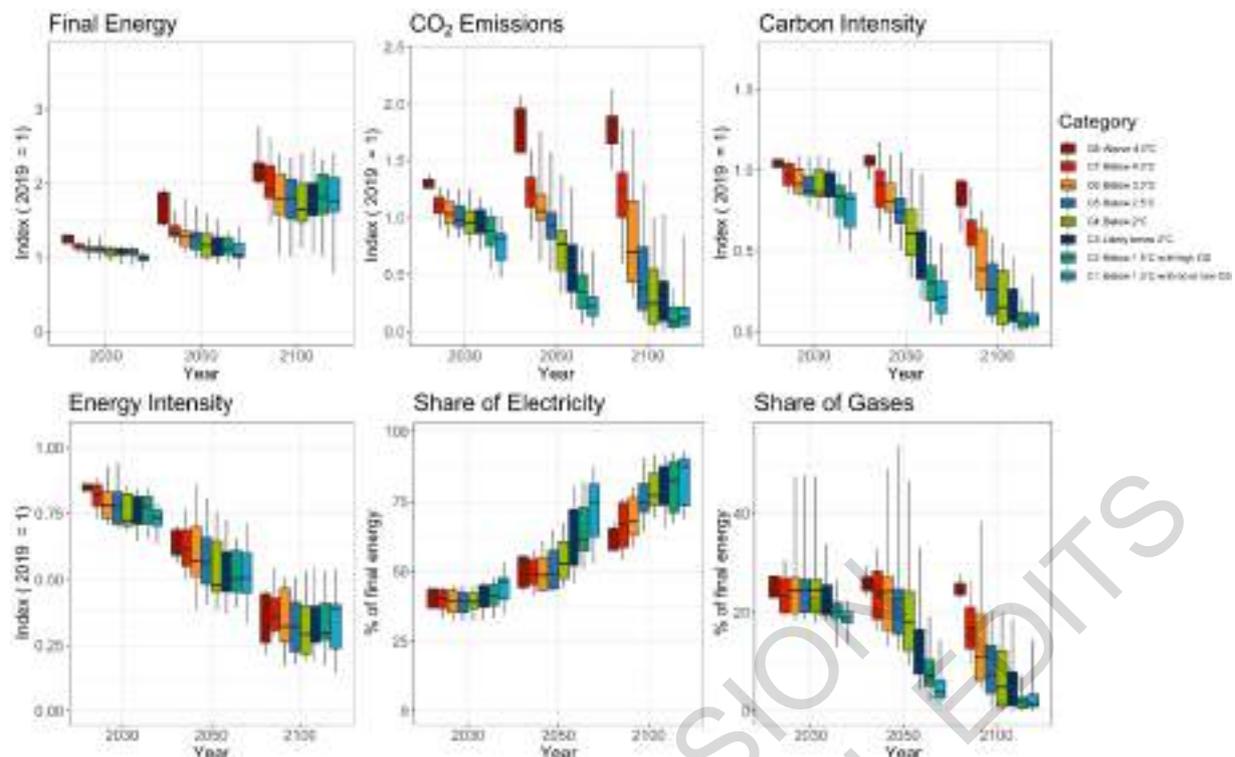

3 **Figure 3.23: Electricity (top left), share of low carbon electricity (top right), and hydrogen (bottom left)**
 4 **production across all scenarios, grouped by the categories introduced in section 3.2. Low carbon includes**
 5 **non-biomass renewables, biomass, nuclear, and CCS.**

3

6 3.4.3 Buildings

7

8 Global final energy use in the building sector increases in all pathways as a result of population
 9 growth and increasing affluence (Figure 3.24). There is very little difference in final energy intensity
 10 for the buildings sector across scenarios. Direct CO₂ emissions from the buildings sector vary more
 11 widely across temperature stabilization levels than energy consumption. In 2100, scenarios above 3°C
 12 [C7-C8] still show an increase of CO₂ emissions from buildings around 29% above 2019, while all
 13 scenarios likely to limit warming to 2°C and below have emission reductions of around 85% (8-
 100%). Carbon intensity declines in all scenarios, but much more sharply as the warming level is
 reduced.

1 **Figure 3.24: Buildings final energy (top left), CO₂ emissions (top middle), carbon intensity (top right),**
 2 **energy intensity (bottom left), share of final energy from electricity (bottom middle), and share of final**
 3 **energy from gases (bottom right). Energy intensity is final energy per unit of GDP. Carbon intensity is**
 4 **CO₂ emissions per EJ of final energy. The first four indicators are indexed to 2019¹¹, where values less**
 5 **than 1 indicate a reduction.**
 6

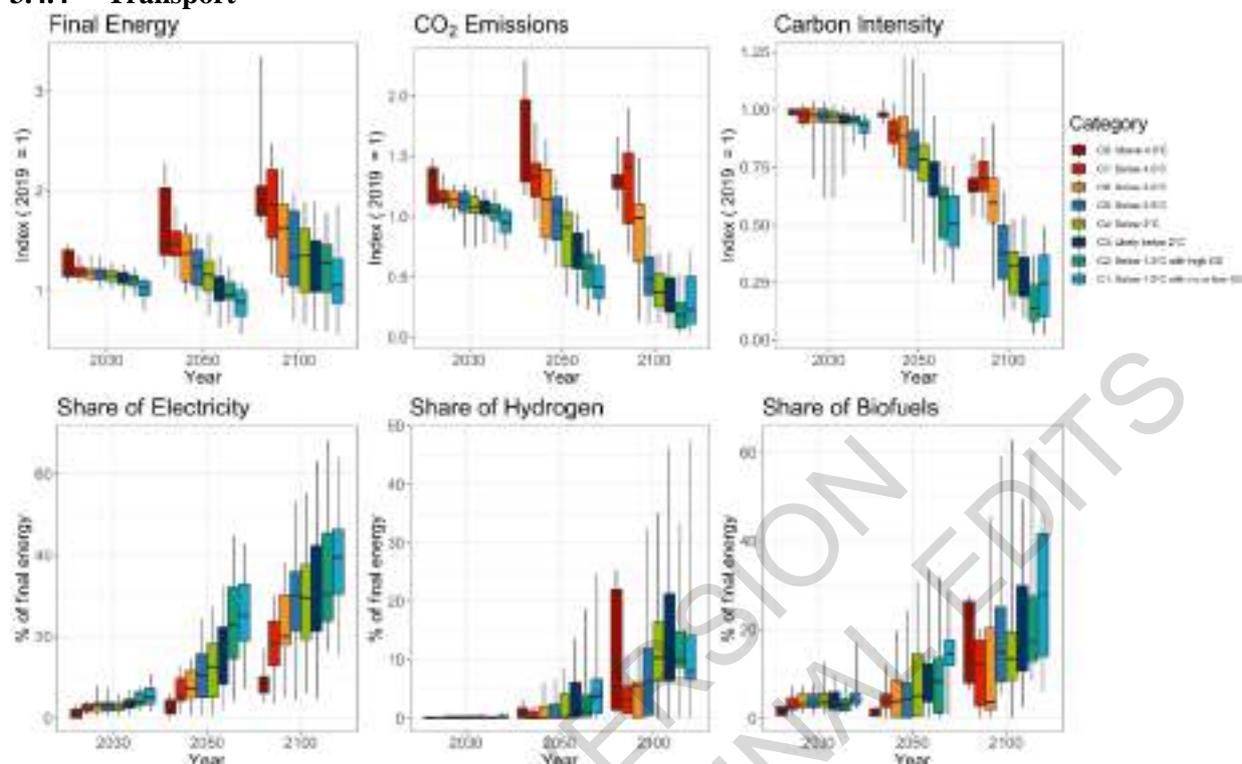

7 In all scenarios, the share of electricity in final energy use increases, a trend that is accelerated by
 8 2050 for the scenarios likely to limit warming to 2°C and below (Figure 3.23). By 2100, the low
 9 warming scenarios show large shares of electricity in final energy consumption for buildings. The
 10 opposite is observed for gases.
 11

12 While several global IAM models have developed their buildings modules considerably over the past
 13 decade (Daioglou et al. 2012; Knobloch et al. 2017; Clarke et al. 2018; Edelenbosch et al. 2021;
 14 Mastrucci et al. 2021), the extremely limited availability of key sectoral variables in the AR6
 15 scenarios database (such as floor space and energy use for individual services) prohibit a detailed
 16 analysis of sectoral dynamics. Individual studies in the literature often focus on single aspects of the
 17 buildings sector, though collectively providing a more comprehensive overview (Edelenbosch et al.
 18 2020; Üрге-Vorsatz et al. 2020). For example, energy demand is driven by economic development
 19 that fulfills basic needs (Mastrucci et al. 2019; Rao et al. 2019a), but also drives up floorspace in
 20 general (Daioglou et al. 2012; Levesque et al. 2018; Mastrucci et al. 2021) and ownership of energy
 21 intensive appliances such as air conditioners (Isaac and van Vuuren 2009; Colelli and Cian 2020;
 22 Poblete-Cazenave et al. 2021). These dynamics are heterogeneous and lead to differences in energy
 23 demand and emission mitigation potential across urban/rural buildings and income levels (Krey et al.
 24 2012; Poblete-Cazenave et al. 2021). Mitigation scenarios rely on fuel switching and technology
 25 (Dagnachew et al. 2020; Knobloch et al. 2017), efficiency improvement in building envelopes
 26 (Edelenbosch et al. 2021; Levesque et al. 2018) and behavioural changes (Niamir et al. 2018, 2020;

FOOTNOTE ¹¹ 2019 values are from model results and interpolated from other years when not directly reported.

1 van Sluisveld et al. 2016). The in-depth dynamics of mitigation in the building sector are explored in
 2 Chapter 9.

3 3.4.4 Transport

4 **Figure 3.25: Transport final energy (top left), CO₂ emissions (top middle), carbon intensity (top right),**
 5 **and share of final energy from electricity (bottom left), hydrogen (bottom middle), and biofuels (bottom**
 6 **right). See Chapter 10 for a discussion of energy intensity. Carbon intensity is CO₂ emissions per EJ of**
 7 **final energy. The first three indicators are indexed to 2019¹², where values less than 1 indicate a**
 8 **reduction.**
 9

10 Reference scenarios show growth in transport demand, particularly in aviation and freight (Yeh et al.
 11 2017; Sharmina et al. 2020; Müller-Casseres et al. 2021b). Energy consumption continues to be
 12 dominated by fossil fuels in reference scenarios, with some increases in electrification (Edelenbosch
 13 et al. 2020; Yeh et al. 2017). CO₂ emissions from transport increase for most models in reference
 14 scenarios (Yeh et al. 2017; Edelenbosch et al. 2020).

15 The relative contribution of demand-side reduction, energy efficiency improvements, fuel switching,
 16 and decarbonisation of fuels, varies by model, level of mitigation, mitigation options available, and
 17 underlying socio-economic pathway (Longden 2014; Wise et al. 2017; Luderer et al. 2018; Yeh et al.
 18 2017; Edelenbosch et al. 2020; Müller-Casseres et al. 2021a,b). IAMs typically rely on technology-
 19 focused measures like energy efficiency improvements and fuel switching to reduce carbon emissions
 20 (Pietzcker et al. 2014; Edelenbosch et al. 2017a; Yeh et al. 2017; Zhang et al. 2018a,b; Rogelj et al.
 21 2018b; Sharmina et al. 2020). Many mitigation pathways show electrification of the transport system
 22 (Luderer et al. 2018; Pietzcker et al. 2014; Longden 2014; Zhang et al. 2018a); however, without
 23 decarbonization of the electricity system, transport electrification can increase total energy system
 24 emissions (Zhang and Fujimori 2020). A small number of pathways include demand-side mitigation
 25 measures in the transport sector; these studies show reduced carbon prices and reduced dependence on

FOOTNOTE ¹² 2019 values are from model results and interpolated from other years when not directly reported.

1 CDR (Grubler et al. 2018; Méjean et al. 2019; van de Ven et al. 2018; Zhang et al. 2018c) (Section
2 3.4.1).

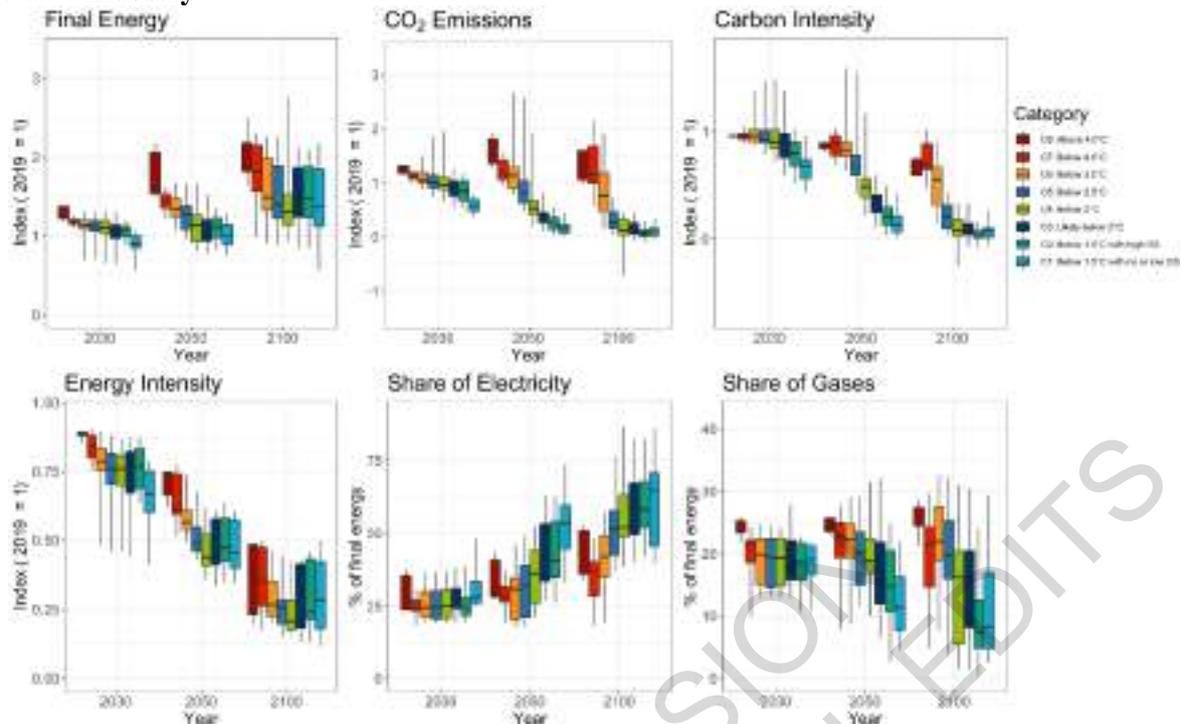

3 Across all IAM scenarios assessed, final energy demand for transport continues to grow, including in
4 many stringent mitigation pathways (Figure 3.25). The carbon intensity of energy declines
5 substantially by 2100 in likely 2°C and below scenarios, leading to substantial declines in transport
6 sector CO₂ emissions with increased electrification of the transport system (Figure 3.23).

7 The transport sector has more detail than other sectors in many IAMs (Edelenbosch et al. 2020);
8 however, there is considerable variation across models. Some models (e.g., GCAM, IMAGE,
9 MESSAGE-GLOBIOM) represent different transport modes with endogenous shifts across modes as
10 a function of income, price, and modal speed (Edelenbosch et al. 2020).¹³ However, IAMs, including
11 those with detailed transport, exclude several supply-side (e.g., synthetic fuels) and demand-side (e.g.,
12 behaviour change, reduced shipping, telework and automation) mitigation options (Davis et al. 2018;
13 Köhler et al. 2020; Mittal et al. 2017; Gota et al. 2019; Wilson et al. 2019; Creutzig et al. 2016;
14 Sharmina et al. 2020; Pietzcker et al. 2014; Lefèvre et al. 2021; Müller-Casseres et al. 2021a,b).

15
16 As a result of these missing options and differences in how mitigation is implemented, IAMs tend to
17 show less mitigation than the potential from national transport/energy models (Wachsmuth and
18 Duscha 2019; Gota et al. 2019; Yeh et al. 2017; Edelenbosch et al. 2020). For the transport sector as a
19 whole, studies suggest a mitigation potential of 4-5 GtCO₂ per year in 2030 (Edelenbosch et al. 2020)
20 with complete decarbonization possible by 2050 (Gota et al. 2019; Wachsmuth and Duscha 2019).
21 However, in the scenarios assessed in this chapter that limit warming to below 1.5°C with no or
22 limited overshoot, transport sector CO₂ emissions are reduced by only 59% (28% to 81%) in 2050
23 compared to 2015. IAM pathways also show less electrification than the potential from other studies;
24 pathways that limit warming to below 1.5°C with no or limited overshoot show a median of 25% (7 to
25 43%) of final energy from electricity in 2050, while the IEA NZE scenario includes 45% (IEA
26 2021a).

27

FOOTNOTE ¹³ Some of these models are treated as global transport energy sectoral models (GTEMs) in Chapter 10.

1 **3.4.5 Industry**

2
3 **Figure 3.26: Industrial final energy, including feedstocks (top left), CO₂ emissions (top middle), carbon**
4 **intensity (top right), energy intensity (bottom left), share of final energy from electricity (bottom middle),**
5 **and share of final energy from gases (bottom right). Energy intensity is final energy per unit of GDP.**
6 **Carbon intensity is CO₂ emissions per EJ of final energy. The first four indicators are indexed to 2019,¹⁴**
7 **where values less than 1 indicate a reduction. Industrial sector CO₂ emissions include fuel combustion**
8 **emissions only.**

9 Reference scenarios show declines in energy intensity, but increases in final energy use in the
10 industrial sector (Edelenbosch et al. 2017b). These scenarios show increases in CO₂ emissions both
11 for the total industrial sector (Edelenbosch et al. 2020; Luderer et al. 2018; Edelenbosch et al. 2017b)
12 and individual subsectors like cement and iron and steel (van Ruijven et al. 2016; van Sluisveld et al.
13 2021) or chemicals (Daioglou et al. 2014; van Sluisveld et al. 2021).

14 In mitigation pathways, CO₂ emissions reductions are achieved through a combination of energy
15 savings (via energy efficiency improvements and energy conservation), structural change, fuel
16 switching, and decarbonization of fuels (Grubler et al. 2018; Luderer et al. 2018; Edelenbosch et al.
17 2017b, 2020). Mitigation pathways show reductions in final energy for industry compared to the
18 baseline (Edelenbosch et al. 2017b; Luderer et al. 2018; Edelenbosch et al. 2020) and reductions in
19 the carbon intensity of the industrial sector through both fuel switching and the use of CCS (Paltsev et
20 al. 2021; Luderer et al. 2018; Edelenbosch et al. 2017b, 2020; van Ruijven et al. 2016; van Sluisveld
21 et al. 2021). The mitigation potential differs depending on the industrial subsector and the availability
22 of CCS, with larger potential reductions in the steel sector (van Ruijven et al. 2016) and cement
23 industry (Sanjuán et al. 2020) than in the chemicals sector (Daioglou et al. 2014). Many scenarios,
24 including stringent mitigation scenarios, show continued growth in final energy; however, the carbon
25 intensity of energy declines in all mitigation scenarios (Figure 3.26).

26 The representation of the industry sector is very aggregate in most IAMs, with only a small subset of
27 models disaggregating key sectors such as cement, fertilizer, chemicals, and iron and steel (Pauliuk et

FOOTNOTE ¹⁴ 2019 values are from model results and interpolated from other years when not directly reported.

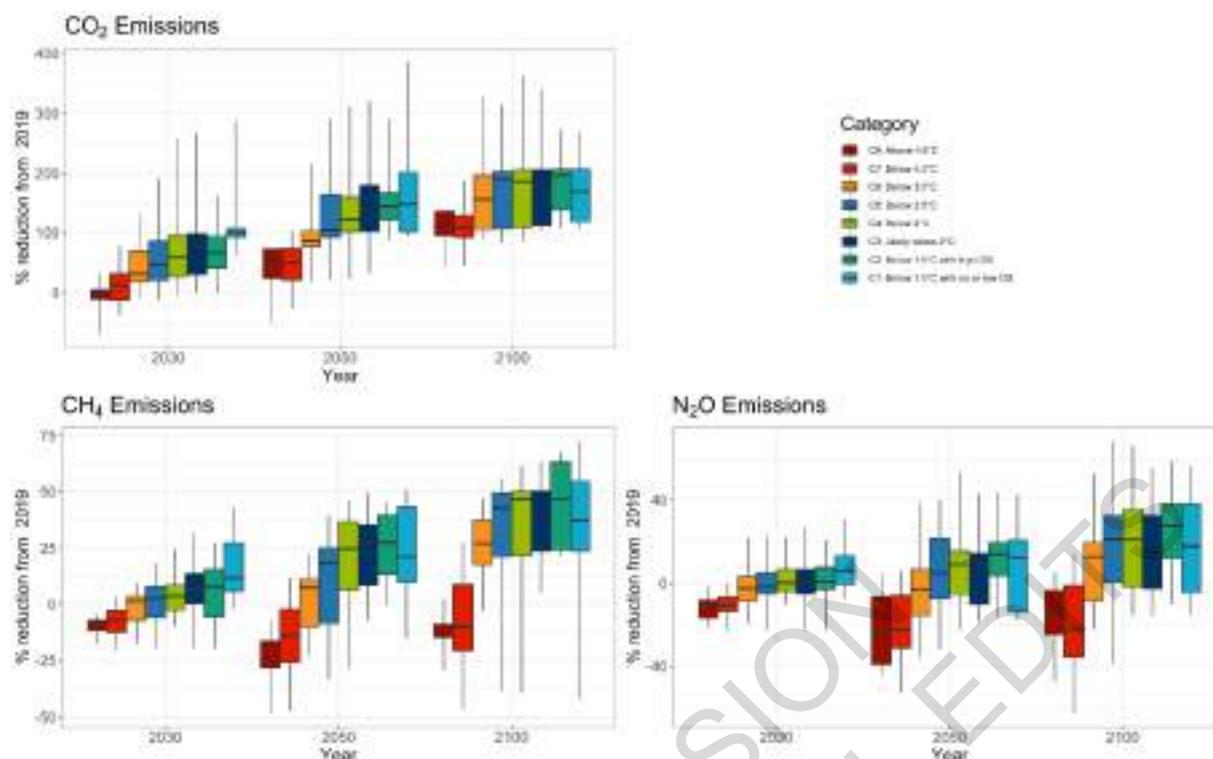

1 al. 2017; Edelenbosch et al. 2017b; Daioglou et al. 2014; van Sluisveld et al. 2021) (Napp et al. 2019).
2 IAMs often account for both energy combustion and feedstocks (Edelenbosch et al. 2017b), but IAMs
3 typically ignore material flows and miss linkages between sectors (Kermeli et al. 2019; Pauliuk et al.
4 2017). By excluding these processes, IAMs misrepresent the mitigation potential of the industry
5 sector, e.g. by overlooking mitigation from material efficiency and circular economies (Sharmina et
6 al. 2020), which can have substantial mitigation potential (Chapter 5.3.4, Chapter 11.3).

7 Sectoral studies indicate a large mitigation potential in the industrial sector by 2050, including the
8 potential for net zero CO₂ emissions for steel, plastics, ammonia, and cement (Section 11.4.1).
9 Detailed industry sector pathways show emissions reductions between 39 and 94% by mid-century
10 compared to present day¹⁵ (Section 11.4.2) and a substantial increase in direct electrification (IEA
11 2021a). IAMs show comparable mitigation potential to sectoral studies with median reductions in
12 CO₂ emissions between 2019 and 2050 of 70% in scenarios likely to limit warming to 2°C and below
13 and a maximum reduction of 96% (Figure 3.26). Some differences between IAMs and sectoral models
14 can be attributed to differences in technology availability, with IAMs sometimes including more
15 technologies (van Ruijven et al. 2016) and sometimes less (Sharmina et al. 2020). Figure 3.27:
16 Reduction in AFOLU GHG emissions from 2019. The AFOLU CO₂ estimates in this figure are not
17 necessarily comparable with country GHG inventories (see Chapter 7).

18 **3.4.6 Agriculture, Forestry and Other Land Use (AFOLU)**

19 Mitigation pathways show substantial reductions in CO₂ emissions, but more modest reductions in
20 AFOLU CH₄ and N₂O emissions (*high confidence*) (Popp et al. 2017; Roe et al. 2019; Reisinger et al.
21 2021) (Figure 3.27). Pathways limiting warming to likely 2°C or below are projected to reach net zero
22 CO₂ emissions in the AFOLU sector around 2033 (2024-2060); however AFOLU CH₄ and N₂O
23 emissions remain positive in all pathways (Figure 3.27). While IAMs include many land-based
24 mitigation options, these models exclude several options with large mitigation potential, such as
25 biochar, agroforestry, restoration/avoided conversion of coastal wetlands, and restoration/avoided
26 conversion of peatland (Smith et al. 2019; IPCC 2019a) (see also Chapter 7, Section 3.4). Sectoral
27 studies show higher mitigation potential than IAM pathways, as these studies include more mitigation
28 options than IAMs (*medium confidence*) (Chapter 7).
29

FOOTNOTE ¹⁵ Some studies calculate emissions reductions in 2050 compared to 2014, while others note emissions reductions in 2060 relative to 2018.

1
2 **Figure 3.27: Reduction in AFOLU GHG emissions from 2019. The AFOLU CO₂ estimates in this figure**
3 **are not necessarily comparable with country GHG inventories (see Chapter 7).**

4 Limiting warming to likely 2°C or below can result in large scale transformation of the land surface
5 (*high confidence*) (Popp et al. 2017; Rogelj et al. 2018a,b; Brown et al. 2019; Roe et al. 2019). The
6 scale of land transformation depends, *inter alia*, on the temperature goal and the mitigation options
7 included (Popp et al. 2017; Rogelj et al. 2018a; IPCC 2019a). Pathways with more demand-side
8 mitigation options show less land transformation than those with more limited options (van Vuuren et
9 al. 2018; Grubler et al. 2018; IPCC 2019a). Most of these pathways show increases in forest cover,
10 with an increase of 322 million ha (-67 to 890 million ha) in 2050 in 1.5°C pathways with no or
11 limited overshoot, whereas bottom up models portray an economic potential of 300-500 million ha of
12 additional forest (Chapter 7). Many IAM pathways also include large amounts of energy cropland
13 area, to supply biomass for bioenergy and BECCS, with 199 (56-482) million ha in 2050 in 1.5°C
14 pathways with no or limited overshoot. Large land transformations, such as afforestation/reforestation
15 and widespread planting of energy crops, can have implications for biodiversity and sustainable
16 development (see Section 3.7, Chapter 7 - Subsection 7.7.4, Chapter 12 - Section 12.5).

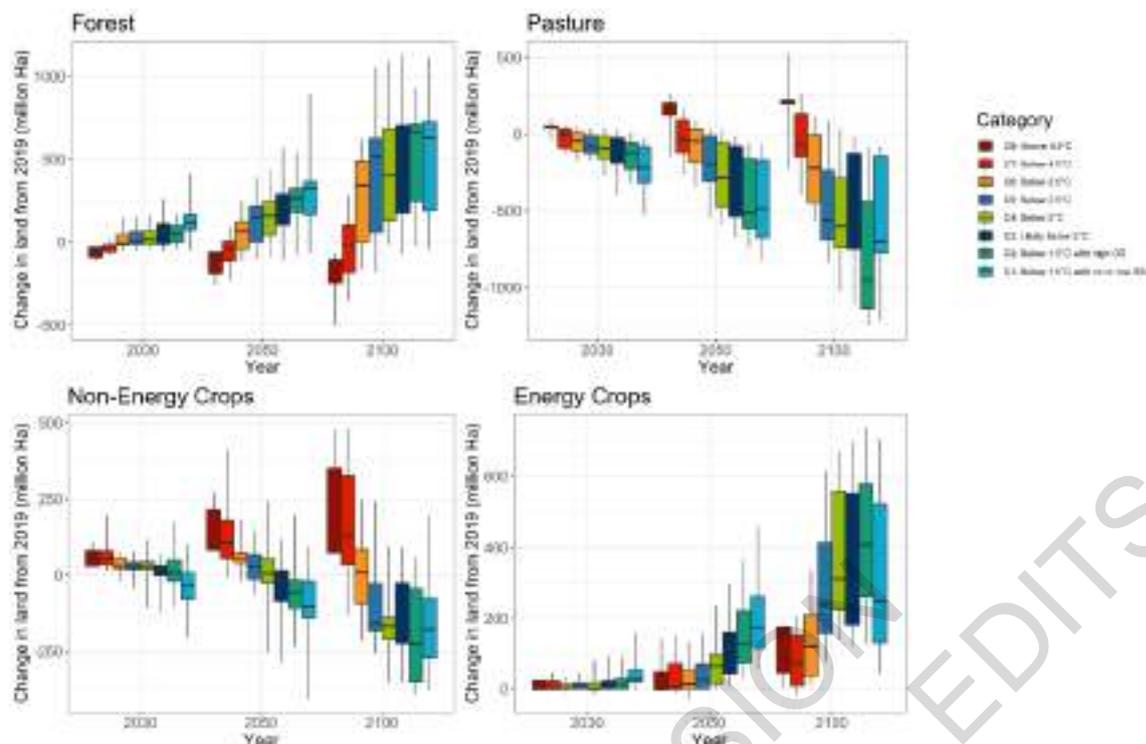

Figure 3.28: Change in Land Cover from 2019 in million hectares. Positive values indicate an increase in area.

Delayed mitigation has implications for land use transitions (Hasegawa et al. 2021a). Delaying mitigation action can result in a temporary overshoot of temperature and large-scale deployment of CDR in the second half of the century to reduce temperatures from their peak to a given level (Smith et al. 2019; Hasegawa et al. 2021a). IAM pathways rely on afforestation and BECCS as CDR measures, so delayed mitigation action results in substantial land use change in the second half of the century with implications for sustainable development (Hasegawa et al. 2021a) (see also Section 3.7). Shifting to earlier mitigation action reduces the amount of land required for this, though at the cost of larger land use transitions earlier in the century (Hasegawa et al. 2021a). Earlier action could also reduce climate impacts on agriculture and land-based mitigation options (Smith et al. 2019).

Some AFOLU mitigation options can enhance vegetation and soil carbon stocks such as reforestation, restoration of degraded ecosystems, protection of ecosystems with high carbon stocks and changes to agricultural land management to increase soil carbon (*high confidence*) (Fuss et al. 2018; Griscom et al. 2017; de Coninck et al. 2018; Smith et al. 2019) (WGIII Chapter 7). The timescales associated with these options indicate that carbon sinks in terrestrial vegetation and soil systems can be maintained or enhanced so as to contribute towards long-term mitigation (*high confidence*); however, many AFOLU mitigation options do not continue to sequester carbon indefinitely (IPCC 2019a; Fuss et al. 2018; de Coninck et al. 2018)(WGIII Chapter 7). In the very long term (latter part of the century and beyond), it will become more challenging to continue to enhance vegetation and soil carbon stocks, so that the associated carbon sinks could diminish or even become sources (*high confidence*) (IPCC 2019a; de Coninck et al. 2018) (WGI Chapter 5). Sustainable forest management, including harvest and forest regeneration, can help to remediate and slow any decline in the forest carbon sink, for example by restoring degraded forest areas, and so go some way towards addressing the issue of sink saturation (IPCC 2019) (WGI Chapter 5; WGIII Chapter 7). The accumulated carbon resulting from mitigation options that enhance carbon sequestration (e.g., reforestation, soil carbon sequestration) is also at risk of future loss due to disturbances (e.g., fire, pests) (Anderegg et al. 2020; Boysen et al. 2017; IPCC 2019a; Smith et al. 2019; Fuss et al. 2018; de Coninck et al. 2018)(WGI

Chapter 5). Maintaining the resultant high vegetation and soil carbon stocks could limit future land use options, as maintaining these carbon stocks would require retaining the land use and land cover configuration implemented to achieve the increased stocks.

Anthropogenic land CO₂ emissions and removals in IAM pathways cannot be directly compared with those reported in national GHG inventories (high confidence) (Grassi et al. 2018, 2021) (Chapter 7.2).

Due to differences in definitions for the area of managed forests and what is emissions and removals are considered anthropogenic, the reported anthropogenic land CO₂ emissions and removals differ by ~5.5 GtCO₂ yr⁻¹ between IAMs, which rely on bookkeeping approaches (e.g., (Houghton and Nassikas 2017), and national GHG inventories (Grassi et al. 2021). Such differences in definitions can alter the reported time at which anthropogenic net zero CO₂ emissions are reached for a given emission scenario. Using national inventories would lead to an earlier reported time of net zero (van Soest et al. 2021b) or to lower calculated cumulative emissions until the time of net zero (Grassi et al. 2021) as compared to IAM pathways. The numerical differences are purely due to differences in the conventions applied for reporting the anthropogenic emissions and do not have any implications for the underlying land-use changes or mitigation measures in the pathways. Grassi et al. (Grassi et al. 2021) offers a methodology for adjusting to reconcile these differences and enable a more accurate assessment of the collective progress achieved under the Paris Agreement (Chapter 7, Cross-Chapter Box 6 in Chapter 7).

3.4.7 Other Carbon Dioxide Removal Options

Table 3.5: Carbon dioxide removal in assessed pathways. Scenarios are grouped by temperature categories, as defined in section 3.2.4. Quantity indicates the median and 5-95% range of cumulative sequestration from 2020 to 2100 in GtCO₂. Count indicates the number of scenarios with positive values for that option.

CDR Option	Below 1.5°C with no or limited OS		Below 1.5°C with high OS		Likely below 2°C	
	Quantity	Count	Quantity	Count	Quantity	Count
Total CDR	584 (192 to 959)	95	645 (333 to 1221)	123	533 (193 to 895)	294
CO ₂ removal on managed land including A/R	262 (17 to 397)	64	330 (28 to 439)	82	209 (20 to 415)	196
BECCS	334 (32 to 780)	91	464 (226 to 842)	122	291 (174 to 653)	294
Enhanced weathering	0 (0 to 47)	2	0 (0 to 0)	1	0 (0 to 0)	1
DACCS	30 (0 to 308)	31	109 (0 to 539)	24	19 (0 to 253)	91

This subsection includes other CDR options not discussed in the previous subsections, including direct air carbon capture and storage (DACCS), enhanced weathering, and ocean-based approaches, focusing on the role of these options in long-term mitigation pathways, using both IAMs (Rickels et al. 2018; Realmonte et al. 2019; Chen and Tavoni 2013; Marcucci et al. 2017; Strefler et al. 2021a; Fuhrman et al. 2019, 2020, 2021; Akimoto et al. 2021) and non-IAMs (Fuss et al. 2013; González and Ilyina 2016; Bednar et al. 2021; Shayegh et al. 2021). There are other options discussed in the literature, like methane capture (Jackson et al. 2019), however, the role of these options in long-term mitigation pathways has not been quantified and are thus excluded here. Chapter 12 includes a more

1 detailed description of the individual technologies, including their costs, potentials, financing, risks,
2 impacts, maturity and upscaling.

3 Very few studies and pathways include other CDR options (Table 3.5). Pathways with DACCS
4 include potentially large removal from DACCS (up to 37 GtCO₂ yr⁻¹ in 2100) in the second half of the
5 century (Realmonte et al. 2019; Marcucci et al. 2017; Chen and Tavoni 2013; Fuhrman et al. 2020,
6 2021; Shayegh et al. 2021; Akimoto et al. 2021) and reduced cost of mitigation (Bistline and Blanford
7 2021; Strefler et al. 2021a). At large scales, the use of DACCS has substantial implications for energy
8 use, emissions, land, and water; substituting DACCS for BECCS results in increased energy usage,
9 but reduced land use change and water withdrawals (Fuhrman et al., 2020, 2021; Chapter 12.3.2;
10 IPCC WGI Chapter 5). The level of deployment of DACCS is sensitive to the rate at which it can be
11 scaled up, the climate goal or carbon budget, the underlying socioeconomic scenario, the availability
12 of other decarbonization options, the cost of DACCS and other mitigation options, and the strength of
13 carbon cycle feedbacks (Honegger and Reiner 2018; Fuss et al. 2013; Fuhrman et al. 2021; Bistline
14 and Blanford 2021; Chen and Tavoni 2013; Strefler et al. 2021a; Fuhrman et al. 2020; Realmonte et
15 al. 2019) (IPCC WGI Chapter 5). Since DACCS consumes energy, its effectiveness depends on the
16 type of energy used; the use of fossil fuels would reduce its sequestration efficiency (Creutzig et al.
17 2019; Babacan et al. 2020; NASEM 2019). Studies with additional CDR options in addition to
18 DACCS (e.g., enhanced weathering, BECCS, afforestation, biochar, and soil carbon sequestration)
19 find that CO₂ removal is spread across available options (Holz et al. 2018; Strefler et al. 2021a).
20 Similar to DACCS, the deployment of deep ocean storage depends on cost and the strength of carbon
21 cycle feedbacks (Rickels et al. 2018).

22
23

24 **3.5 Interaction between near-, medium- and long-term action in** 25 **mitigation pathways**

26 This section assesses the relationship between long-term climate goals and short- to medium-term
27 emissions reduction strategies based on the mitigation pathway literature. After an overview of this
28 relationship (3.5.1), it provides an assessment of what currently planned near-term action implies for
29 limiting warming to 1.5-2°C (3.5.2), and to what extent pathways with accelerated action beyond
30 current NDCs can improve the ability to keep long-term targets in reach (3.5.3).

31 The assessment in this section shows that if mitigation ambitions in current NDCs¹⁶ are followed until
32 2030, leading to estimated emissions of 47-57 GtCO₂-eq in 2030¹⁷ (Chapter 4.2.2), it is no longer
33 possible to stay below 1.5°C warming with no or limited overshoot (*high confidence*). Instead, it
34 would entail high overshoot (typically >0.1°C) and reliance on net negative CO₂ emissions with
35 uncertain potential to return warming to 1.5°C by the end of the century. It would also strongly
36 increase mitigation challenges to likely limit warming to 2°C (*high confidence*). GHG emissions

FOOTNOTE ¹⁶ The term “**current NDCs**” used in this section and throughout the report refers to the most recent nationally determined contributions submitted to the UNFCCC as well as those publicly announced with sufficient detail on targets, but not yet submitted, up to 11 October 2021, and reflected in studies published up to 11 October 2021. In contrast, “**original NDCs**” refers to nationally determined contributions that were initially submitted to the Paris Agreement by parties, largely reflecting the state of submissions until the year 2019. See Chapter 4.2.

FOOTNOTE ¹⁷ In this section, the emissions range associated with current (or original) NDCs refer to the combined emissions ranges from the two cases of implementing only the unconditional elements of current NDCs (50-57 GtCO₂-eq) and implementing both unconditional and conditional elements of current NDCs (47-53 GtCO₂-eq), if not specified otherwise.

1 reductions would need to abruptly increase after 2030 to an annual average rate of 1.3-2.1 GtCO₂-eq
2 during the period 2030-2050, around 70% higher than in mitigation pathways assuming immediate
3 action¹⁸ to likely limit warming to 2°C. The higher post-2030 reduction rates would have to be
4 obtained in an environment of continued build-up of fossil fuel infrastructure and less development of
5 low carbon alternatives until 2030. A lock-in into fossil-fuel intensive production systems (carbon
6 lock-in) will increase the societal, economic and political strain of a rapid low-carbon transition after
7 2030 (*high confidence*).

8 The section builds on previous assessments in the IPCC's Fifth Assessment Report (Clarke et al.
9 2014) and Special Report on 1.5°C Warming (Rogelj et al. 2018a). The literature assessed in these
10 two reports has focused on delayed action until 2030 in the context of limiting warming to 2°C (den
11 Elzen et al. 2010; van Vuuren and Riahi 2011; Kriegler et al. 2015; Luderer et al. 2013, 2016; Riahi et
12 al. 2015; Rogelj et al. 2013a) and 1.5°C (Strefler et al. 2018; Luderer et al. 2018; Rogelj et al. 2013b).
13 Here we provide an update of these assessments drawing on the most recent literature on global
14 mitigation pathways. New studies have focused, inter alia, on constraining near term developments by
15 peak warming limits (Rogelj et al. 2019b; Strefler et al. 2021b; Riahi et al. 2021) and updating
16 assumptions about near- and medium term emissions developments based on national plans and long-
17 term strategies (Roelfsema et al. 2020) (Chapter 4.2). Several studies have explored new types of
18 pathways with accelerated action bridging between current policy plans and the goal of limiting
19 warming below 2°C (Kriegler et al. 2018a; van Soest et al. 2021a) and looked at hybrid international
20 policy regimes to phase in global collective action (Bauer et al. 2020).

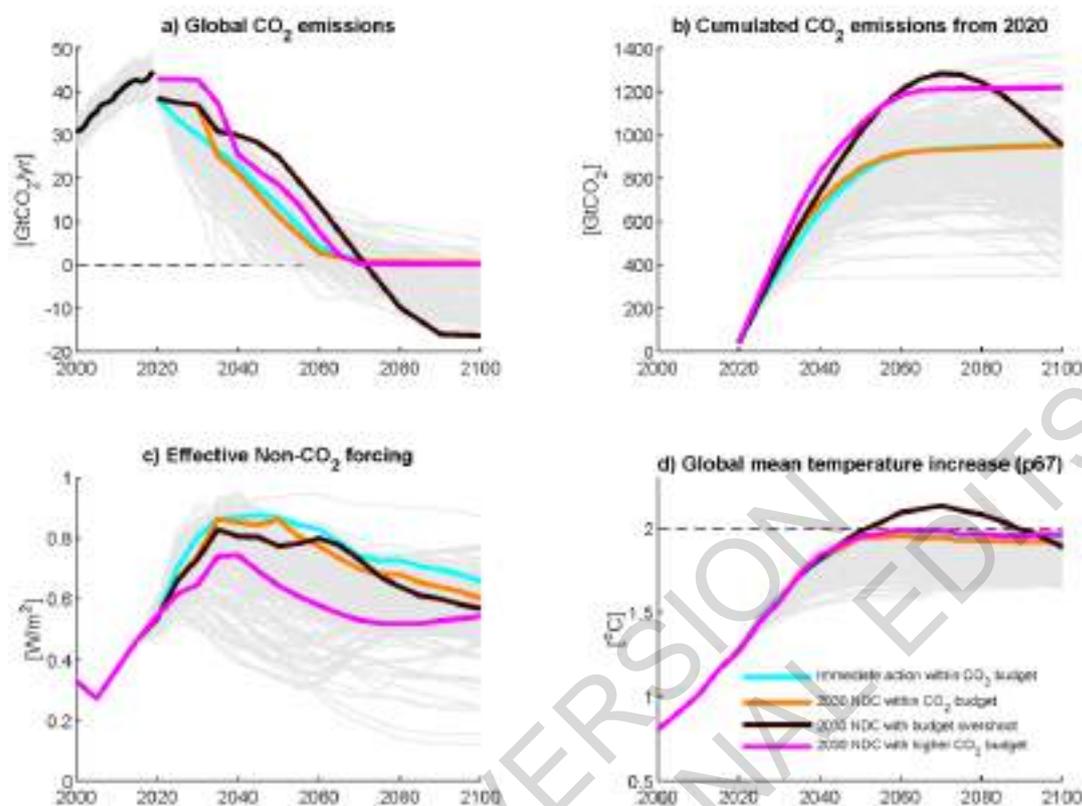

21 **3.5.1 Relationship between long-term climate goals and near- to medium-term emissions** 22 **reductions**

23 The close link between cumulative CO₂ emissions and warming has strong implications for the
24 relationship between near-, medium-, and long-term climate action to limit global warming. The AR6
25 WGI Assessment has estimated a remaining carbon budget of 500 (400) GtCO₂ from the beginning of
26 2020 onwards for staying below 1.5°C with 50% (67%) likelihood, subject to additional uncertainties
27 about historic warming and the climate response and variations in warming from non-CO₂ climate
28 forcers (Canadell and Monteiro 2019) (see also WGI Chapter 5, Section 5.5). For comparison, if
29 current CO₂ emissions of more than 40 GtCO₂ are keeping up until 2030, more than 400 GtCO₂ will
30 be emitted during 2021–2030, already exhausting the remaining carbon budget for 1.5°C by 2030.

31 The relationship between warming limits and near term action is illustrated in Figure 3.29, using a set
32 of 1.5-2°C scenarios with different levels of near term action, overshoot and non-CO₂ warming
33 contribution from a recent study (Riahi et al. 2021). In general, the more CO₂ is emitted until 2030,
34 the less CO₂ can be emitted thereafter to stay within a remaining carbon budget and below a warming
35 limit. Scenarios with immediate action to observe the warming limit give the longest time to exhaust
36 the associated remaining carbon budget and reach net zero CO₂ emissions (light blue line in Figure
37 3.29, Cross-Chapter Box 3 in this chapter). In comparison, following projected NDC emissions until
38 2030 would imply a more pronounced drop in emissions from 2030 levels to net zero to make up for
39 the additional near-term emissions (orange lines in Figure 3.29). If such a drop does not occur, the
40 remaining carbon budget is exceeded and net negative CO₂ emissions are required to return global
41 mean temperature below the warming limit (black lines in Figure 3.29) (Fuss et al. 2014; Clarke et al.
42 2014; Rogelj et al. 2018a).
43

FOOTNOTE ¹⁸ In this section, near term emissions outcomes are often compared to near term emissions in mitigation **pathways with immediate action** towards a warming limit. These are defined as pathways that immediately after imposing the warming limit turn to global mitigation action tapping into all least cost abatement options available globally. These pathways are often called cost-effective or least-cost pathways in the literature. The onset of immediate action is defined by scenario design and is typically chosen to be the first time step after 2020 in immediate action scenarios assessed in this report.

1 The relationship between warming limits and near-term action is also affected by the warming
2 contribution of non-CO₂ greenhouse gases and other short lived climate forcers (3.3, Working Group I
3 6.7). The estimated budget values for limiting warming to 1.5-2°C already assume stringent
4 reductions in non-CO₂ greenhouse gases and non-CO₂ climate forcing as found in 1.5-2°C pathways
5 (3.3, Cross-Working Group Box 1; Working Group I 5.5, Box 5.2). Further variations in non-CO₂
6 warming observed across 1.5-2°C pathways can vary the median estimate for the remaining carbon
7 budget by 220 GtCO₂ (Working Group I 5.5). In 1.5-2°C pathways, the non-CO₂ warming
8 contribution differs strongly between the near-, medium and long term. Changes to the atmospheric
9 composition of short-lived climate forcers dominate the warming response in the near term (Working
10 Group I 6.7). CO₂ reductions are combined with strong reductions in air pollutant emissions due to
11 rapid reduction in fossil fuel combustion and in some cases the assumption of stringent air quality
12 policies (Rao et al. 2017b; Smith et al. 2020c). As air pollutants exert a net cooling effect, their
13 reduction drives up non-CO₂ warming in the near term, which can be attenuated by the simultaneous
14 reduction of methane and black carbon (Smith et al. 2020b; Shindell and Smith 2019) (Working
15 Group I 6.7). After 2030, the reduction in methane concentrations and associated reductions in
16 tropospheric ozone levels tend to dominate so that a peak and decline in non-CO₂ forcing and non-
17 CO₂ induced warming can occur before net zero CO₂ is reached (Figure 3.29) (Rogelj et al. 2018a)
18 The more stringent the reductions in methane and other short-lived warming agents like black carbon,
19 the lower this peak and the earlier the decline of non-CO₂ warming, leading to a reduction of warming
20 rates and overall warming in the near to medium term (Smith et al. 2020b; Harmsen et al. 2020). This
21 is important for keeping warming below a tight warming limit that is already reached around mid-
22 century as is the case in 1.5°C pathways (Xu and Ramanathan 2017). Early and deep reductions of
23 methane emissions, and other short-lived warming agents like black carbon, provide space for residual
24 CO₂-induced warming until the point of net zero CO₂ emissions is reached (purple lines in Figure
25 3.29). Such emissions reductions have also been advocated due to co-benefits for, e.g., reducing air
26 pollution (Rao et al. 2016; Shindell et al. 2017a, 2018; Shindell and Smith 2019; Rauner et al. 2020a;
27 Vandyck et al. 2020).

1
2 **Figure 3.29: Illustration of emissions and climate response in four mitigation pathways with different**
3 **assumptions about near term policy developments, global warming limit and non-CO₂ warming**
4 **contribution drawn from Riahi et al. (2021). Shown are (a) CO₂ emissions trajectories, (b) cumulative**
5 **CO₂ emissions, (c) effective non-CO₂ radiative forcing, and (d) the resulting estimate of the 67th percentile**
6 **of global mean temperature response relative to 1850-1900. Light blue lines show a scenario that acts**
7 **immediately on a remaining carbon budget of 900 GtCO₂ from 2020 without allowing net negative CO₂**
8 **emissions, i.e., temporary budget overshoot (COFFEE 1.1, Scenario EN_NPi2020_900). Orange and black**
9 **lines show scenarios drawn from the same model that follow the NDCs until 2030 and thereafter**
10 **introduce action to stay within the same budget – in one case excluding net negative CO₂ emissions like**
11 **before (orange lines; COFFEE 1.1, Scenario EN-INDCi2030_900) and in the other allowing for a**
12 **temporary overshoot of the carbon budget until 2100 (black lines; COFFEE 1.1, Scenario EN-**
13 **INDCi2030_900f). Light blue lines describe a scenario following the NDCs until 2030, and then aiming for**
14 **a higher budget of 2300 GtCO₂ without overshoot (AIM/CGE 2.2, Scenario EN-INDCi2030_1200). It is**
15 **drawn from another model which projects a lower anthropogenic non-CO₂ forcing contribution and**
16 **therefore achieves about the same temperature outcome as the other two non-overshoot scenarios despite**
17 **the higher CO₂ budget. Grey funnels include the trajectories from all scenarios that likely limit warming**
18 **to 2°C (Category C3). Historical CO₂ emissions until 2019 are from Chapter SM.2.1 EDGAR v6.0.**

19 The relationship between long-term climate goals and near term action is further constrained by
20 social, technological, economic and political factors (Aghion et al. 2019; Mercure et al. 2019; van
21 Sluisveld et al. 2018b; Cherp et al. 2018; Jewell and Cherp 2020; Trutnevte et al. 2019b). These
22 factors influence path dependency and transition speed (Vogt-Schilb et al. 2018; Pahle et al. 2018).
23 While detailed integrated assessment modelling of global mitigation pathways accounts for
24 technology inertia (Bertram et al. 2015a; Mercure et al. 2018) and technology innovation and
25 diffusion (Wilson et al. 2013; van Sluisveld et al. 2018a; Luderer et al. 2021), there are limitations in
26 capturing socio-technical and political drivers of innovation, diffusion and transition processes
27 (Keppo et al. 2021; Gambhir et al. 2019; Hirt et al. 2020; Köhler et al. 2019). Mitigation pathways
28 show a wide range of transition speeds that have been interrogated in the context of socio-technical

1 inertia (Gambhir et al. 2017; Kefford et al. 2018; Kriegler et al. 2018a; Brutschin et al. 2021) vs.
2 accelerating technological change and self-enforcing socio-economic developments (Creutzig et al.
3 2017; Zenghelis 2019) (Section 3.8). Diagnostic analysis of detailed IAMs found a lag of 8-20 years
4 between the convergence of emissions pricing and the convergence of emissions response after a
5 period of differentiated emission prices (Harmsen et al. 2021). This provides a measure of the inertia
6 to changing policy signals in the model response. It is about half the timescale of 20-40 years
7 observed for major energy transitions (Grubb et al. 2021). Hence, the mitigation pathways assessed
8 here capture socio-technical inertia in reducing emissions, but the limited modelling of socio-political
9 factors may alter the extent and persistence of this inertia.

10 11 **3.5.2 Implications of near-term emission levels for keeping long-term climate goals within** 12 **reach**

13 The implications of near-term climate action for long-term climate outcomes can be explored by
14 comparing mitigation pathways with different near-term emissions developments aiming for the same
15 climate target (Vrontisi et al. 2018; Riahi et al. 2015; Roelfsema et al. 2020). A particular example is
16 the comparison of cost-effective pathways with immediate action to limit warming to 1.5-2°C with
17 mitigation pathways pursuing more moderate mitigation action until 2030. After the adoption of the
18 Paris Agreement, near term action was often modelled to reflect conditional and unconditional
19 elements of originally submitted NDCs (2015-2019) (Fawcett et al. 2015; Fujimori et al. 2016a;
20 Kriegler et al. 2018a; Vrontisi et al. 2018; Roelfsema et al. 2020). The most recent modelling studies
21 also include submission of updated NDCs or announcements of planned updates in the first half of
22 2021 (Network for Greening the Financial System 2021; Riahi et al. 2021). Emissions levels under
23 current NDCs (see footnote 15) are assessed to range between 47–57 GtCO₂-eq in 2030 (Chapter
24 4.2.2). This assessed range corresponds well to 2030 emissions levels in 2°C mitigation pathways in
25 the literature that are designed to follow the original or current NDCs until 2030¹⁹. For the 139
26 scenarios of this kind that are collected in the AR6 scenario database and that still likely limit
27 warming to 2°C, the 2030 emissions range is 52.5 (44.5-57) GtCO₂-eq (based on native model
28 reporting) and 52 (46.5-56) GtCO₂-eq, respectively (based on harmonized emissions data for climate
29 assessment (Annex III part II section 2.4); median and 5th to 95th percentile). This close match allows
30 a robust assessment of the implications of implementing current NDCs for post-2030 mitigation
31 efforts and warming outcomes based on the literature and the AR6 scenarios database.

32 The assessed emission ranges from implementing the unconditional (unconditional and conditional)
33 elements of current NDCs implies an emissions gap to cost-effective mitigation pathways of 20-26
34 (16-24) GtCO₂-eq in 2030 for limiting warming to 1.5°C with no or limited overshoot and 10-17 (7-
35 14) GtCO₂-eq in 2030 for likely limiting warming to 2°C (Chapter 4, Cross-Chapter Box 2 in chapter
36 2). The emissions gap gives rise to a number of mitigation challenges (Rogelj et al. 2013a; Kriegler et
37 al. 2013a, 2018b,a; Riahi et al. 2015; Luderer et al. 2013, 2018; Fujimori et al. 2016b; Fawcett et al.
38 2015; Strefler et al. 2018; Winning et al. 2019; UNEP 2020; SEI et al. 2020): (i) larger transitional
39 challenges post-2030 to still remain under the warming limit (, in particular higher CO₂ emissions
40 reduction rates and technology transition rates required during 2030-2050; (ii) larger lock-in into
41 carbon-intensive infrastructure and increased risk of stranded fossil fuel assets (3.5.2.2); and (iii)
42 larger reliance on CDR to reach net zero CO₂ more rapidly and compensate excess emissions in the
43 second half of the century (3.5.2.1). All these factors exacerbate socio-economic strain of

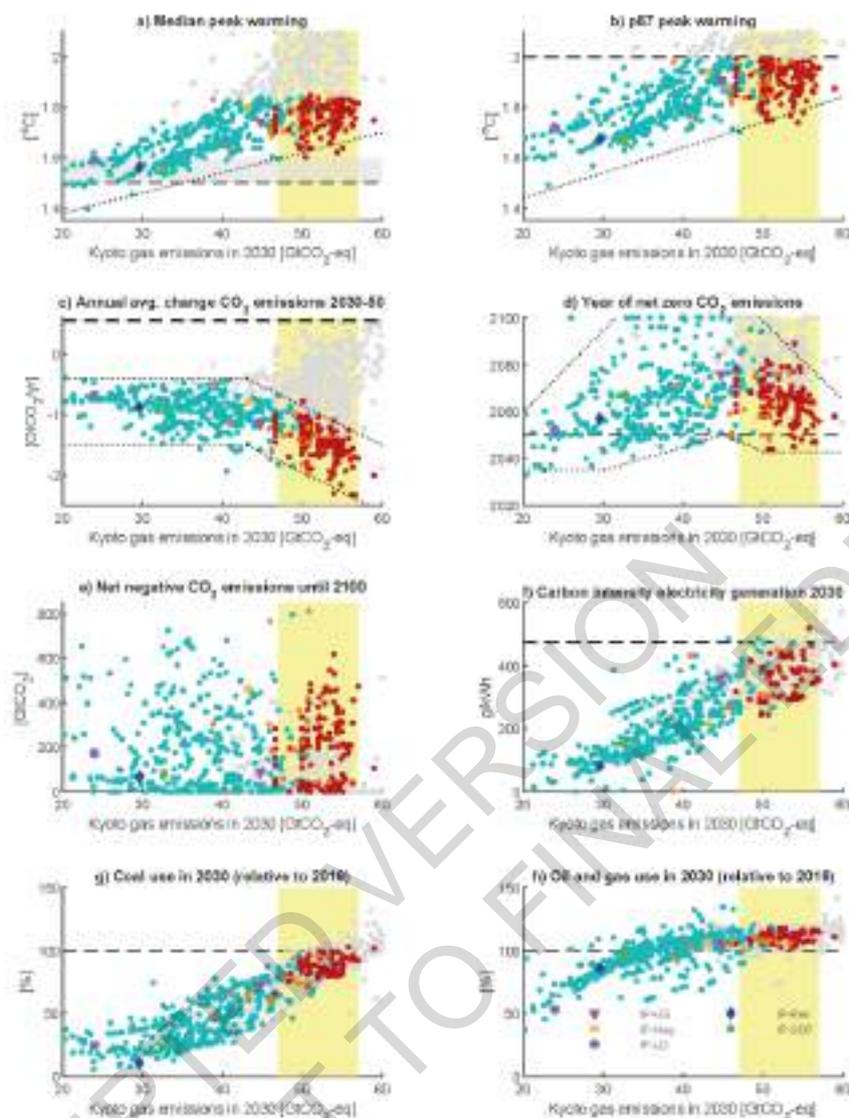

FOOTNOTE ¹⁹ The intended design of mitigation pathways in the literature can be deduced from underlying publications and study protocols. This information was collected as part of this assessment to establish a categorization of policy assumptions underpinning the mitigation pathways collected in the AR6 scenario database (3.2; Annex III Part II section 3.2).

1 implementing the transition, leading to an increased risk of overshooting the warming and a higher
2 risk of climate change impacts (Drouet et al. 2021).

3 The challenges are illustrated in Table 3.6 and Figure 3.30, surveying global mitigation pathways in
4 the literature that were collected in the AR6 scenarios database. There is a clear trend of increasing
5 peak warming with increasing 2030 GHG emission levels (Figure 3.30a+b). In particular, there is no
6 mitigation pathway designed to follow the NDCs until 2030 in 2030 that can limit warming to 1.5°C
7 with no or limited overshoot. Our assessment confirms the finding of the IPCC Special Report on
8 1.5°C Warming for the case of current NDCs, including updates until 11 October 2021 that were
9 assessed in the literature, that pathways following the NDCs until 2030 “*would not limit global*
10 *warming to 1.5°C, even if supplemented by very challenging increases in the scale and ambition of*
11 *emissions reductions after 2030*” (SR1.5 SPM). This assessment is now more robust than in SR1.5 as
12 it is based on a larger set of 1.5-2°C pathways with better representation of current trends and plans
13 covering a wider range of post-2030 emissions developments. In particular, a recent multi-model
14 study limiting peak cumulative CO₂ emissions for a wide range of carbon budgets and immediate vs
15 NDC-type action until 2030 established a feasibility frontier for the existence of such pathways across
16 participating models (Riahi et al. 2021).

17 2030 emissions levels in the NDC range also tighten the remaining space to likely limit warming 2°C.
18 As shown in Figure 3.30b, the 67th percentile of peak warming reaches values above 1.7°C warming
19 in pathways with 2030 emissions levels in this range. To still have a likely chance to stay below 2°C,
20 the global post-2030 GHG emission reduction rates would need to be abruptly raised in 2030 from 0-
21 0.8 GtCO₂-eq yr⁻¹ to an average of 1.3-2.1 GtCO₂-eq yr⁻¹ during the period 2030-2050 (Figure 3.30c),
22 around 70% of that in immediate mitigation pathways confirming findings in the literature (Winning
23 et al. 2019). Their average reduction rate of 0.6-1.4 GtCO₂ yr⁻¹ would already be unprecedented at the
24 global scale and with a few exceptions national scale for an extended period of time (Riahi et al.
25 2015). For comparison, the impact of COVID-19 on the global economy is projected to lead to a
26 decline of ca. 2.5-3 GtCO₂ of global CO₂ emissions from fossil fuel and industry in 2020
27 (Friedlingstein et al. 2020) (Chapter 2.2).

28 The increased post-2030 transition challenge in mitigation pathways with moderate near term action is
29 also reflected in the timing of reaching net zero CO₂ emissions (Figure 3.30d and Table 3.6) (Cross-
30 Chapter Box 3 in this chapter). As 2030 emission levels and the cumulated CO₂ emissions until 2030
31 increase, the remaining time for dropping to net zero CO₂ and staying within the remaining carbon
32 budget shortens (Figure 3.29). This gives rise to an inverted v-shape of the lower bound on the year of
33 reaching net zero as a function of 2030 emissions levels. Reaching low in 2030 facilitates reaching net
34 zero early (left leg of the inverted v), but staying high until 2030 also requires to reach net zero CO₂
35 faster to compensate for higher emissions early on (right leg of the inverted v). Overall, there is a
36 considerable spread of the timing of net zero CO₂ for any 2030 emissions level due to variation in the
37 timing of spending the remaining carbon budget and the non-CO₂ warming contribution (Cross-
38 Chapter Box 3 in this chapter).

2 **Figure 3.30: Relationship between level of global GHG emissions in 2030 and selected indicators as listed**
3 **in the panel titles for scenarios collected in the AR6 scenario database. Emissions data based on**
4 **harmonized emissions used for the climate assessment. All scenarios likely to limit warming to 2°C or**
5 **below are coloured blue or red (see p67 peak warming in panel b). The large majority of blue coloured**
6 **scenarios act immediately on the temperature target, while red coloured scenarios depict all those that**
7 **were designed to follow the NDCs or lesser action until 2030 and orange coloured scenarios comprise a**
8 **small set of pathways with additional regulatory action beyond NDCs (3.5.3). Grey coloured scenarios**
9 **exceed the 2°C (p67), either by temporary overshoot or towards the end of the century. Large markers**
10 **denote the 5 illustrative mitigation pathways (legend in Panel h; Section 3.2). Shaded yellow areas depict**
11 **the estimated range of 2030 emissions from current NDCs (Chapter 4.2.2). Dotted lines are inserted in**
12 **some panels to highlight trends in the dependency of selected output variables on 2030 GHG emissions**
13 **levels (see text)**

14 There is also a profound impact on the underlying transition of energy and land use (Table 3.6 and
15 Figure 3.30f-h). Scenarios following NDCs until 2030 show a much smaller reduction in fossil fuel
16 use, only half of the growth in renewable energy use, and a smaller reduction in CO₂ and CH₄ land
17 use emissions in 2030 compared to immediate action scenarios. This is then followed by a much faster
18 reduction of land use emissions and fossil fuels, and a larger increase of nuclear energy, bioenergy
19 and non-biomass renewable energy during the medium term in order to get close to the levels of the

1 immediate action pathways in 2050. This is combined with a larger amount of net negative CO₂
 2 emissions that are used to compensate the additional emissions before 2030. The faster transition
 3 during 2030-2050 is taking place from a greater investment in fossil fuel infrastructure and lower
 4 deployment of low carbon alternatives in 2030, adding to the socio-economic challenges to realize the
 5 higher transition rates (Section 3.5.2.2). Therefore, these pathways also show higher mitigation costs,
 6 particularly during the period 2030-2050, than immediate action scenarios (3.6.1, Figure 3.34d) (Liu
 7 et al. 2016; Vrontisi et al. 2018; Kriegler et al. 2018a).. Given these circumstances and the fact the
 8 modelling of socio-political and institutional constraints is limited in integrated assessment models
 9 (Keppo et al. 2021; Gambhir et al. 2019; Hirt et al. 2020; Köhler et al. 2019), the feasibility of
 10 realizing these scenarios is assessed to be lower (Gambhir et al. 2017; Napp et al. 2017; Brutschin et
 11 al. 2021) (cf. Section 3.8), increasing the risk of an overshoot of climate goals.

13 **Table 3.6: Comparison of key scenario characteristics for four scenario classes (see Table 3.2): (i)**
 14 **immediate action to limit warming to 1.5°C with no or limited overshoot, (ii) near term action following**
 15 **the NDCs until 2030 and returning warming to below 1.5°C (50% chance) by 2100 with high overshoot,**
 16 **(iii) immediate action to likely limit warming to 2°C, and (iv) near term action following the NDCs until**
 17 **2030 followed by post-2030 action to likely limit warming to 2°C. The classes (ii) and (iv) comprise the**
 18 **large majority of scenarios indicated by red dots, and the classes (i) and (iii) the scenarios depicted by**
 19 **blue dots in Figure 3.30. Shown are median and interquartile ranges (in brackets) for selected global**
 20 **indicators. Emissions ranges are based on harmonized emissions data for the climate assessment with the**
 21 **exception of land use CO₂ emissions for which uncertainty in historic estimates is large. Numbers are**
 22 **rounded to the nearest 5.**

Global indicators	1.5°C	1.5°C by 2100	Likely < 2°C	
	Immediate action, with no or limited overshoot (C1, 97 scenarios)	NDCs until 2030, with overshoot before 2100 (subset of 42 scenarios in C2)	Immediate action (C3a, 204 scenarios)	NDCs until 2030 (C3b; 97 scenarios)
Kyoto GHG emissions in 2030 (% rel to 2019)	-45 (-50,-40)	-5 (-5,0)	-25 (-35,-20)	-5 (-10,0)

in 2050 (% rel to 2019)	-80 (-85,-75)	-70 (-75,-70)	-60 (-65,-55)	-65 (-70,-55)

3.5.2.1 Overshoot and net negative CO₂ emissions

If near to medium term emissions developments deplete the remaining carbon budget, the associated warming limit will be overshoot. Some pathways that return median warming to below 1.5°C by the end of the century show mid-century overshoots of up to 1.8°C median warming. The overshoot tends to be the higher, the higher 2030 emissions. Mitigation pathways with 2030 emissions levels in the NDC range consistently overshoot 1.5°C by 0.15-0.3°C. This leads to higher risks from climate change impacts during the time of overshoot compared to pathways that limit warming to 1.5°C with no or limited overshoot (Tachiiri et al. 2019; Hofmann et al. 2019; Schleussner et al. 2016a; Mengel et al. 2018; Drouet et al. 2021; Lenton et al. 2019). Furthermore, even if warming is reversed by net negative emissions, other climate changes such as sea level rise would continue in their current direction for decades to millennia (WGI Chapter 4.6 and Chapter 5.6).

Returning warming to lower levels requires net negative CO₂ emissions in the second half of the century (Fuss et al. 2014; Clarke et al. 2014; Rogelj et al. 2018a). The amount of net negative CO₂ emissions in pathways limiting warming to 1.5-2°C climate goals varies widely, with some pathways not deploying net negative CO₂ emissions at all and others deploying up to -600 to -800 GtCO₂. The amount of net negative CO₂ emissions tends to increase with 2030 emissions levels (Figure 3.30e and Table 3.6). Studies confirmed the ability of net negative CO₂ emissions to reduce warming, but pointed to path dependencies in the storage of carbon and heat in the Earth system and the need for further research particularly for cases of high overshoot (Keller et al. 2018a,b; Tokarska et al. 2019; Zickfeld et al. 2016, 2021). WGI assessed the reduction in global surface temperature to be approximately linearly related to cumulative CO₂ removal and, with lower confidence, that the amount of cooling per unit CO₂ removed is approximately independent of the rate and amount of removal (WGI TS.3.3.2). Still there remains large uncertainty about a potential asymmetry between the warming response to CO₂ emissions and the cooling response to net negative CO₂ emissions (Zickfeld et al. 2021). It was also shown that warming can adversely affect the efficacy of carbon dioxide removal measures and hence the ability to achieve net negative CO₂ emissions (Boysen et al. 2016).

1 Obtaining net negative CO₂ emissions requires massive deployment of carbon dioxide removal (CDR)
2 in the second half of the century, on the order of 220 (160-370) GtCO₂ for each 0.1°C degree of
3 cooling (based on the assessment of the likely range of the transient response to cumulative CO₂
4 emissions in WGI Chap. 5.5, not taking into account potential asymmetries in the temperature
5 response to CO₂ emissions and removals). CDR is assessed in detail in Chapter 12.3 of this report (see
6 also Cross-Chapter Box 8 in Chapter 12). Here we only point to the finding that CDR ramp-up rates
7 and absolute deployment levels are tightly limited by techno-economic, social, political, institutional
8 and sustainability constraints (Smith et al. 2016; Boysen et al. 2017; Nemet et al. 2018; Fuss et al.
9 2018, 2020; Hilaire et al. 2019; Jia et al. 2019) (Chapter 12.3). CDR therefore cannot be deployed
10 arbitrarily to compensate any degree of overshoot. A fraction of models was not able to compute
11 pathways that would follow the mitigation ambition in unconditional and conditional NDCs until
12 2030 and return warming to below 1.5°C by 2100 (Luderer et al. 2018; Roelfsema et al. 2020; Riahi
13 et al. 2021). There exists a three-way trade-off between near-term emissions developments until 2030,
14 transitional challenges during 2030-50, and long-term CDR deployment post 2050 (Sanderson et al.
15 2016; Holz et al. 2018; Strefler et al. 2018). For example, Strefler et al. (2018) find that if CO₂
16 emission levels stay around 40 GtCO₂ until 2030, within the range of what is projected for current
17 unconditional and conditional NDCs, rather than being halved to 20 GtCO₂ until 2030, CDR
18 deployment in the second half of the century would have to increase by 50%-100%, depending on
19 whether the 2030-2050 CO₂ emissions reduction rate is doubled from 6% to 12% or kept at 6% per
20 year. This three-way trade-off has also been identified at the national level (Pan et al. 2020).

21
22 In addition to enabling a temporary budget overshoot by net negative CO₂ emissions in the second
23 half of the century, CDR can also be used to compensate – on an annual basis - residual CO₂
24 emissions from sources that are difficult to eliminate and to reach net zero CO₂ emissions more
25 rapidly if deployed before this point (Kriegler et al. 2013b; Rogelj et al. 2018a). This explains its
26 continued deployment in pathways that exclude overshoot and net negative CO₂ emissions (Riahi
27 et al. 2021). However, given the timescales that would likely be needed to ramp-up CDR to Gigaton
28 scale (Nemet et al. 2018), it can be expected to only make a limited contribution to reaching net zero
29 CO₂ as fast as possible. In the vast majority (95%) of 1.5-2°C mitigation pathways assessed in this
30 report, cumulative CDR deployment did not exceed 100 GtCO₂ until mid-century. This adds to the
31 risk of excessively relying on CDR to compensate for weak mitigation action until 2030 by either
32 facilitating massive net CO₂ emissions reduction rates during 2030-2050 or allowing a high temporary
33 overshoot of 1.5°C until the end of the century. If international burden sharing considerations are
34 taken into account, the CDR penalty for weak action could increase further, in particular for
35 developed countries (Fyson et al. 2020). Further assessment of CDR deployment in 1.5-2°C
36 mitigation pathways is found in Section 3.4.7.

37 38 **3.5.2.2 Carbon lock-in and stranded assets**

39 There already exists a substantial and growing carbon lock-in today, as measured by committed
40 emissions associated with existing long-lived infrastructure {Chapter 2.7, Figure 2.31}. If existing
41 fossil-fuel infrastructure would continue to be operated as historically, they would entail CO₂
42 emissions exceeding the carbon budget for 1.5°C {Chapter 2.7.2, Figure 2.32}. However, owner-
43 operators and societies may choose to retire existing infrastructure earlier than in the past, and
44 committed emissions are thus contingent on the competitiveness of non-emitting alternative
45 technologies and climate policy ambition. Therefore, in mitigation pathways, some infrastructure may
46 become stranded assets. Stranded assets have been defined as “assets that have suffered from
47 unanticipated or premature write-downs, devaluations or conversion to liabilities” (Caldecott 2017).

48 A systematic map of the literature on carbon lock-in has synthesized quantification of stranded-assets
49 in the mitigation pathways literature, and showed that (i) coal power plants are the most exposed to

1 risk of becoming stranded, (ii) delayed mitigation action increases stranded assets and (iii) sectoral
2 distribution and amount of stranded assets differ between countries (Fisch-Romito et al. 2020). There
3 is high agreement that existing fossil fuel infrastructure would need to be retired earlier than
4 historically, used less, or retrofitted with CCS, to stay within the remaining carbon budgets of limiting
5 warming to 1.5°C or 2°C (Johnson et al. 2016; Kefford et al. 2018; Pfeiffer et al. 2018; Cui et al.
6 2019; Fofrich et al. 2020; Rogelj et al. 2018a). Studies estimate that cumulative early retired power
7 plant capacities by 2060 can be up to 600 GW for gas and 1700 GW for coal (Iyer et al. 2015a;
8 Kefford et al. 2018), that only 42% of the total capital stock of both operating and planned coal-fired
9 powers plants can be utilized to be compatible with the 2°C target (Pfeiffer et al. 2018), and that coal-
10 fired power plants in scenarios consistent with keeping global warming below 2°C or 1.5°C retire one
11 to three decades earlier than historically has been the case (Cui et al. 2019; Fofrich et al. 2020). After
12 coal, electricity production based on gas is also projected to be phased out, with some capacity
13 remaining as back-up (van Soest et al. 2017a). Kefford et al. (2018) find USD541 billion worth of
14 stranded fossil fuel power plants could be created by 2060, with China and India the most exposed.

15 Some publications have suggested that stranded long-lived assets may be even more important outside
16 of the power sector. While stranded power sector assets by 2050 could reach up to USD1.8 trillion in
17 scenarios consistent with a 2°C target, Saygin et al. (2019) found a range of USD5-11 trillion in the
18 buildings sectors. Muldoon-Smith and Greenhalgh (2019) have even estimated a potential value at
19 risk for global real estate assets up to USD21 trillion. More broadly, the set of economic activities that
20 are potentially affected by a low carbon transition is wide and includes also energy-intensive
21 industries, transport and housing, as reflected in the concept of climate policy relevant sectors
22 introduced in Battiston et al. (2017). The sectoral distribution and amount of stranded assets differ
23 across countries (Fisch-Romito et al. 2020). Capital for fossil fuel production and distribution
24 represents a larger share of potentially stranded assets in fossil fuel producing countries such as the
25 United States and Russia. Electricity generation would be a larger share of total stranded assets in
26 emerging countries because this capital is relatively new compared to its operational lifetime.
27 Conversely, buildings could represent a larger part of stranded capital in more developed countries
28 such as the United States, EU or even Russia because of high market value and low turnover rate.

29 Many quantitative estimates of stranded assets along mitigation pathways have focused on fossil fuel
30 power plants in pathways characterized by mitigation ambition until 2030 corresponding to the
31 current NDCs followed by strengthened action afterwards to limit warming to 2°C or lower (Bertram
32 et al. 2015a; Iyer et al. 2015b; Lane et al. 2016; Farfan and Breyer 2017; van Soest et al. 2017a;
33 Luderer et al. 2018; Kriegler et al. 2018a; Cui et al. 2019; Saygin et al. 2019; SEI et al. 2020).
34 Pathways following current NDCs until 2030 do not show a significant reduction of coal, oil and gas
35 use (Figure 3.30f-h, Table 3.6) compared to immediate action pathways. Stranded coal power assets
36 are evaluated to be higher by a factor of 2-3 if action is strengthened after 2030 rather than now (Iyer
37 et al. 2015b; Cui et al. 2019). There is high agreement that the later climate policies are implemented,
38 the higher the expected stranded assets and the societal, economic and political strain of strengthening
39 action. Associated price increases for carbon-intensive goods and transitional macro-economic costs
40 have been found to scale with the emissions gap in 2030 (Kriegler et al. 2013a). At the aggregate level
41 of the whole global economy, Rozenberg et al. (2015) showed that each year of delaying the start of
42 mitigation decreases the required CO₂ intensity of new production by 20-50 gCO₂/USD. Carbon lock-
43 in can have a long-lasting effect on future emissions trajectories after 2030. Luderer et al. (2018)
44 compared cost-effective pathways with immediate action to limit warming to 1.5-2°C with pathways
45 following the NDCs until 2030 and adopting the pricing policy of the cost-effective pathways
46 thereafter and found that the majority of additional CO₂ emissions from carbon lock-in occurs after
47 2030, reaching a cumulative amount of 290 (160–330) GtCO₂ by 2100 (2.7.2). Early action and
48 avoidance of investments in new carbon-intensive assets can minimize these risks.

1 The risk of stranded assets has implications for workers depending from those assets, asset owners,
2 assets portfolio managers, financial institutions and the stability of the financial system. Chapter 6
3 assesses the risks and implications of stranded assets for energy systems (6.7.3, Box 6.11) and fossil
4 fuels (6.7.4). The implications of stranded assets for inequality and just transition are assessed in
5 Chapter 17 (17.3.2.3). Chapter 15 assesses the literature on those implications for the financial system
6 as well as on coping options (15.5.2, 15.6.1).

7 On the other hand, mitigation, by limiting climate change, reduces the risk of destroyed or stranded
8 assets from the physical impacts of climate change on natural and human systems, from more
9 frequent, intense or extended extreme events and from sea level rise (O'Neill et al. 2020a). The
10 literature on mitigation pathways rarely includes an evaluation of stranded assets from climate change
11 impacts. Unruh (Unruh 2019) suggest that these are the real stranded assets of carbon lock-in and
12 could prove much more costly.

13 14 **3.5.2.3 Global accelerated action towards long-term climate goals**

15 A growing literature explores long-term mitigation pathways with accelerated near-term action going
16 beyond the NDCs (Jiang et al. 2017; Roelfsema et al. 2018; Graichen et al. 2017; Kriegler et al.
17 2018a; van Soest et al. 2021a; Fekete et al. 2021). Global accelerated action pathways are designed to
18 transition more gradually from current policies and planned implementation of NDCs onto a 1.5-2°C
19 pathway and at the same time alleviate the abrupt transition in 2030 that would be caused by
20 following the NDCs until 2030 and strengthening towards limiting warming to 2°C thereafter (Section
21 3.5.2). Therefore they have sometimes been called bridging scenarios / pathways in the literature (IEA
22 2011; Spencer et al. 2015; van Soest et al. 2021a). They rely on regionally differentiated regulatory
23 and pricing policies to gradually strengthening regional and sectoral action beyond the mitigation
24 ambition in the NDCs. There are limitations to this approach. The tighter the warming limit, the more
25 is disruptive action becoming inevitable to achieve the speed of transition that would be required
26 (Kriegler et al. 2018a). Cost effective pathways already have abrupt shifts in deployments,
27 investments and prices at the time a stringent warming limit is imposed reflecting the fact that the
28 overall response to climate change has so far been misaligned with long-term climate goals (Geiges et
29 al. 2019; Rogelj et al. 2016; Fawcett et al. 2015; Schleussner et al. 2016b). Disruptive action can help
30 to break lock-ins and enable transformative change (Vogt-Schilb et al. 2018).

31
32 The large literature on accelerating climate action was assessed in the IPCC Special Report on 1.5°C
33 Warming (de Coninck et al. 2018) and is taken up in this report primarily in Chapters 4, 13, and 14.
34 Accelerating climate action and facilitating transformational change requires a perspective on socio-
35 technical transitions (Geels et al. 2016b; Geels 2018; Geels et al. 2016a), a portfolio of policy
36 instruments to manage technological and environmental change (Goulder and Parry 2008; Fischer and
37 Newell 2008; Acemoglu et al. 2012, 2016), a notion of path dependency and policy sequencing
38 (Meckling et al. 2017; Pahle et al. 2018; Pierson 2000) and the evolvement of poly-centric governance
39 layers of institutions and norms in support of the transformation (Messner 2015; Leach et al. 2007;
40 Dietz et al. 2003). This subsection is focused on an assessment of the emerging quantitative literature
41 on global accelerated action pathways towards 1.5-2°C, which to a large extent abstracts from the
42 underlying processes and uses a number of stylized approaches to generate these pathways. A
43 representative of accelerated action pathways has been identified as one of the illustrative mitigation
44 pathways in this assessment (GS, Figure 3.31).

45
46 One approach relies on augmenting initially moderate emissions pricing policies with robust
47 anticipation of ratcheting up climate action in the future (Spencer et al. 2015). If announcements of
48 strong future climate policies are perceived to be credible, they can help to prevent carbon lock-in as
49 investors anticipating high future costs of GHG emissions would reduce investment into fossil fuel
50 infrastructure, such as coal power plants (Bauer et al. 2018b). However, the effectiveness of such

1 announcements strongly hinges on their credibility. If investors believe that policy makers could drop
2 them if anticipatory action did not occur, they may not undertake such action.

3
4 Another approach relies on international cooperation to strengthen near term climate action. These
5 studies build on international climate policy architectures that could incentivize a coalition of like-
6 minded countries to raise their mitigation ambition beyond what is stated in their current NDC
7 (Graichen et al. 2017). Examples are the idea of climate clubs characterized by harmonized carbon
8 and technology markets (Pihl 2020; Nordhaus 2015; Keohane et al. 2017; Paroussos et al. 2019) and
9 the Powering Past Coal Alliance (Jewell et al. 2019). Paroussos et al. (2019) find economic benefits of
10 joining a climate club despite the associated higher mitigation effort, in particular due to access to
11 technology and climate finance. Graichen et al. (2017) find an additional reduction of 5-11 GtCO₂eq
12 compared to the mitigation ambition in the NDCs from the successful implementation of international
13 climate initiatives. Other studies assess benefits from international transfers of mitigation outcomes
14 (Stua 2017; Edmonds et al. 2021). Edmonds et al. (2021) find economic gains from sharing NDC
15 emissions reduction commitments compared to purely domestic implementation of NDCs. If
16 reinvested in mitigation efforts, the study projects an additional reduction of 9 billion tonnes of CO₂ in
17 2030.

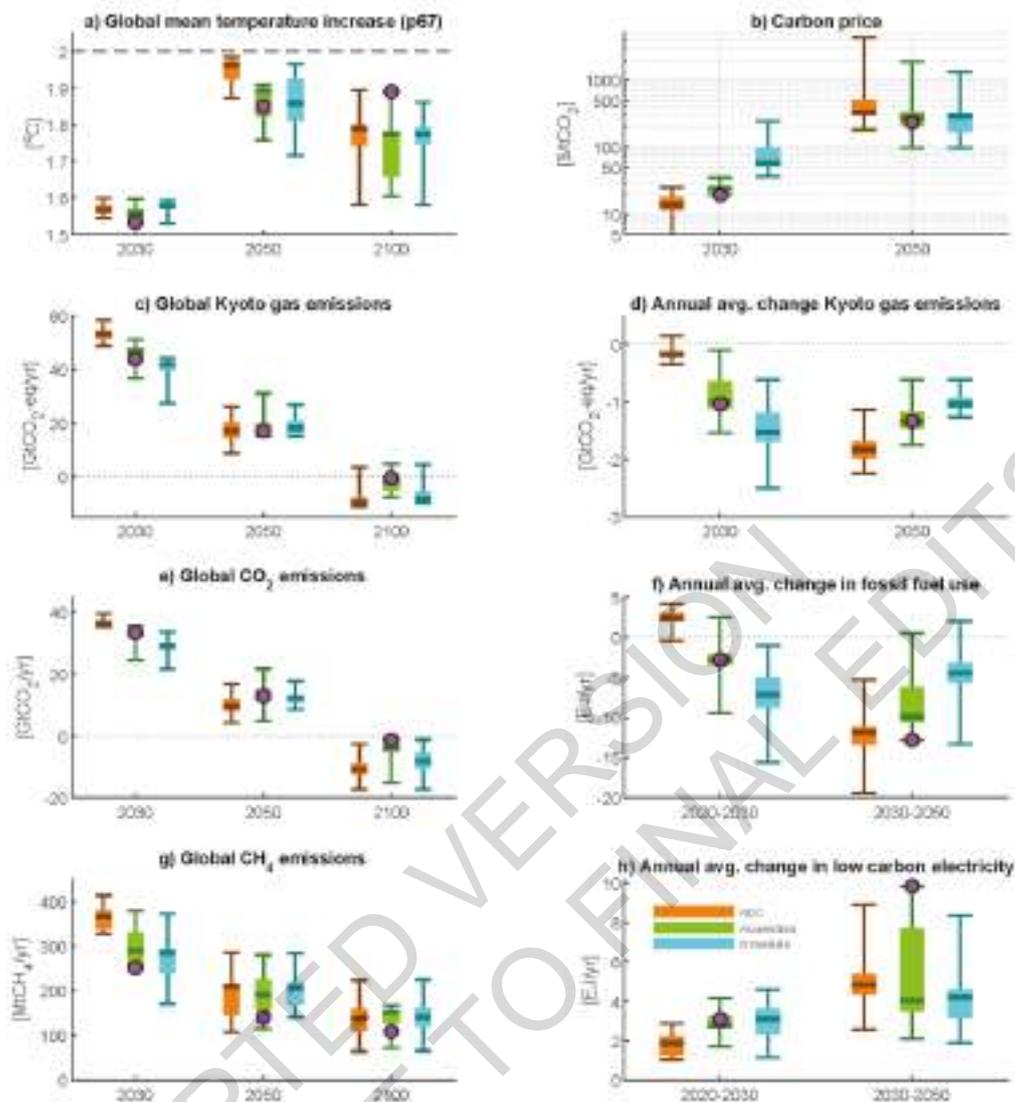

18
19 The most common approach relies on strengthening regulatory policies beyond current policy trends,
20 also motivated by the finding that such policies have so far been employed more often than
21 comprehensive carbon pricing (Roelfsema et al. 2018; Kriegler et al. 2018a; van Soest et al. 2021a;
22 Fekete et al. 2021; IEA 2021a). Some studies have focused on generic regulatory policies such as low
23 carbon support policies, fossil fuel sunset policies, and resource efficiency policies (Bertram et al.
24 2015b; Hatfield-Dodds et al. 2017). Bertram et al. (2015b) found that a moderate carbon price
25 combined with a coal moratorium and ambitious low carbon support policies can limit efficiency
26 losses until 2030 if emissions pricing is raised thereafter to limit warming to 2°C. They also showed
27 that all three components are needed to achieve this outcome. Hatfield-Dodds et al. (2017) found that
28 resource efficiency can lower 2050 emissions by an additional 15-20% while boosting near-term
29 economic growth. The International Energy Agency (IEA 2021a) developed a detailed net zero
30 scenario for the global energy sector characterized by a rapid phase out of fossil fuels, a massive clean
31 energy and electrification push, and the stabilization of energy demand, leading to 10 GtCO₂ lower
32 emissions from energy use in 2030 than in a scenario following the announced pledges.

33
34 The Paris Agreement has spurred the formulation of NDCs for 2030 and mid-century strategies
35 around the world (cf. Chapter 4). This is giving researchers a rich empirical basis to formulate
36 accelerated policy packages taking national decarbonisation pathways as a starting point (van Soest et
37 al. 2017b; Waisman et al. 2019; Graichen et al. 2017; Jiang et al. 2017). The concept is to identify
38 good practice policies that had demonstrable impact on pushing low carbon options or reducing
39 emissions in a country or region and then consider a wider roll-out of these policies taking into
40 account regional specificities (den Elzen et al. 2015; Kuramochi et al. 2018; Roelfsema et al. 2018;
41 Kriegler et al. 2018a; Fekete et al. 2015, 2021). A challenge for this approach is to account for the fact
42 that policy effectiveness varies with different political environments in different geographies. As a
43 result, a global roll-out of good practice policies to close the emissions gap will still be an idealized
44 benchmark, but it is useful to understand how much could be gained from it.

45
46 Accelerated action pathways derived with this approach show considerable scope for narrowing the
47 emissions gap between pathways reflecting the ambition level of the NDCs and cost-effective
48 mitigation pathways in 2030. Kriegler et al. (2018a) find around 10 GtCO₂eq lower emissions
49 compared to original NDCs from a global roll-out of good practice plus net zero policies and a
50 moderate increase in regionally differentiated carbon pricing. Fekete et al. (2021) show that global

1 replication of sector progress in five major economies would reduce GHG emissions in 2030 by about
2 20% compared to a current policy scenario. These findings were found in good agreement with a
3 recent model comparison study based on results from 9 integrated assessment models (van Soest et al.
4 2021a). Based on these three studies, implementing accelerated action in terms of a global roll out of
5 regulatory and moderate pricing policies is assessed to lead to global GHG emissions of 47 (38-51)
6 GtCO₂-eq in 2030 (median and 5th to 95th percentile based on 10 distinct modelled pathways). This
7 closes the implementation gap for the NDCs, and in addition falls below the emissions range implied
8 by implementing unconditional and conditional elements of NDCs by 3-9 GtCO₂-eq. However, it
9 does not close the emissions gap to immediate action pathways likely limiting warming to 2°C, and,
10 based on our assessment in Section 3.5.2, emission levels above 40 GtCO₂-eq in 2030 still have a very
11 low prospect for keeping limiting warming to 1.5°C with no or limited overshoot in reach.
12

13 Figure 3.31 shows the intermediate position of accelerated action pathways derived by van Soest et al.
14 (2021a) between pathways that follow the NDCs until 2030 and immediate action pathways likely
15 limiting warming to 2°C. Accelerated action is able to reduce the abrupt shifts in emissions, fossil fuel
16 use and low carbon power generation in 2030 and also limits peak warming more effectively than
17 NDC pathways. But primarily due to the moderate carbon price assumptions (Fig. 3.31b), the
18 reductions in emissions and particular fossil fuel use are markedly smaller than what would be
19 obtained in the case of immediate action. The assessment shows that accelerated action until 2030 can
20 have significant benefits in terms of reducing the mitigation challenges from following the NDCs
21 until 2030. But putting a significant value on GHG emissions reductions globally remains a key
22 element of moving onto 1.5-2°C pathways. The vast majority of pathways that limit warming to 2°C
23 or below, independently of their differences in near term emission developments, converge to a global
24 mitigation regime putting such a significant value on GHG emission reductions in all regions and
25 sectors.

Figure 3.31: Comparison of (i) pathways with immediate action likely limiting warming to 2°C (Immediate, light blue), (ii) pathways following the NDCs until 2030 and aiming to likely stay below 2°C thereafter (NDC; orange) and (iii) pathways accelerating near term action until 2030 beyond NDC ambition levels and aiming to likely stay below 2°C thereafter (Accelerated) for selected indicators as listed in the panel titles, based on pathways from van Soest et al. (2021a). Low carbon electricity comprises renewable and nuclear power. Indicator ranges are shown as boxplots (full range, interquartile range, and median) for the years 2030, 2050 and 2100 (absolute values) and for the periods 2020-2030, 2030-2050 (change indicators). Ranges are based on nine models participating in (van Soest et al. 2021a) with only 7 models reporting emissions and climate results and 8 models reporting carbon prices. The purple dot denotes the illustrative mitigation pathway GS that was part of the study by van Soest et al.

3.6 Economics of long-term mitigation and development pathways, including mitigation costs and benefits

A complete appraisal of economic effects and welfare effects at different temperature levels would include the macroeconomic impacts of investments in low-carbon solutions and structural change away from emitting activities, co-benefits and adverse side effects of mitigation, (avoided) climate

1 damages, as well as (reduced) adaptation costs, with high temporal, spatial and social heterogeneity
2 using a harmonized framework. If no such complete appraisal in a harmonized framework exists, key
3 elements are emerging from the literature, and assessed in the following subsections: on aggregated
4 economy-wide global mitigation costs (section 3.6.1), on the economic benefits of avoiding climate
5 impacts (section 3.6.2), on economic benefits and costs associated with mitigation co-benefits and co-
6 harms (section 3.6.3) and on the distribution of economic implications between economic sectors and
7 actors (section 3.6.4).

8 9 **3.6.1 Economy-wide implications of mitigation**

10 **3.6.1.1 Global economic effects of mitigation and carbon values in mitigation pathways**

11 12 **START BOX HERE**

13 14 **Box 3.5 Concepts and modelling frameworks used for quantifying macro-economic effects of mitigation**

15 Most studies that have developed mitigation pathways have used a Cost-effectiveness analysis (CEA)
16 framework, which aim at comparing the costs of different mitigation strategies designed to meet a
17 given climate change mitigation goal (e.g., an emission-reduction target or a temperature stabilization
18 target) but does not represent economic impacts from climate change itself, nor the associated
19 economic benefits of avoided impacts. Other studies use modelling frameworks that represent the
20 feedback of damages from climate change on the economy in a Cost-benefit analysis (CBA)
21 approach, which balances mitigation costs and benefits. This second type of studies is represented in
22 section 3.6.2.

23 The marginal abatement cost of carbon, also called carbon price, is determined by the mitigation
24 target under consideration: it describes the cost of reducing the last unit of emissions to reach the
25 target at a given point in time. Total macro-economic mitigation costs (or gains) aggregate the
26 economy-wide impacts of investments in low-carbon solutions and structural changes away from
27 emitting activities. The total macro-economic effects of mitigation pathways are reported in terms of
28 variations in economic output or consumption levels, measured against a Reference Scenario, also
29 called Baseline, at various points in time or discounted over a given time period. Depending on the
30 study, the Reference Scenario reflects specific assumptions about patterns of socio-economic
31 development and assumes either no climate policies or the climate policies in place or planned at the
32 time the study was carried out. When available in the AR6 scenarios database, this second type of
33 Reference Scenario, with current policies, has been chosen for computation of mitigation costs. In the
34 vast majority of studies that have produced the body of work on the cost of mitigation assessed here,
35 and in particular in all studies that have submitted global scenarios to the AR6 scenarios database
36 except (Schultes et al. 2021), the feedbacks of climate change impacts on the economic development
37 pathways are not accounted for. This omission of climate impacts leads to overly optimistic economic
38 projections in the reference scenarios, in particular in reference scenarios with no or limited mitigation
39 action where the extent of global warming is the greatest. Mitigation cost estimates computed against
40 no or limited policy reference scenarios therefore omit economic benefits brought by avoided climate
41 change impact along mitigation pathways, and should be interpreted with care (Grant et al. 2020).
42 When aggregate economic benefits from avoided climate change impacts are accounted for,
43 mitigation is a welfare-enhancing strategy (see section 3.6.2).

44 If GDP or consumption in mitigation pathways are below the reference scenario levels, they are
45 reported as losses or macro-economic costs. Such cost estimates give an indication on how economic
46 activity slows relative to the reference scenario; they do not necessarily describe, in absolute terms, a
47 reduction of economic output or consumption levels relative to previous years along the pathway.
48 Aggregate mitigation costs depend strongly on the modelling framework used and the assumptions

1 about the reference scenario against which mitigation costs are measured, in particular whether the
2 reference scenario is, or not, on the efficiency frontier of the economy. If the economy is assumed to
3 be at the efficiency frontier in the reference scenario, mitigation inevitably leads to actual costs, at
4 least in the short run until the production frontier evolves with technical and structural change.
5 Starting from a reference scenario that is not on the efficiency frontier opens the possibility to
6 simultaneously reduce emissions and obtain macroeconomic gains, depending on the design and
7 implementation of mitigation policies. A number of factors can result in reference scenarios below the
8 efficiency frontier, for instance distorting labour taxes and/or fossil fuel subsidies, misallocation or
9 under-utilization of production factors such as involuntary unemployment, imperfect information or
10 non-rational behaviours. Although these factors are pervasive, the modelling frameworks used to
11 construct mitigation pathways are often limited in their ability to represent them (Köberle et al. 2021).
12 The absolute level of economic activity and welfare also strongly depends on the socioeconomic
13 pathway assumptions regarding inter alia evolutions in demography, productivity, education levels,
14 inequality and technical change and innovation. The GDP or consumption indicators reported in the
15 database of scenarios, and synthesized below, represent the absolute level of aggregate economic
16 activity or consumption but do not reflect welfare and well-being (Roberts et al. 2020), that notably
17 depend on human needs satisfaction, distribution within society and inequality (see section 3.6.4).
18 Chapter 1 and Annex III give further elements on the economic concepts and on the modelling
19 frameworks, including their limitations, used in this report, respectively.

20 **END BOX HERE**

21
22 Estimates for the marginal abatement cost of carbon in mitigation pathways vary widely, depending
23 on the modelling framework used and socioeconomic, technological and policy assumptions.
24 However, it is robust across modelling frameworks that the marginal abatement cost of carbon
25 increases for lower temperature categories, with a higher increase in the short-term than in the longer-
26 term (Figure 3.32, left panel) (*high confidence*). The marginal abatement cost of carbon increases non-
27 linearly with the decrease of CO₂ emissions level, but the uncertainty in the range of estimates also
28 increases (Figure 3.33). Mitigation pathways with low-energy consumption patterns exhibit lower
29 carbon values (Méjean et al. 2019; Meyer et al. 2021). In the context of the COVID-19 pandemic
30 recovery, Kikstra et al. (2021a) also show that a low energy demand recovery scenario reduces carbon
31 prices for a 1.5°C consistent pathway by 19% compared to a scenario with energy demand trends
32 restored to pre-pandemic levels.

33
34 For optimization modelling frameworks, the time profile of marginal abatement costs of carbon
35 depends on the discount rate, with lower discount rates implying higher carbon values in the short
36 term but lower values in the long term (Emmerling et al. 2019) (see also Discounting in glossary and
37 Annex III part I section 2). In that case, the discount rate also influences the shape of the emissions
38 trajectory, with low discount rates implying more emission reduction in the short-term and, for low
39 temperature categories, limiting CDR and temperature overshoot.

40
41 Pathways that correspond to NDCs in 2030 and strengthen action after 2030 imply higher marginal
42 abatement costs of carbon in the longer run than pathways with stronger immediate global mitigation
43 action (Figure 3.32, right panel) (*high confidence*).
44

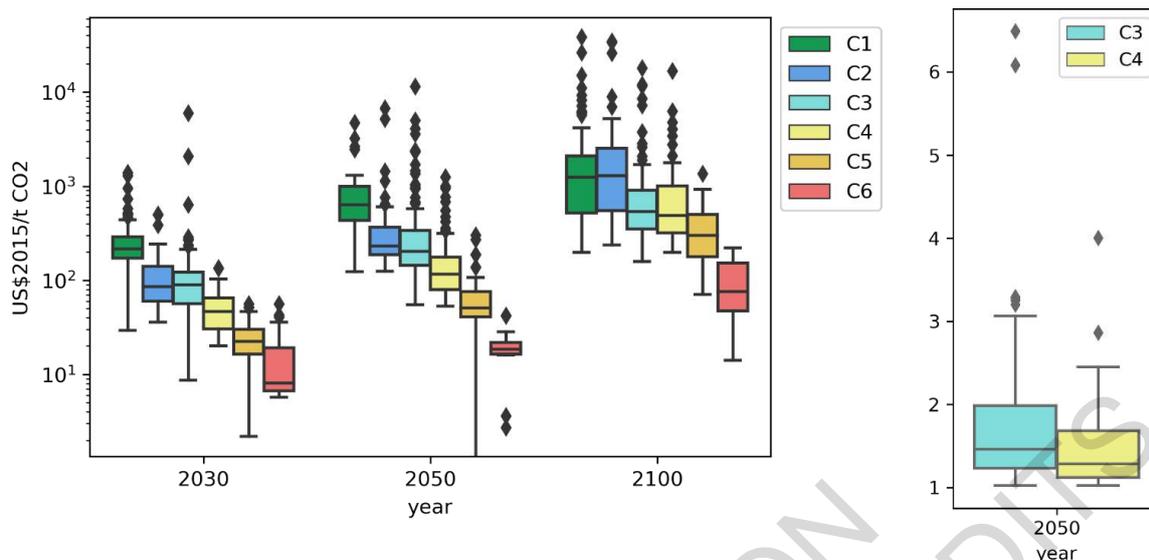

Figure 3.32: Marginal abatement cost of carbon in 2030, 2050 and 2100 for mitigation pathways with immediate global mitigation action (left panel), and ratio in 2050 between pathways that correspond to NDC in 2030 and strengthen action after 2030 and pathways with immediate global mitigation action, for C3 and C4 temperature categories (right panel).

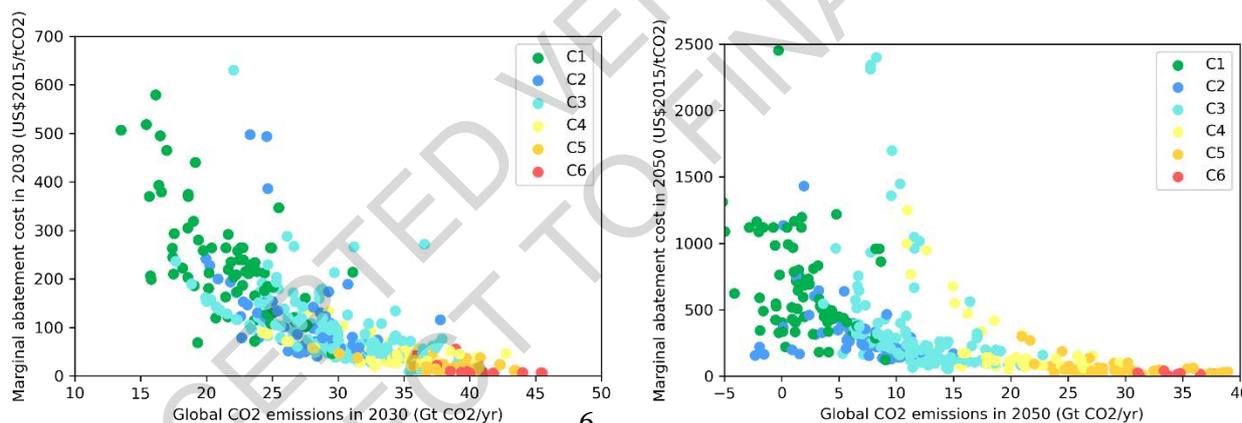

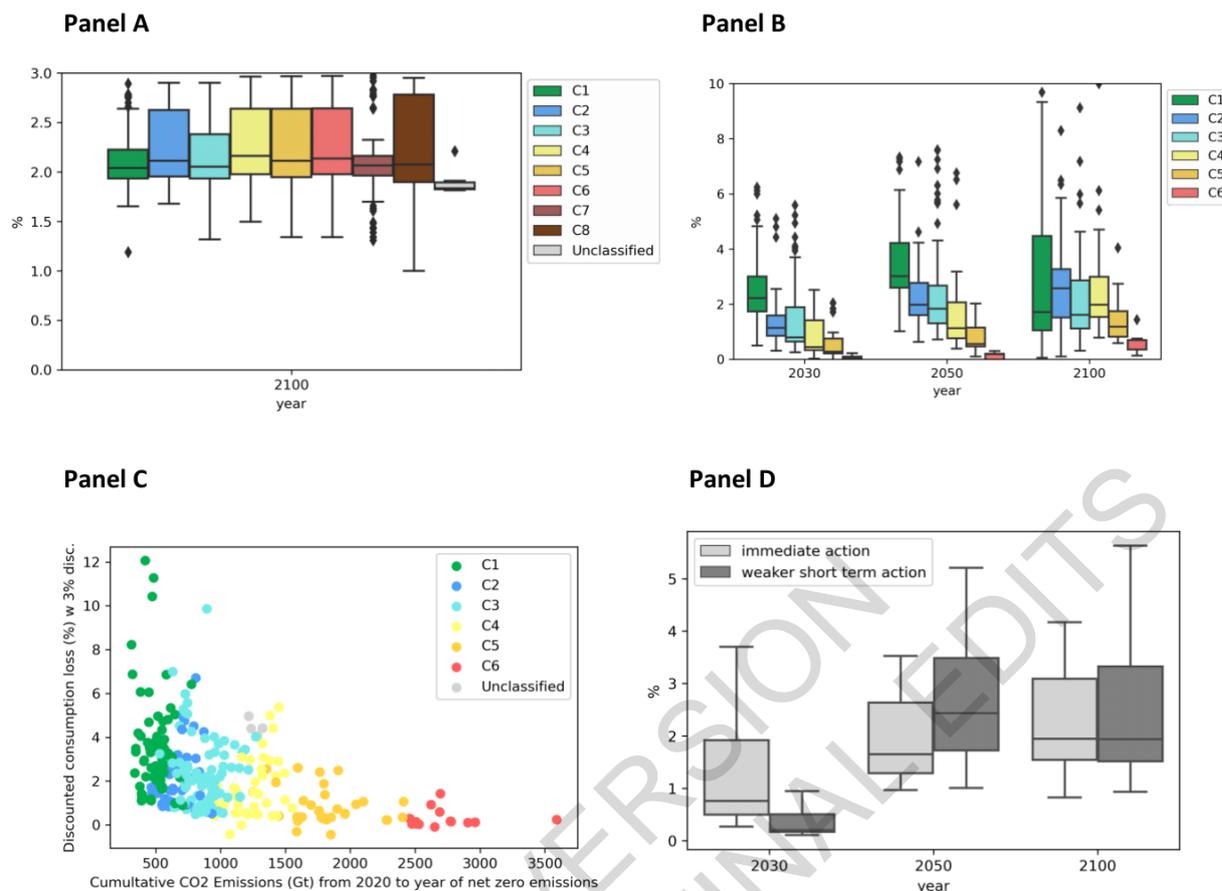

Figure 3.33: Marginal abatement cost of carbon with respect to CO₂ emissions for mitigation pathways with immediate global mitigation action, in 2030 (left panel) and 2050 (right panel).

Aggregate economic activity and consumption levels in mitigation pathways are primarily determined by socioeconomic development pathways but are also influenced by the stringency of the mitigation goal and the policy choices to reach the goal (*high confidence*). Mitigation pathways in temperature categories C1 and C2 entail losses in global consumption with respect to their baselines – not including benefits of avoided climate change impacts nor co-benefits or co-harms of mitigation action – that correspond to an annualized reduction of consumption growth by 0.04 (median value) (interquartile range [0.02-0.06]) percentage points over the century. For pathways in temperature categories C3 and C4 this reduction in global consumption growth is 0.03 (median value) (interquartile range [0.01-0.05]) percentage points over the century. In the majority of studies that focus on the economic effects of mitigation without accounting for climate damages, global economic growth and consumption growth is reduced compared to baseline scenarios (that omit damages from climate change), but mitigation pathways do not represent an absolute decrease of economic activity level (Figure 3.34, panels b and c).

1 However, the possibility for increased economic activity following mitigation action, and conversely
2 the risk of large negative economic effects, are not excluded. Some studies find that mitigation
3 increases the speed of economic growth compared to baseline scenarios (Pollitt and Mercure 2018;
4 Mercure et al. 2019). These studies are based on a macroeconomic modelling framework that
5 represent baselines below the efficiency frontier, based on non-equilibrium economic theory, and
6 assume that mitigation is undertaken in such a way that green investments do not crowd-out
7 investment in other parts of the economy – and therefore offers an economic stimulus. In the context
8 of the recovery from the COVID-19 crisis, it is estimated that a green investment push, would initially
9 boost the economy while also reducing GHG emissions (IMF 2020; Pollitt et al. 2021). Conversely,
10 several studies find that only a GDP non-growth/degrowth or post-growth approach allow to reach
11 climate stabilization below 2°C (Hardt and O’Neill 2017; D’Alessandro et al. 2020; Hickel and Kallis
12 2020; Nieto et al. 2020), or to minimize the risks of reliance on high energy-GDP decoupling, large-
13 scale CDR and large-scale renewable energy deployment (Keyßer and Lenzen 2021). Similarly,
14 feedbacks of financial system risk to amplify shocks induced by mitigation policy and lead to higher
15 impact on economic activity (Stolbova et al. 2018).

16
17 Mitigation cost increases with the stringency of mitigation (Figure 3.34, panels b and c) (Hof et al.
18 2017; Vrontisi et al. 2018), but are reduced when energy demand is moderated through energy
19 efficiency and lifestyle changes (Fujimori et al. 2014; Bibas et al. 2015; Liu et al. 2018; Méjean et al.
20 2019), when sustainable transport policies are implemented (Zhang et al. 2018c), and when
21 international technology cooperation is fostered (Schultes et al. 2018; Paroussos et al. 2019).
22 Mitigation costs also depend on assumptions on availability and costs of technologies (Clarke et al.
23 2014; Bosetti et al. 2015; Dessens et al. 2016; Creutzig et al. 2018; Napp et al. 2019; Giannousakis et
24 al. 2021), on the representation of innovation dynamics in modelling frameworks (Hoekstra et al.
25 2017; Rengs et al. 2020) (see also chapter 16), as well as the representation of investment dynamics
26 and financing mechanisms (Iyer et al. 2015c; Mercure et al. 2019; Battiston et al. 2021). In particular,
27 endogenous and induced innovation reduce technology cost over time, create path-dependencies and
28 reduce the macroeconomic cost of reaching a mitigation target (see also 1.7.1.2). Mitigation costs also
29 depend on the socioeconomic assumptions (van Vuuren et al. 2020; Hof et al. 2017).

10 **scenarios depicting immediate action pathways and delayed action pathways.**

11 Mitigation pathways with early emissions reductions represent higher mitigation costs in the short run
12 but bring long-term gains for the economy compared to delayed transition pathways (*high*
13 *confidence*). Pathways with earlier mitigation action bring higher long-term GDP than pathways
14 reaching the same end-of-century temperature with weaker early action (Figure 3.34, panel d).
15 Comparing counterfactual history scenarios, Sanderson and O'Neill (2020) also find that delayed
16 mitigation action leads to higher peak costs. Rogelj et al. (2019b) and Riahi et al. (2021) also show
17 that pathways with earlier timing of net zero CO₂ lead to higher transition costs but lower long term
18 mitigation costs, due to dynamic effects arising from lock-in avoidance and learning effects. For
19 example, Riahi et al (2021) find that for a 2°C target, the GDP losses (compared to a reference
20 scenario without impacts from climate change) in 2100 are 5-70% lower in pathways that avoid net
21 negative CO₂ emissions and temperature overshoot than in pathways with overshoot. Accounting also
22 for climate change damage, van der Wijst et al. (2021a) show that avoiding net negative emissions
23 leads to a small increase in total discounted mitigation costs over 2020-2100, between 5% and 14% in
24 their medium assumptions, but does not increase mitigation costs when damages are high and when
25 using a low discount rate, and becomes economically attractive if damages are not fully reversible.
26 The modelled cost-optimal balance of mitigation action over time strongly depends on the discount
27 rate used to compute or evaluate mitigation pathways: lower discount rates favour earlier mitigation,

1 reducing both temperature overshoot and reliance on net negative carbon emissions (Emmerling et al.
2 2019; Riahi et al. 2021). Mitigation pathways with weak early action corresponding to NDCs in 2030
3 and strengthening action after 2030 to reach end-of-century temperature targets imply limited
4 mitigation costs in 2030, compared to immediate global action pathways, but faster increase in costs
5 post-2030, with implications for intergenerational equity (Aldy et al. 2016; Liu et al. 2016; Vrontisi et
6 al. 2018). Emissions trading policies reduce global aggregate mitigation costs, in particular in the
7 context of achieving NDCs (Fujimori et al. 2015, 2016a; Edmonds et al. 2021; Böhringer et al. 2021),
8 and change the distribution of mitigation costs between regions and countries (see section 3.6.1.2).

9 **3.6.1.2 Regional mitigation costs and effort-sharing regimes**

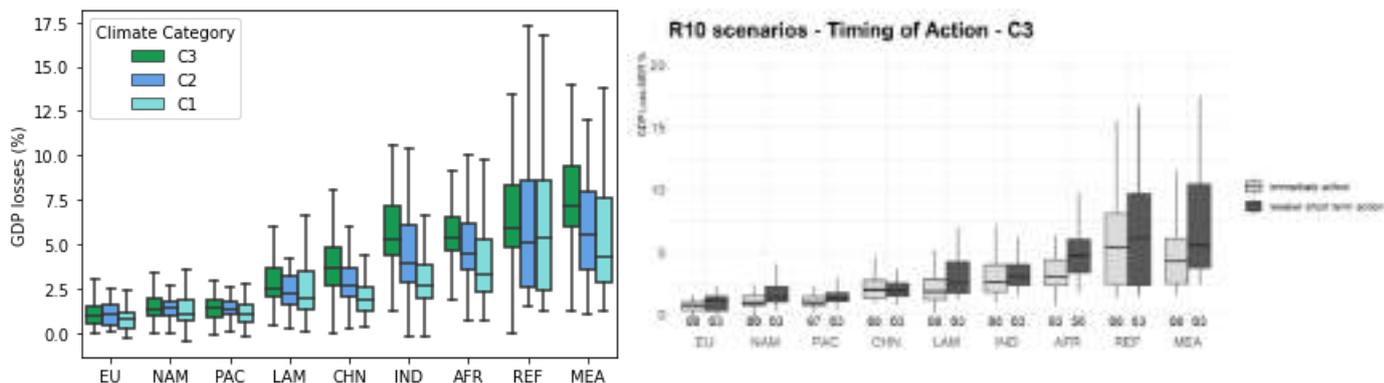

11 The economic repercussions of mitigation policies vary across countries (Hof et al. 2017; Aldy et al.
12 2016): regional variations exist in institutions, economic and technological development, and
13 mitigation opportunities. For a globally uniform carbon price, carbon intensive and energy exporting
14 countries bear the highest economic costs because of a deeper transformation of their economies and
15 of trade losses in the fossil markets (Stern et al. 2012; Tavoni et al. 2015; Böhringer et al. 2021). This
16 finding is confirmed in

17 Figure 3.35. Since carbon intensive countries are often poorer, uniform global carbon prices raises
18 equity concerns (Tavoni et al. 2015). On the other hand, the climate economic benefits of mitigating
19 climate change will be larger in poorer countries (Cross-Working Group Box 1). This reduces policy
20 regressivity but does not eliminate it (Taconet et al. 2020; Gazzotti et al. 2021). Together with co-
21 benefits, such as health benefits of improved air quality, the economic benefits of mitigating climate
22 change are likely to outweigh mitigation costs in many regions (Li et al. 2018, 2019; Scovronick et al.
23 2021).

25 Regional policy costs depend on the evaluation framework (Budolfson et al. 2021), policy design,
26 including revenue recycling, and on international coordination, especially among trade partners. By
27 fostering technological change and finance, climate cooperation can generate economic benefits, both
28 in large developing economies such as China and India (Paroussos et al. 2019) and industrialized
29 countries such as Europe (Vrontisi et al. 2020). International coordination is a major driver of regional
30 policy costs. Delayed participation in global mitigation efforts raises participation costs, especially in
31 carbon intensive economies (

32 Figure 3.35, right panel). Trading systems and transfers can deliver cost savings and improve equity
33 (Rose et al. 2017a). On the other hand, measures that reduce imports of energy intensive goods such
34 as carbon border tax adjustment may imply costs outside of the policy jurisdiction and have
35 international equity repercussions, depending on how they are designed (Böhringer et al. 2012, 2017;
36 Cosbey et al. 2019) (see also 13.6.6).

38 An equitable global emission trading scheme would require very large international financial
39 transfers, in the order of several hundred billion USD per year (Tavoni et al. 2015; van den Berg et al.
40 2020; Bauer et al. 2020). The magnitude of transfers depends on the stringency of the climate goals
41 and on the burden sharing principle. Equitable burden sharing compliant with the Paris Agreement
42 leads to negative carbon allowances for developed countries as well as China by mid-century (van den
43 Berg et al. 2020), more stringent than cost-optimal pathways. International transfers also depend on
44 the underlying socio-economic development (Leimbach and Giannousakis 2019), as these drive the
45 mitigation costs of meeting the Paris Agreement (Rogelj et al. 2018b). By contrast, achieving equity
46 without international markets would result in a large discrepancy in regional carbon prices, up to a
47 factor (Bauer et al. 2020). The efficiency-sovereignty trade-off can be partly resolved by allowing for
48 limited differentiation of regional carbon prices: moderate financial transfers substantially reduce
49 inefficiencies by narrowing the carbon price spread (Bauer et al. 2020).

9 **short-term, strengthening to reach the same end-of-century temperature target.**

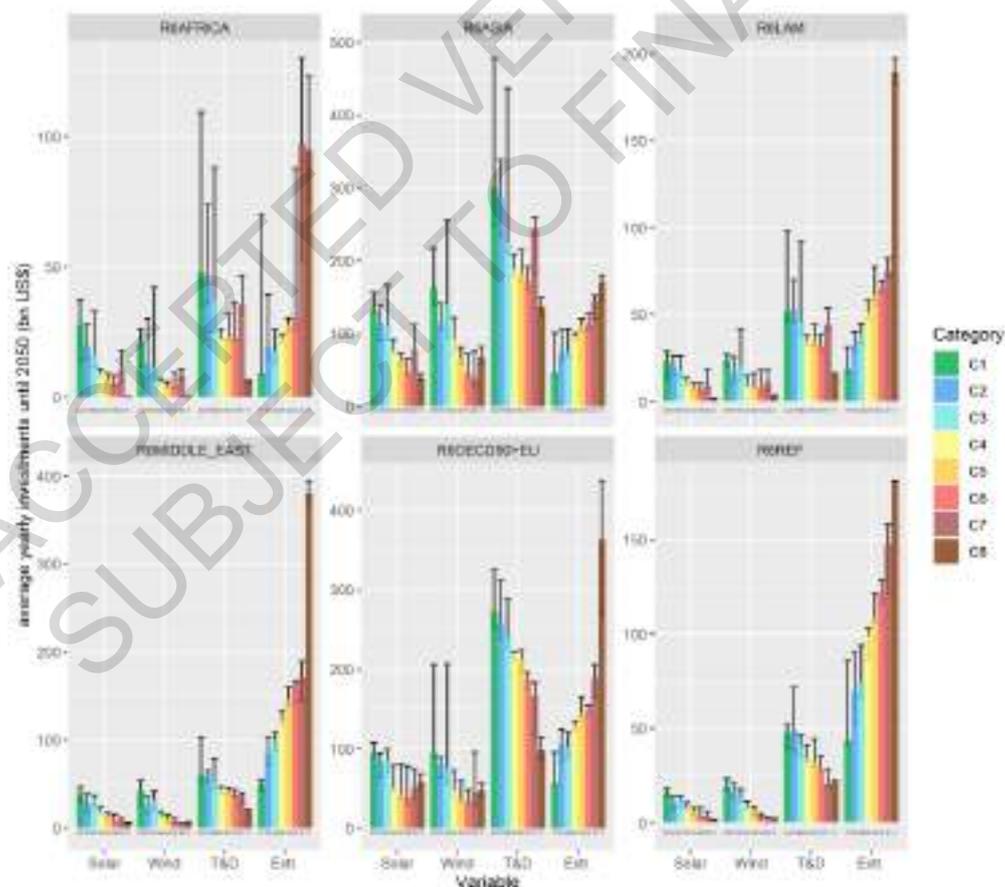

10 3.6.1.3 Investments in mitigation pathways

11 Figure 3.36 and Figure 3.37 show increased investment needs in the energy sector in lower
12 temperature categories, and a major shift away from fossil generation and extraction towards
13 electricity, including for system enhancements for electricity transmission, distribution and storage,
14 and low-carbon technologies. Investment needs in the electricity sector are USD2.3 trillion 2015 yr⁻¹
15 over 2023-2050 on average for C1 pathways, USD2.0 trillion for C2 pathways, USD1.7 trillion for
16 C3, USD1.2 trillion for C4 and USD0.9-1.1 billion for C5/C6/C7 (mean values for pathways in each
17 temperature categories). The regional pattern of power sector investments broadly mirrors the global
18 picture. However, the bulk of investment requirements are in medium- and low-income regions.
19 These results from the AR6 scenarios database corroborate the findings from McCollum et al.
20 (2018a), Zhou et al. (2019) and Bertram et al. (2021).

21
22
23 In the context of the COVID-19 pandemic recovery, (Kikstra et al. 2021a) show that a low energy
24 demand recovery scenario reduces energy investments required until 2030 for a 1.5°C consistent
25 pathway by 9% (corresponding to reducing total required energy investment by USD1.8 trillion)
26 compared to a scenario with energy demand trends restored to pre-pandemic levels.
27

9 **temperature categories. T&D: transmissions and distribution of electricity. Extr.: extraction of fossil**

1 **fuels. Bars show the median values (number of pathways at the bottom), and whiskers the interquartile**
2 **ranges.**

3
4 Few studies extend the scope of the investment needs quantification beyond the energy sector. Fisch-
5 Romito and Guivarch (2019) and Ó Broin and Guivarch (2017) assess investment needs for
6 transportation infrastructures and find lower investment needs in low-carbon pathways, due to a
7 reduction in transport activity and a shift towards less road construction, compared to high-carbon
8 pathways. Rozenberg and Fay (2019) estimate the funding needs to close the service gaps in water
9 and sanitation, transportation, electricity, irrigation, and flood protection in thousands of scenarios,
10 showing that infrastructure investment paths compatible with full decarbonization in the second half
11 of the century need not cost more than more-polluting alternatives. Investment needs are estimated
12 between 2 percent and 8 percent of GDP, depending on the quality and quantity of services targeted,
13 the timing of investments, construction costs, and complementary policies.

14
15 Chapter 15 also reports investment requirements in global mitigation pathways in the near-term,
16 compares them to recent investment trends, and assesses financing issues.

17 18 **3.6.2 Economic benefits of avoiding climate changes impacts**

19 20 **START BOX HERE**

21 22 **Cross-Working Group Box 1: Economic benefits from avoided climate impacts along long-term** 23 **mitigation pathways**

32
33 Mitigation reduces the extent of climate change and its impacts on ecosystems, infrastructure, and
34 livelihoods. This box summarizes elements from the WGII report on aggregate climate change
35 impacts and risks, putting them into the context of mitigation pathways. AR6 Working Group II
36 provides an assessment of current lines of evidence regarding potential climate risks with future
37 climate change, and therefore, the avoided risks from mitigating climate change. Regional and
38 sectoral climate risks to physical and social systems are assessed (WGII Chapters 2-15). Over 100 of
39 these are identified as Key Risks (KRs) and further synthesized by WGII Chapter 16 into eight
40 overarching Representative Key Risks (RKRs) relating to low-lying coastal systems; terrestrial and
41 ocean ecosystems; critical physical infrastructure, networks and services; living standards; human
42 health; food security; water security; and peace and mobility (WGII 16.5.2). The RKR assessment
43 finds that risks increase with global warming level, and also depend on socioeconomic development
44 conditions, which shape exposure and vulnerability, and adaptation opportunities and responses.
45 “Reasons For Concern”, another WGII aggregate climate impacts risk framing, are also assessed to
46 increase with climate change, with increasing risk for unique and threatened systems, extreme weather
47 events, distribution of impacts, global aggregate impacts, and large-scale singular events (WGII
48 Chapter 16). For human systems, in general, the poor and disadvantaged are found to have greater
49 exposure level and vulnerability for a given hazard. With some increase in global average warming

1 from today expected regardless of mitigation efforts, human and natural systems will be exposed to
2 new conditions and additional adaptation will be needed (WGII Chapter 18). The range of dates for
3 when a specific warming level could be reached depends on future global emissions, with significant
4 overlap of ranges across emissions scenarios due to climate system response uncertainties (WGI
5 Tables 4.2 and 4.5). The speed at which the climate changes is relevant to adaptation timing,
6 possibilities, and net impacts.

7
8 WGII also assesses the growing literature estimating the global aggregate economic impacts of
9 climate change and the social cost of carbon dioxide and other greenhouse gases (Cross-Working Box
10 Economic: Estimating Global Economic Impacts from Climate Change and the Social Cost of
11 Carbon”, in WGII Chapter 16). The former represents aggregate estimates that inform assessment of
12 the economic benefits of mitigation. This literature is characterized by significant variation in the
13 estimates, including for today's level of global warming, due primarily to fundamental differences in
14 methods, but also differences in impacts included, representation of socioeconomic exposure,
15 consideration of adaptation, aggregation approach, and assumed persistence of damages. WGII's
16 assessment identifies different approaches to quantification of aggregated economic impacts of
17 climate change, including: physical modelling of impact processes, such as projected mortality rates
18 from climate risks such as heat, vector- or waterborne diseases that are then monetized; structural
19 economic modelling of impacts on production, consumption, and markets for economic sectors and
20 regional economies; and statistical estimation of impacts based on observed historical responses to
21 weather and climate. WGII finds that variation in estimated global economic impacts increases with
22 warming in all methodologies, indicating higher risk in terms of economic impacts at higher
23 temperatures (*high confidence*). Many estimates are nonlinear with marginal economic impacts
24 increasing with temperature, although some show declining marginal economic impacts with
25 temperature, and functional forms cannot be determined for all studies. WGII's assessment finds that
26 the lack of comparability between methodologies does not allow for identification of robust ranges of
27 global economic impact estimates (*high confidence*). Further, WGII identifies evaluating and
28 reconciling differences in methodologies as a research priority for facilitating use of the different lines
29 of evidence (*high confidence*). However, there are estimates that are higher than AR5, indicating that
30 global aggregate economic impacts could be higher than previously estimated (*low confidence* due to
31 the lack of comparability across methodologies and lack of robustness of estimates) (Cross-Working
32 Box Economic).

33
34 Conceptually, the difference in aggregate economic impacts from climate change between two given
35 temperature levels represents the aggregate economic benefits arising from avoided climate change
36 impacts due to mitigation action. A subset of the studies whose estimates were evaluated by WGII (5
37 of 15) are used to derive illustrative estimates of aggregate economic benefits in 2100 arising from
38 avoided climate change (Howard and Sterner 2017; Burke et al. 2018; Pretis et al. 2018; Kahn et al.
39 2019; Takakura et al. 2019). Burke et al. (2018), Pretis et al. (2018) and Kahn et al. (2019) are
40 examples of statistical estimation of historical relationships between temperature and economic
41 growth, whereas Takakura et al. (2019) is an example of structural modelling, which evaluates
42 selected impact channels (impacts on agriculture productivity, undernourishment, heat-related
43 mortality, labour productivity, cooling/heating demand, hydroelectric and thermal power generation
44 capacity and fluvial flooding) with a general equilibrium model. Howard and Sterner (2017) and
45 Rose et al. (2017b) estimate damage functions that can be used to compute the economic benefits of
46 mitigation from avoiding a given temperature level for a lower one. Howard and Sterner (2017)
47 estimate a damage function from a meta-analysis of aggregate economic impact studies, while Rose et
48 al. (2017b) derive global functions by temperature and socioeconomic drivers from stylized aggregate
49 Cost-Benefit-Analysis integrated assessment models using diagnostic experiments. Cross-Working
50 Group Box 1 Figure 1 summarizes the global aggregate economic benefits in 2100 of avoided climate

1 change impacts from individual studies corresponding to shifting from a higher temperature category
2 (above 3°C, below 3°C or below 2.5°C) to below 2°C, as well as from below 2°C to below 1.5°C.
3 Benefits are positive and increase with the temperature gap for any given study, and this result is
4 robust across socioeconomic scenarios. The Figure provides evidence of a wide range of
5 quantifications, and illustrates the important differences associated with methods. Panel a puts the
6 studies used to calculate aggregate economic benefits arising from avoided impacts into the context of
7 the broader set of studies assessed in WGII (WGII Cross-Working Group Box Economic, 16.6.2).
8 However, economic benefits in 2100 arising from avoided impacts cannot be directly computed from
9 damage estimates across this broader set of studies, due to inconsistencies - different socioeconomic
10 assumptions, scenario designs, and counterfactual reference scenarios across studies. Furthermore,
11 these types of estimates cannot be readily compared to mitigation cost estimates. The comparison
12 would require a framework that ensures consistency in assumptions and dynamics and allows for
13 consideration of benefits and costs along the entire pathway.

14
15 **Cross-Working Group Box 1 Figure 1: Global aggregate economic benefits of mitigation from avoided**
16 **climate change impacts in 2100 corresponding to shifting from a higher temperature category (4°C**
17 **(3.75°C-4.25°C), 3°C(2.75°C-3.25°C) or above 2°C (2°C-2.5°C)) to below 2°C (1.5°C-2°C), as well as from**
18 **below 2°C to below 1.5°C (1°C-1.5°C), from the five studies discussed in the text. Panel a is adapted from**
19 **WGII CWGB ECONOMIC Figure 1, showing global aggregate economic impact estimates (% global**
20 **GDP loss relative to GDP without additional climate change) by temperature change level. All estimates**
21 **are shown in grey. Estimates used for the computation of estimated benefits in 2100 in Panel b are**
22 **coloured for the selected studies, which provide results for different temperature change levels. See the**
23 **WGII Chapter 16 box for discussion and assessment of the estimates in Panel a and the differences in**
24 **methodologies. For B18 and T19, median estimates in the cluster are considered. Shape distinguishes the**
25 **baseline scenarios. Temperature ranges are highlighted. HS17 estimates are based on their preferred**
26 **model - 50th percentile of non-catastrophic damage. Panel b shows the implied aggregate economic**
27 **benefits in 2100 of a lower temperature increase. Economic benefits for point estimates are computed as a**
28 **difference, while economic benefits from the curve HS17 are computed as ranges from the segment**
29 **differences.**
30

31 Aggregate benefits from avoided impacts expressed in GDP terms, as in Figure 1, do not encompass
32 all avoided climate risks, adaptation possibilities, and does not represent their influence on well-being
33 and welfare (WGII Cross-Working Group Box Economic). Methodological challenges for economic
34 impact estimates include representing uncertainty and variability, capturing interactions and spill
35 overs, considering distributional effects, representing micro and macro adaptation processes,
36 specifying non-gradual damages and non-linearities, and improving understanding of potential long-
37 run growth effects. In addition, the economic benefits aggregated at the global scale provide limited
38 insights into regional heterogeneity. Global economic impact studies with regional estimates find
39 large differences across regions in absolute and percentage terms, with developing and transitional
40 economies typically more vulnerable. Furthermore, (avoided) impacts for poorer households and
41 poorer countries can represent a smaller share in aggregate quantifications expressed in GDP terms or
42 monetary terms, compared to their influence on well-being and welfare (Hallegatte et al. 2020;
43 Markhvida et al. 2020). Finally, as noted by WGII, other lines of evidence regarding climate risks,
44 beyond monetary estimates, should be considered in decision-making, including key risks and
45 Reasons for Concern.

46
47 **END CCB HERE**
48

49 Cost-benefit analyses (CBA) aim to balance all costs and benefits in a unified framework (Nordhaus,
50 2008). Estimates of economic benefits from avoided climate change impacts depend on the types of
51 damages accounted for, the assumed exposure and vulnerability to these damages as well as the
52 adaptation capacity, which in turn are based on the development pathway assumed (Cross-Working

1 Group Box 1). CBA integrated assessment models raised critics, in particular for omitting elements of
2 dynamic realism, such as inertia, induced innovation and path dependence, in their representation of
3 mitigation (Grubb et al. 2021), and for underestimating damages from climate change, missing non-
4 monetary damages, the uncertain and heterogeneous nature of damages and the risk of catastrophic
5 damages (Stern 2013, 2016; Stern and Stiglitz 2021; Diaz and Moore 2017; Pindyck 2017; NASEM
6 2017; Stoerk et al. 2018). Emerging literature has started to address those gaps, and integrated into
7 cost-benefit frameworks the account of heterogeneity of climate damage and inequality (Dennig et al.
8 2015; Budolfson et al. 2017; Fleurbaey et al. 2019; Kornek et al. 2021), damages with higher
9 persistence, including damages on capital and growth (Dietz and Stern 2015; Moore and Diaz 2015;
10 Moyer et al. 2014; Guivarch and Pottier 2018; Piontek et al. 2019; Ricke et al. 2018), risks of tipping
11 points (Cai et al. 2015, 2016; Lontzek et al. 2015; Lemoine and Traeger 2016; van der Ploeg and de
12 Zeeuw 2018; Cai and Lontzek 2019; Nordhaus 2019; Yumashev et al. 2019; Taconet et al. 2021) and
13 damages to natural capital and non-market goods (Tol 1994; Sterner and Persson 2008; Bastien-
14 Olvera and Moore 2020; Drupp and Hänsel 2021).

15
16 Each of these factors, when accounted for in a CBA framework, tends to increase the welfare benefit
17 of mitigation, thus leading to stabilization at lower temperature in optimal mitigation pathways. The
18 limitations in CBA modelling frameworks remain significant, their ability to represent all damages
19 incomplete, and the uncertainty in estimates remains large. However, emerging evidence suggests
20 that, even without accounting for co-benefits of mitigation on other sustainable development
21 dimensions (see section 3.6.3 for elements on co-benefits), global benefits of pathways *likely* to limit
22 warming to 2°C outweigh global mitigation costs over the 21st century: depending on the study, the
23 reason for this result lies in assumptions of economic damages from climate change in the higher end
24 of available estimates (Moore and Diaz 2015; Ueckerdt et al. 2019; Brown and Saunders 2020;
25 Glanemann et al. 2020), in the introduction of risks of tipping-points (Cai and Lontzek 2019), in the
26 consideration of damages to natural capital and non-market goods (Bastien-Olvera and Moore 2020)
27 or in the combination of updated representations of carbon cycle and climate modules, updated
28 damage estimates and/or updated representations of economic and mitigation dynamics (Dietz and
29 Stern 2015; Hänsel et al. 2020; Wei et al. 2020; van der Wijst et al. 2021b). In the above studies that
30 perform a sensitivity analysis, this result is found to be robust to a wide range of assumptions on
31 social preferences (in particular on inequality aversion and pure rate of time preference) and holds
32 except if assumptions of economic damages from climate change are in the lower end of available
33 estimates and the pure rate of time preference is in the higher range of values usually considered
34 (typically above 1.5%). However, although such pathways bring net benefits over time (in terms of
35 aggregate discounted present value), they involve distributional consequences and transition costs
36 (Brown and Saunders 2020; Brown et al. 2020) (see also sections 3.6.1.2 and 3.6.4).

37
38 The standard discounted utilitarian framework dominates CBA, thus often limiting the analysis to the
39 question of discounting. CBA can be expanded to accommodate a wider variety of ethical values to
40 assess mitigation pathways (Fleurbaey et al. 2019). The role of ethical values with regard to inequality
41 and the situation of the worse-off (Adler et al. 2017), risk (van den Bergh and Botzen 2014; Drouet et
42 al. 2015), and population size (Scovronick et al. 2017; Méjean et al. 2020) has been explored. In most
43 of these studies, the optimal climate policy is found to be more stringent than the one obtained using a
44 standard discounted utilitarian criterion.

45
46 Comparing economic costs and benefits of mitigation raises a number of methodological and
47 fundamental difficulties. Monetizing the full range of climate change impacts is extremely hard, if not
48 impossible (WGII chapter 16), as is aggregating costs and benefits over time and across individuals
49 when values are heterogeneous (AR5, WGIII chapter 3; this assessment, Chapter 1). Other approaches
50 should thus be considered in supplement for decision making (Chapter 1, section 1.7), in particular

1 cost-effectiveness approaches that analyse how to achieve a defined mitigation objective at least cost
2 or while also reaching other societal goals (Kooimey 2013; Kaufman et al. 2020; Köberle et al. 2021;
3 Stern and Stiglitz 2021). In cost effectiveness studies too, incorporating benefits from avoided climate
4 damages influences the results and leads to more stringent mitigation in the short-term (Drouet et al.
5 2021; Schultes et al. 2021).

6 7 **3.6.3 Aggregate economic implication of mitigation co-benefits and trade-offs**

8 Mitigation actions have co-benefits and trade-offs with other sustainable development dimensions
9 (section 3.7), beyond climate change, which imply welfare effects and economic effects, as well as
10 other implications beyond the economic dimension. The majority of quantifications of mitigation
11 costs and benefits synthesized in sections 3.6.1 and 3.6.2 do not account for these economic benefits
12 and costs associated with co-benefits and trade-offs along mitigation pathways.

13
14 Systematic reviews of the literature on co-benefits and trade-offs from mitigation actions have shown
15 that only a small portion of articles provide economic quantifications (Deng et al. 2017; Karlsson et
16 al. 2020). Most economic quantifications use monetary valuation approaches. Improved air quality,
17 and associated health effects, are the co-benefit category dominating the literature (Markandya et al.
18 2018; Vandyck et al. 2018; Scovronick et al. 2019; Howard et al. 2020; Karlsson et al. 2020b; Rauner
19 et al. 2020a,b), but some studies cover other categories, including health effects from diet change
20 (Springmann et al. 2016b) and biodiversity impacts (Rauner et al. 2020a). Regarding health effects
21 from air quality improvement and from diet change, co-benefits are shown to be of the same order of
22 magnitude as mitigation costs (Thompson et al. 2014; Springmann et al. 2016a,b; Markandya et al.
23 2018; Scovronick et al. 2019b; Howard et al. 2020; Rauner et al. 2020a,b; Liu et al. 2021; Yang et al.
24 2021). Co-benefits from improved air quality are concentrated sooner in time than economic benefits
25 from avoided climate change impacts (Karlsson et al. 2020), such that when accounting both for
26 positive health impacts from reduced air pollution and for negative climate effect of reduced cooling
27 aerosols, optimal greenhouse gas mitigation pathways exhibit immediate and continual net economic
28 benefits (Scovronick et al. 2019a). However, WGI chapter 6 (section 6.7.3) shows a delay in air
29 pollution reduction benefits when they come from climate change mitigation policies compared with
30 air pollution reduction policies.

31
32 Achieving co-benefits is not automatic but results from coordinated policies and implementation
33 strategies (Clarke et al. 2014; McCollum et al. 2018a). Similarly, avoiding trade-offs requires targeted
34 policies (van Vuuren et al. 2015; Bertram et al. 2018). There is limited evidence of such pathways, but
35 the evidence shows that pathways mitigation pathways designed to reach multiple sustainable
36 development goals instead of focusing exclusively on emissions reductions, result in limited
37 additional costs compared to the increased benefits (Cameron et al. 2016; McCollum et al. 2018b;
38 Fujimori et al. 2020a; Sognaes et al. 2021).

39 40 **3.6.4 Structural change, employment and distributional issues along mitigation pathways**

41
42 Beyond aggregate effects at the economy wide level, mitigation pathways have heterogeneous
43 economic implications for different sectors and different actors. Climate-related factors are only one
44 driver of the future structure of the economy, of the future of employment, and of future inequality
45 trends, as overarching trends in demographics, technological change (innovation, automation, etc.),
46 education and institutions will be prominent drivers. For instance, Rao et al. (2019b) and Benveniste
47 et al. (2021) have shown that income inequality projections for the 21st century vary significantly,
48 depending on socioeconomic assumptions related to demography, education levels, social public
49 spending and migrations. However, the sections below focus on climate-related factors, both climate

1 mitigation actions themselves and the climate change impacts avoided along mitigation pathways,
2 effects on structural change, including employment, and distributional effects.

3 4 **3.6.4.1 Economic structural change and employment in long-term mitigation pathways**

5 Mitigation pathways entail transformation of the energy sector, with structural change away from
6 fossil energy and towards low-carbon energy (section 3.3), as well as broader economic structural
7 change, including industrial restructuring and reductions in carbon-intensive activities in parallel to
8 extensions in low-carbon activities.

9
10 Mitigation affects work through multiple channels, which impacts geographies, sectors and skill
11 categories differently (Fankhaeser et al. 2008; Bowen et al. 2018; Malerba and Wiebe 2021).
12 Aggregate employment impacts of mitigation pathways mainly depend on the aggregate
13 macroeconomic effect of mitigation (see 3.6.1, 3.6.2) and of mitigation policy design and
14 implementation (Freire-González 2018) (section 4.2.6.3). Most studies that quantify overall
15 employment implications of mitigation policies are conducted at the national or regional scales
16 (section 4.2.6.3), or sectoral scales (e.g., see chapter 6 for energy sector jobs). The evidence is limited
17 at the multi-national or global scale, but studies generally find small differences in aggregate
18 employment in mitigation pathways compared to baselines: the sign of the difference depends on the
19 assumptions and modelling frameworks used and the policy design tested, with some studies or policy
20 design cases leading to small increases in employment (Chateau and Saint-Martin 2013; Pollitt et al.
21 2015; Barker et al. 2016; Garcia-Casals et al. 2019; Fujimori et al. 2020a; Vrontisi et al. 2020;
22 Malerba and Wiebe 2021) and other studies or policy design cases leading to small decreases
23 (Chateau and Saint-Martin 2013; Vandyck et al. 2016). The small variations in aggregate employment
24 hide substantial reallocation of jobs across sectors, with jobs creation in some sectors and jobs
25 destruction in others. Mitigation action through thermal renovation of buildings, installation and
26 maintenance of low-carbon generation, the build-out of public transit lead to jobs creation, while jobs
27 are lost in fossil fuel extraction, energy supply and energy intensive sectors in mitigation pathways
28 (von Stechow et al. 2015, 2016; Barker et al. 2016; Fuso Nerini et al. 2018; Perrier and Quirion 2018;
29 Pollitt and Mercure 2018; Dominish et al. 2019; Garcia-Casals et al. 2019). In the energy sector, jobs
30 losses in the fossil fuel sector are found to be compensated by gains in wind and solar jobs, leading to
31 a net increase in energy sector jobs in 2050 in a mitigation pathway compatible with stabilization of
32 the temperature increase below 2°C (Pai et al. 2021). Employment effects also differ by geographies,
33 with energy-importing regions benefiting from net job creations but energy-exporting regions
34 experiencing very small gains or suffering from net job destruction (Barker et al. 2016; Pollitt and
35 Mercure 2018; Garcia-Casals et al. 2019; Malerba and Wiebe 2021). Coal phase-out raises acute
36 issues of just transition for the coal-dependent countries (Spencer et al. 2018; Jakob et al. 2020)
37 (section 4.5 and Box 6.2).

38
39 Mitigation action also affects employment through avoided climate change impacts. Mitigation
40 reduces the risks to human health and associated impacts on labour and helps protect workers from
41 the occupational health and safety hazards imposed by climate change (Kjellstrom et al. 2016, 2018,
42 2019 ; Levi et al. 2018; Day et al. 2019) (see WGII chapter 16).

43 44 **3.6.4.2 Distributional implications of long-term mitigation pathways**

45 Mitigation policies can have important distributive effects between and within countries, either
46 reducing or increasing economic inequality and poverty, depending on policy instruments design and
47 implementation (see section 3.6.1.2 for an assessment of the distribution of mitigation costs across
48 regions in mitigation pathways, section 3.7, Box 3.6 and chapter 4 section 4.2.2.6 for an assessment of
49 the fairness and ambition of NDCs, and section 4.5 for an assessment of national mitigation pathways
50 along the criteria of equity, including just transition, as well as chapter 17, section 17.4.5 for equity in

1 a just transition). For instance, emissions taxation has important distributive effects, both between and
2 within income groups (Klenert et al. 2018; Cronin et al. 2018b; Pizer and Sexton 2019; Douenne
3 2020; Steckel et al. 2021). These effects are more significant in some sectors, such as transport, and
4 depend on country-specific consumption structures (Dorband et al. 2019; Fullerton and Muehlegger
5 2019; Ohlendorf et al. 2021). However, revenues from emissions taxation can be used to lessen their
6 regressive distributional impacts or even turn the policy into a progressive policy reducing inequality
7 and/or leading to gains for lower income households (Cameron et al. 2016; Jakob and Steckel 2016;
8 Fremstad and Paul 2019; Fujimori et al. 2020b; Böhringer et al. 2021; Steckel et al. 2021; Soergel et
9 al. 2021b; Budolfson et al. 2021). Mitigation policies may affect the poorest through effects on energy
10 and food prices (Hasegawa et al. 2015; Fujimori et al. 2019). Markkanen and Anger-Kraavi (2019)
11 and Lamb et al. (2020) synthesize evidence from the existing literature on social co-impacts of
12 climate change mitigation policy and their implications for inequality. They show that most policies
13 can compound or lessen inequalities depending on contextual factors, policy design and policy
14 implementation, but that negative inequality impacts of climate policies can be mitigated (and
15 possibly even prevented), when distributive and procedural justice are taken into consideration in all
16 stages of policy making, including policy planning, development and implementation, and when
17 focusing on the carbon intensity of lifestyles, sufficiency and equity, wellbeing and decent living
18 standards for all (see also 13.6).

19
20 Mitigation pathways also affect economic inequalities between and within countries, and poverty,
21 through the reduction of climate change impacts that fall more heavily on low-income countries,
22 communities and households and exacerbate poverty (WGII chapters 8 and 16). Higher levels of
23 warming are projected to generate higher inequality between countries as well as within them (WGII
24 chapter 16). Through avoiding impacts, mitigation thus reduces economic inequalities and poverty
25 (*high confidence*).

26
27 A few studies consider both mitigation policies distributional impacts and avoided climate change
28 impacts on inequalities along mitigation pathways. Rezai et al. (2018) find that unmitigated climate
29 change impacts increase inequality, whereas mitigation has the potential to reverse this effect.
30 Considering uncertainty in socioeconomic assumptions, emission pathways, mitigation costs,
31 temperature response, and climate damage, Taconet et al. (2020) show that the uncertainties
32 associated with socioeconomic assumptions and damage estimates are the main drivers of future
33 inequalities between countries and that in most cases mitigation policies reduce future inequalities
34 between countries. Gazzotti et al. (2021) show that inequality persists in 2°C consistent pathways due
35 to regressivity of residual climate damages. However, the evidence on mitigation pathways
36 implications for global inequality and poverty remains limited, and the modelling frameworks used
37 have limited ability to fully represent the different dimensions of inequality and poverty and all the
38 mechanisms by which mitigation affects inequality and poverty (Rao et al. 2017a; Emmerling and
39 Tavoni 2021; Jafino et al. 2021).

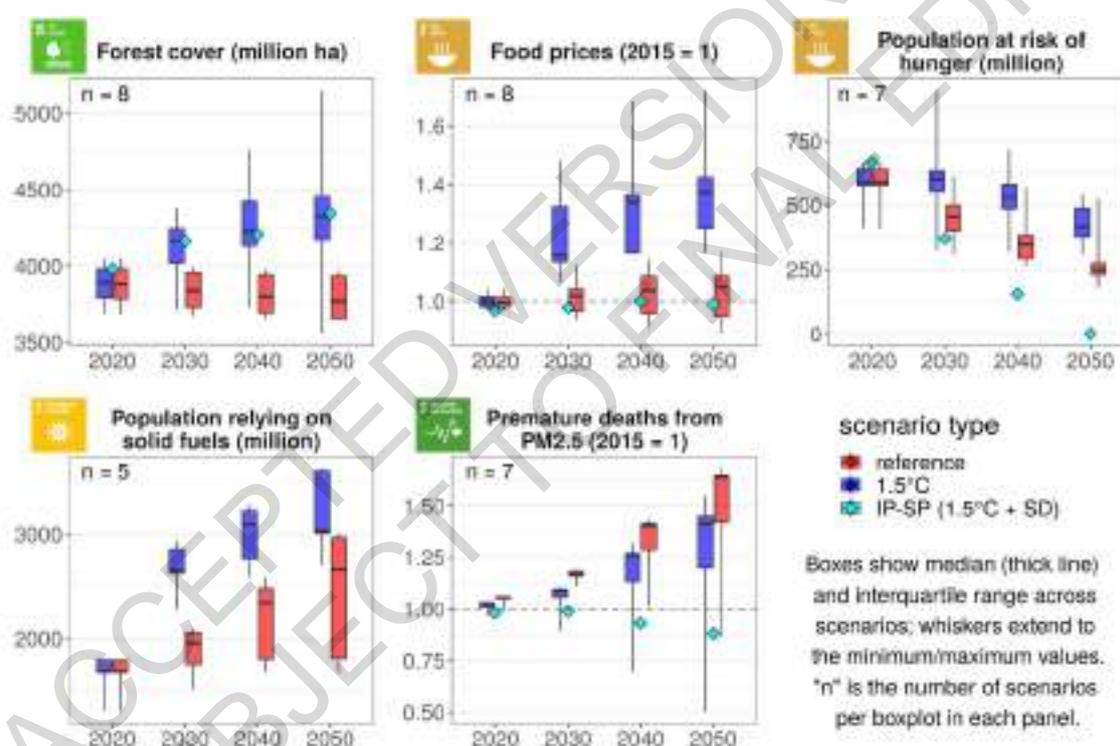

40 41 42 **3.7 Sustainable development, mitigation and avoided impacts**

43 **3.7.1 Synthesis findings on mitigation and sustainable development**

44 Rapid and effective climate mitigation is a necessary part of sustainable development (*high*
45 *confidence*) (see Cross-Chapter Box 5 in Chapter 4), but the latter can only be realized if climate
46 mitigation becomes integrated with sustainable development policies (*high confidence*). Targeted
47 policy areas must include healthy nutrition, sustainable consumption and production, inequality and
48 poverty alleviation, air quality and international collaboration (*high confidence*). Lower energy

1 demand enables synergies between mitigation and sustainability, with lower reliance on CDR (*high*
2 *confidence*).

3
4 This section covers the long-term interconnection of SD and mitigation, taking forward the holistic
5 vision of SD described in the SDGs (Brandi 2015; Leal Filho et al. 2018). Recent studies have
6 explored the aggregated impact of mitigation for multiple sustainable development dimensions
7 (Hasegawa et al. 2014; Bertram et al. 2018; Grubler et al. 2018; McCollum et al. 2018b; Fuso Nerini
8 et al. 2018; van Vuuren et al. 2019; Soergel et al. 2021a). For instance, Figure 3.38 shows selected
9 mitigation co-benefits and trade-offs based on a subset of models and scenarios, since so far many
10 IAMs do not have a comprehensive coverage of sustainable development goals (Rao et al. 2017a; van
11 Soest et al. 2019). Figure 3.38 shows that mitigation likely leads to increased forest cover (SDG 15)
12 and reduced mortality from ambient PM2.5 pollution (SDG 3) compared to reference scenarios.
13 However, mitigation policies can also cause higher food prices and an increased population at risk of
14 hunger (SDG 2) and relying on solid fuels (SDG 3 and SDG 7) as side effects. These trade-offs can be
15 compensated through targeted support measures and/or additional SD policies (Cameron et al. 2016;
16 Bertram et al. 2018; Fujimori et al. 2019; Soergel et al. 2021a).
17

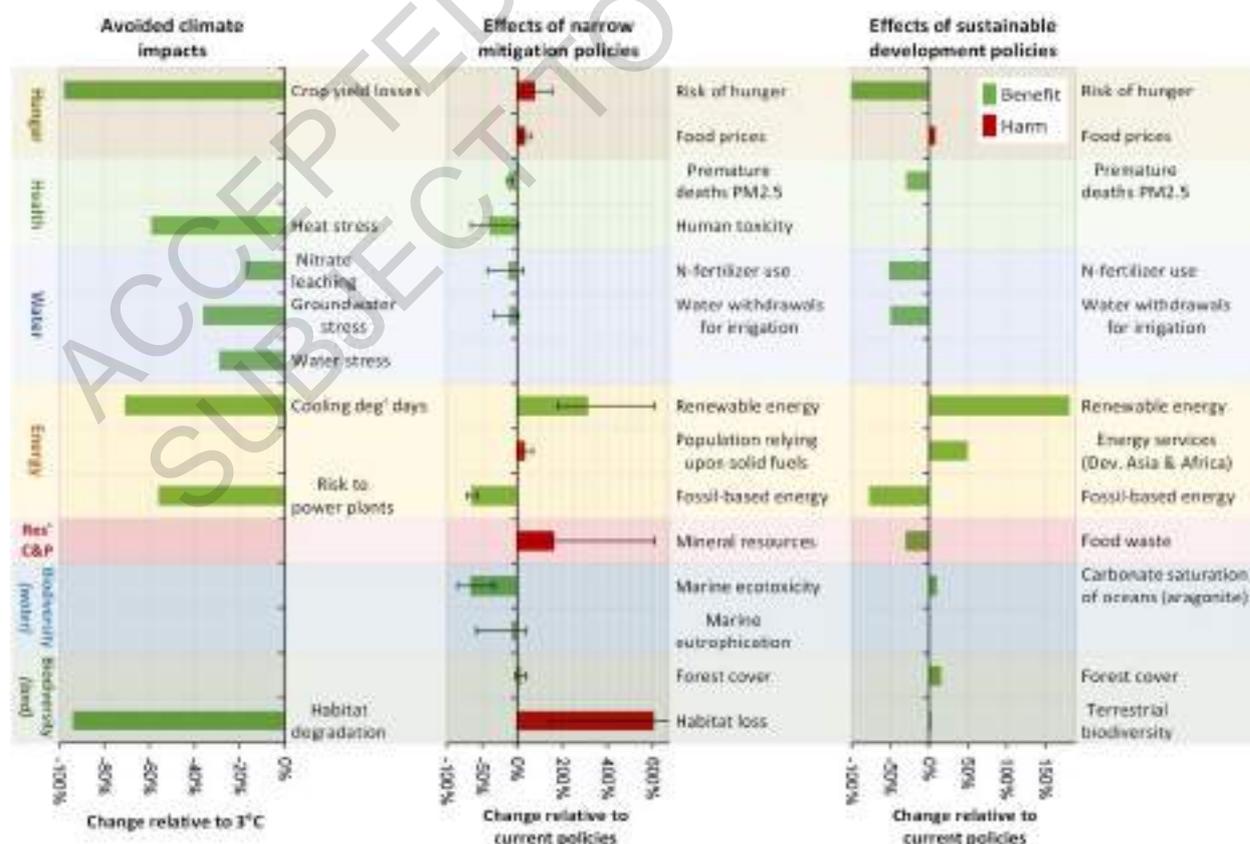

18
19 **Figure 3.38: Effect of climate change mitigation on different dimensions of sustainable development:**
20 **shown are mitigation scenarios compatible with 1.5°C target (blue) and reference scenarios (red). Blue**
21 **boxplots contain scenarios that include narrow mitigation policies from different studies (see below). This**
22 **is compared to a sustainable development scenario (SP, Soergel et al. (2021a), cyan diamonds) integrating**
23 **mitigation and SD policies (e.g., zero hunger in 2050 by assumption). Scenario sources for boxplots: single**
24 **scenarios from i) Fujimori et al. (2020a); ii) Soergel et al. (2021a); multi-model scenario set from CD-**
25 **LINKS (McCollum et al. 2018b; Roelfsema et al. 2020; Fujimori et al. 2019). For associated methods, see**
26 **also Cameron et al. (2016), Rafaj et al. (2021). The reference scenario for (Fujimori et al. 2020a) is no-**
27 **policy baseline; for all other studies, it includes current climate policies. In the “Food prices” and “Risk**
28 **of hunger” panels, scenarios from CD-LINKS include a price cap of 200 USD/tCO₂eq for land-use**
29 **emissions (Fujimori et al. 2019). For the other indicators, CD-LINKS scenarios without price cap**
30 **Roelfsema et al. (2020) are used due to SDG indicator availability. In the “Premature deaths” panel, a**
31 **well-below 2°C scenario from Fujimori et al. (2020a) is used in place of a 1.5°C scenario due to data**
32 **availability, and all scenarios are indexed to their 2015 values due to a spread in reported levels between**
33 **models. SDG icons were created by the United Nations.**

1
2 The synthesis of the interplay between climate mitigation and sustainable development is shown in
3 Figure 3.39. The left panel shows the reduction in population affected by climate impacts at 1.5°C
4 compared to 3°C according to sustainability domains (Byers et al. 2018). Reducing warming reduces
5 the population impacted by all impact categories shown (*high confidence*). The left panel does not
6 take into account any side effects of mitigation efforts or policies to reduce warming: only reductions
7 in climate impacts. This underscores that mitigation is an integral basis for comprehensive SD (Watts
8 et al. 2015).

9
10 The middle and right panels of Figure 3.39 show the effects of 1.5°C mitigation policies compared to
11 current national policies: narrow mitigation policies (averaged over several models, middle panel),
12 and policies integrating sustainability considerations (right panel of Figure 3.39, based on the
13 Illustrative Mitigation Pathway “Shifting Pathways” (*SP*) (Soergel et al. 2021a)). Policies integrating
14 sustainability and mitigation (right panel) have far fewer trade-offs (red bars) and more co-benefits
15 (green bars) than narrow mitigation policies (middle panel). Note that neither middle nor right panels
16 include climate impacts.

17
18 Areas of co-benefits include human health, ambient air pollution and other specific kinds of pollution,
19 while areas of trade-off include food access, habitat loss and mineral resources (*medium confidence*).
20 For example, action consistent with 1.5°C in the absence of energy demand reduction measures
21 require large quantities of CDR, which, depending on the type used, are likely to negatively impact
22 both food availability and areas for biodiversity (Fujimori et al. 2018; Ohashi et al. 2019; Roelfsema
23 et al. 2020).

24
25 Mitigation to 1.5°C reduces climate impacts on sustainability (left). Policies integrating sustainability
26 and mitigation (right) have far fewer trade-offs than narrow mitigation policies (middle).
27

28

1 **Figure 3.39: Sustainable development effects of mitigation to 1.5°C. Left: benefits of mitigation from**
 2 **avoided impacts. Middle: sustainability co-benefits and trade-offs of narrow mitigation policies (averaged**
 3 **over multiple models). Right: sustainability co-benefits and trade-offs of mitigation policies integrating**
 4 **sustainable development goals. Scale: 0% means no change compared to 3°C (left) or current policies**
 5 **(middle and right). Green values correspond to proportional improvements, red values to proportional**
 6 **worsening. Note: only the left panel considers climate impacts on sustainable development; the middle**
 7 **and right panels do not. “Res’ C&P” stands for Responsible Consumption and Production (SDG 12).**
 8 **Data are from Byers et al. (2018) (left), SP/Soergel et al. (2021a) (right). Methods used in middle panel:**
 9 **for biodiversity, Ohashi et al. (2019), for ecotoxicity and eutrophication, Arvesen et al. (2018) and Pehl et**
 10 **al. (2017), for energy access, Cameron et al. (2016). “Energy services” on the right is a measure of useful**
 11 **energy in buildings and transport. “Food prices” and “Risk of hunger” in the middle panel are the same**
 12 **as in Figure 3.38.**

13 *3.7.1.1 Policies combining mitigation and sustainable development*

14
 15 These findings indicate that holistic policymaking integrating sustainability objectives alongside
 16 mitigation will be important in attaining sustainable development goals (van Vuuren et al. 2015, 2018;
 17 Bertram et al. 2018; Fujimori et al. 2018; Hasegawa et al. 2018; Liu et al. 2020a; Honegger et al.
 18 2021; Soergel et al. 2021a). Mitigation policies which target direct sector-level regulation, early
 19 mitigation action, and lifestyle changes have beneficial sustainable development outcomes across air
 20 pollution, food, energy and water (Bertram et al. 2018).

21
 22 These policies include ones around stringent air quality (Kinney 2018; Rafaj et al. 2018; Soergel et al.
 23 2021a); efficient and safe demand-side technologies, especially cook stoves (Cameron et al. 2016);
 24 lifestyle changes (Bertram et al. 2018; Grubler et al. 2018; Soergel et al. 2021a); industrial and
 25 sectoral policy (Bertram et al. 2018); agricultural and food policies (including food waste) (van
 26 Vuuren et al. 2019; Soergel et al. 2021a); international cooperation (Soergel et al. 2021a); as well as
 27 economic policies described in section 3.6. Recent research shows that mitigation is compatible with
 28 reductions in inequality and poverty (see Box 3.6 on poverty and inequality).

29
 30 Lower demand – e.g., for energy and land-intensive consumption such as meat – represents a
 31 synergistic strategy for achieving ambitious climate mitigation without compromising sustainable
 32 development goals (Grubler et al. 2018; van Vuuren et al. 2018; Bertram et al. 2018; Kikstra et al.
 33 2021b; Soergel et al. 2021a) (*high confidence*). This is especially true for reliance on BECCS (Hickel
 34 et al. 2021; Keyßer and Lenzen 2021). Options that reduce agricultural demand (e.g., dietary change,
 35 reduced food waste) can have co-benefits for adaptation through reductions in demand for land and
 36 water (IPCC 2019a; Grubler et al. 2018; Bertram et al. 2018; Soergel et al. 2021a).

37
 38 While the impacts of climate change on agricultural output are expected to increase the population at
 39 risk of hunger, there is evidence suggesting population growth will be the dominant driver of hunger
 40 and undernourishment in Africa in 2050 (Hall et al. 2017). Meeting SDG5 relating to gender equality
 41 and reproductive rights could substantially lower population growth, leading to a global population
 42 lower than the 95% prediction range of the UN projections (Abel et al. 2016). Meeting SDG5 (gender
 43 equality, including via voluntary family planning (O’Sullivan 2018)) could thus minimise the risks to
 44 SDG2 (hunger) that are posed by meeting SDG13 (climate action).

45 **START BOX HERE**

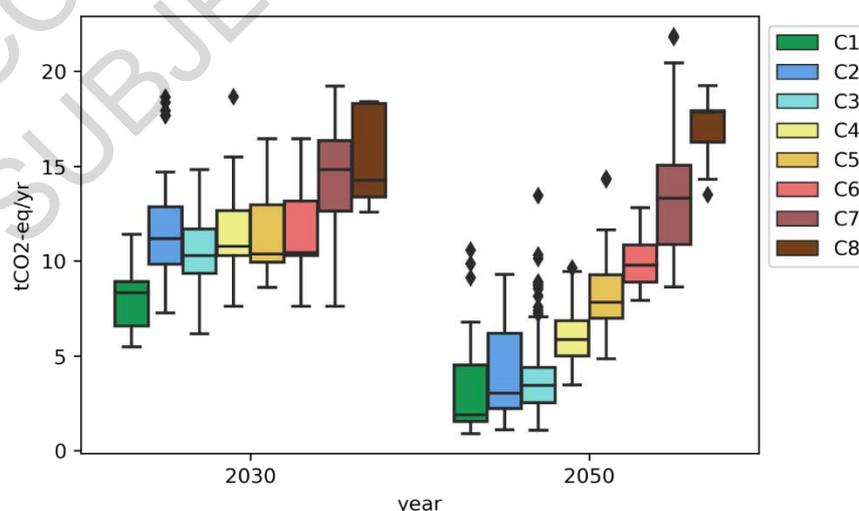

46 **Box 3.6 Poverty and Inequality**

47
 48 There is high confidence (*medium evidence, high agreement*) that the eradication of extreme poverty
 49 and universal access to energy can be achieved without resulting in significant greenhouse gas
 50 emissions (Tait and Winkler 2012; Pachauri 2014; Chakravarty and Tavoni 2013; Rao 2014; Pachauri
 51 et al. 2013; Hubacek et al. 2017b; Pobleto-Cazenave et al. 2021). There is also high agreement in the

1 literature that a focus on wellbeing and decent living standards for all can reduce disparities in access
 2 to basic needs for services concurrently with climate mitigation (Chapter 5, 5.2). Mitigation pathways
 3 in which national redistribution of carbon pricing revenues is combined with international climate
 4 finance, achieve poverty reduction globally (Fujimori et al. 2020b; Soergel et al. 2021b). Carbon
 5 pricing revenues in mitigation pathways consistent with limiting temperature increase to 2°C could
 6 also contribute to finance investment needs for basic infrastructure (Jakob et al. 2016) and SDGs
 7 achievement (Franks et al. 2018).

8
 9 Several studies conclude that reaching higher income levels globally, beyond exiting extreme poverty,
 10 and achieving more qualitative social objectives and well-being, are associated with higher emissions
 11 (Ribas et al. 2017, 2019; Scherer et al. 2018; Fischetti 2018; Hubacek et al. 2017b). Studies give
 12 divergent results on the effect of economic inequality reduction on emissions, with either an increase
 13 or a decrease in emissions (Berthe and Elie 2015; Lamb and Rao 2015; Grunewald et al. 2017;
 14 Hubacek et al. 2017a,b; Jorgenson et al. 2017; Knight et al. 2017; Mader 2018; Rao and Min 2018;
 15 Liu et al. 2019; Sager 2019; Baležentis et al. 2020; Liobikienė 2020; Liobikienė and Rimkuvienė
 16 2020; Liu et al. 2020b; Millward-Hopkins and Oswald 2021). However, the absolute effect of
 17 economic inequality reduction on emissions remains moderate, under the assumptions tested. For
 18 instance, (Sager 2019) finds that a full redistribution of income leading to equality among US
 19 households in a counterfactual scenario for 2009 would raise emissions by 2.3%; and (Rao and Min
 20 2018) limit to 8% the maximum plausible increase in emissions that would accompany the reduction
 21 of the global Gini coefficient from its current level of 0.55 to a level of 0.3 by 2050. Similarly,
 22 reduced income inequality would lead to a global energy demand increase of 7% (Oswald et al. 2021).
 23 Reconciling mitigation and inequality reduction objectives requires policies that take into account
 24 both objectives at all stages of policy making (Markkanen and Anger-Kraavi 2019), including
 25 focusing on the carbon intensity of lifestyles (Scherer et al. 2018), attention to sufficiency and equity
 26 (Fischetti 2018) and targeting the consumption of the richest and highest emitting households (Otto et
 27 al. 2019).

28
 29 In modelled mitigation pathways, inequality in per capita emissions between regions are generally
 30 reduced over time, and the reduction is generally more pronounced in lower temperature pathways
 31 (Box 3.6 Figure 1). Already in 2030, if Nationally Determined Contributions from the Paris
 32 Agreement are fully achieved, inequalities in per capita GHG emissions between countries would be
 33 reduced (Benveniste et al. 2018).

35
 36 **Box 3.6 Figure 1: Difference in per capita emissions of Kyoto gases between the highest emitting and the**
 37 **lowest emitting of the 10 regions, in 2030 and 2050, by temperature category of pathways**

1
2 Through avoiding impacts of climate change, which fall more heavily on low-income countries,
3 communities and households and exacerbate poverty, mitigation reduces inequalities and poverty (see
4 section 3.6.4.2).

5 6 **END BOX HERE**

7
8 The remainder of this section covers specific domains of sustainable development: food (3.7.2), water
9 (3.7.3), energy (3.7.4), health (3.7.5), biodiversity (3.7.6) and multisector - Cities, infrastructure,
10 industry, production & consumption (3.7.7). These represent the areas with the strongest research
11 connecting mitigation to sustainable development. The links to individual SDGs are given within
12 these sections. Each domain covers the benefits of avoided climate impacts and the implications
13 (synergies and trade-offs) of mitigation efforts.

14 15 **3.7.2 Food**

16 The goal of SDG2 is to achieve “zero-hunger” by 2030. According to the UN (2015), over 25% of the
17 global population currently experience food insecurity and nearly 40% of these experience severe
18 food insecurity, a situation worsened by the covid pandemic (Paslakis et al. 2021).

19 20 **3.7.2.1 Benefits of avoided climate impacts along mitigation pathways**

21 Climate change will reduce crop yields, increase food insecurity, and negatively influence nutrition
22 and mortality (*high confidence*) (AR6 WGII Chapter 5). Climate mitigation will thus reduce these
23 impacts, and hence reduce food insecurity (*high confidence*). The yield reduction of global food
24 production will increase food insecurity and influence nutrition and mortality (Springmann et al.
25 2016a; Hasegawa et al. 2014). For instance, (Springmann et al. 2016a) estimate that climate change
26 could lead to 315,000-736,000 additional deaths by 2050, though these could mostly be averted by
27 stringent mitigation efforts. Reducing warming reduces the impacts of climate change, including
28 extreme climates, on food production and risk of hunger (Hasegawa et al. 2014, 2021b).

29 30 **3.7.2.2 Implications of mitigation efforts along pathways**

31 Recent studies explore the effect of climate change mitigation on agricultural markets and food
32 security (Hasegawa et al. 2018; Havlík et al. 2014; Fujimori et al. 2019; Doelman et al. 2019).
33 Mitigation policies aimed at achieving 1.5-2°C, if not managed properly, could negatively affect the
34 food security through changes in land and food prices (*high confidence*), leading to increases in the
35 population at risk of hunger by 80 to 280 million people compared to baseline scenarios. These
36 studies assume uniform carbon prices on AFOLU sectors (with some sectoral caps) and do not
37 account for climate impacts on food production.

38
39 Mitigating climate change while ensuring that food security is not adversely affected requires a range
40 of different strategies and interventions (*high confidence*). (Fujimori et al. 2018) explore possible
41 economic solutions to these unintended impacts of mitigation (e.g., agricultural subsidies, food aid,
42 and domestic reallocation of income) with an additional small (<0.1%) change in global GDP.
43 Targeted food-security support is needed to shield impoverished and vulnerable people from the risk
44 of hunger that could be caused by the economic effects of policies narrowly focussed on climate
45 objectives. Introducing more biofuels and careful selection of bioenergy feedstocks could also reduce
46 negative impacts (FAO WFP, WHO 2017). Reconciling bioenergy demands with food and
47 biodiversity, as well as competition for land and water, will require changes in food systems –
48 agricultural intensification, open trade, less consumption of animal-products and reduced food losses
49 – and advanced biotechnologies (Henry et al. 2018; Xu et al. 2019).

1 There are many other synergistic measures for climate mitigation and food security. Agricultural
2 technological innovation can improve the efficiency of land use and food systems, thus reducing the
3 pressure on land from increasing food demand (Foley et al. 2011; Humpenöder et al. 2018; Popp et al.
4 2014; Obersteiner et al. 2016; Doelman et al. 2019). Furthermore, decreasing consumption of animal
5 products could contribute to SDG3.4 by reducing the risk of non-communicable diseases (Garnett
6 2016).

7
8 Taken together, climate changes will reduce crop yields, increase food insecurity and influence
9 nutrition and mortality (*high confidence*) (see 3.7.2.1). However, if measures are not properly
10 designed, mitigating climate change will also negatively impact on food consumption and security.
11 Additional solutions to negative impacts associated with climate mitigation on food production and
12 consumption include a transition to a sustainable agriculture and food system that is less resource
13 intensive, more resilient to a changing climate, and in line with biodiversity and social targets (Kayal
14 et al. 2019).

15 16 **3.7.3 Water**

17 Water is relevant to SDG 6 (clean water and sanitation), SDG 15 (ecosystem protection and water
18 systems), and SDG Targets 12.4 and 3.9 (water pollution and health). This section discusses water
19 quantity, water quality, and water-related extremes. See 3.7.5 for water-related health effects.

20 21 **3.7.3.1 Benefits of avoided climate impacts along mitigation pathways**

22 Global precipitation, evapotranspiration, runoff and water availability increase with warming
23 (Hanasaki et al. 2013; Greve et al. 2018) (see also WGII Chapter 4). Climate change also affects the
24 occurrence of and exposure to hydrological extremes (*high confidence*) (Arnell and Lloyd-Hughes
25 2014; Asadieh and Krakauer 2017; Dottori et al. 2018; IPCC 2019a; Naumann et al. 2018; Do et al.
26 2020) (see also WGII Chapter 4). Climate models project increases in precipitation intensity (*high*
27 *confidence*), local flooding (*medium confidence*), and drought risk (*very high confidence*) (Arnell and
28 Lloyd-Hughes 2014; Asadieh and Krakauer 2017; Dottori et al. 2018; IPCC 2019a) (see also WGII
29 Chapter 4).

30
31 The effect of climate change on water availability and hydrological extremes varies by region (*high*
32 *confidence*) due to differences in the spatial patterns of projected precipitation changes (Hanasaki et
33 al. 2013; Koutroulis et al. 2019; Schewe et al. 2014; Schlosser et al. 2014; Asadieh and Krakauer
34 2017; Dottori et al. 2018; Naumann et al. 2018) (see also WGII Chapter 4). Global exposure to water
35 stress is projected to increase with increased warming, but increases will not occur in all regions
36 (Arnell and Lloyd-Hughes 2014; Gosling and Arnell 2016; Hanasaki et al. 2013; IPCC 2019a;
37 Schewe et al. 2014).

38
39 Limiting warming could reduce water-related risks (*high confidence*) (O'Neill et al. 2017b; Byers et
40 al. 2018; Hurlbert et al. 2019) (see also WGII Chapter 4) and the population exposed to increased
41 water stress (Arnell and Lloyd-Hughes 2014; Gosling and Arnell 2016; Hanasaki et al. 2013; IPCC
42 2019a; Schewe et al. 2014).

43
44 The effect of climate change on water depends on the climate model, the hydrological model, and the
45 metric (*high confidence*) stress (Arnell and Lloyd-Hughes 2014; Gosling and Arnell 2016; Hanasaki
46 et al. 2013; IPCC 2019a; Schewe et al. 2014; Schlosser et al. 2014). However, the effect of
47 socioeconomic development could be larger than the effect of climate change (*high confidence*)
48 (Arnell and Lloyd-Hughes 2014; Schlosser et al. 2014; Graham et al. 2020).

1 Climate change can also affect water quality (both thermal and chemical) (Liu et al. 2017), leading to
2 increases in stream temperature and nitrogen loading in rivers (Ballard et al. 2019).

3.7.3.2 *Implications of mitigation efforts along pathways*

6 The effect of mitigation on water demand depends on the mitigation technologies deployed (*high*
7 *confidence*) (Bonsch et al. 2016; Chaturvedi et al. 2013a,b; Jakob and Steckel 2016; Hejazi et al.
8 2014; Kyle et al. 2013; Fujimori et al. 2017; Maïzi et al. 2017; Mouratiadou et al. 2016; Parkinson et
9 al. 2019; Bijl et al. 2018; Cui et al. 2018; Graham et al. 2018; Hanasaki et al. 2013). Some mitigation
10 options could increase water consumption (volume removed and not returned) while decreasing
11 withdrawals (total volume of water removed, some of which may be returned) (Kyle et al. 2013;
12 Mouratiadou et al. 2016; Fricko et al. 2016; Parkinson et al. 2019). Bioenergy and BECCS can
13 increase water withdrawals and water consumption (*high confidence*) (Bonsch et al. 2016; Chaturvedi
14 et al. 2013a; Hejazi et al. 2014; Jakob and Steckel 2016; Kyle et al. 2013; Fujimori et al. 2017; Maïzi
15 et al. 2017; Mouratiadou et al. 2016; Parkinson et al. 2019; Yamagata et al. 2018; Séférian et al. 2018)
16 (see also WGII Chapter 4). DACCS (Fuhrman et al. 2020) and CCS (Kyle et al. 2013; Fujimori et al.
17 2017) could increase water demand; however, the implications of CCS depend on the cooling
18 technology and when capture occurs (Magneschi et al. 2017; Maïzi et al. 2017; Giannaris et al. 2020).
19 Demand-side mitigation (e.g., dietary change, reduced food waste, reduced energy demand) can
20 reduce water demand (Bajželj et al. 2014; Aleksandrowicz et al. 2016; Springmann et al. 2018; Green
21 et al. 2018). Introducing specific measures (e.g., environmental flow requirements, improved
22 efficiency, priority rules) can reduce water withdrawals (Bertram et al. 2018; Bijl et al. 2018;
23 Parkinson et al. 2019).

25 The effect of mitigation on water quality depends on the mitigation option, its implementation, and
26 the aspect of quality considered (*high confidence*) (McElwee et al. 2020; Smith et al. 2019; Sinha et
27 al. 2019; Ng et al. 2010; Fuhrman et al. 2020; Flörke et al. 2019; Karlsson et al. 2020).

3.7.4 **Energy**

30 Energy is relevant to SDG7 on sustainable and affordable energy access. Access to sufficient levels of
31 reliable, affordable and renewable energy is essential for sustainable development. Currently, over 1
32 billion people still lack access to electricity (Ribas et al. 2019).

3.7.4.1 *Benefits of avoided climate impacts along mitigation pathways*

35 Climate change alters the production of energy through changes in temperature (hydropower, fossil
36 fuel, nuclear, solar, bioenergy, transmission and pipelines), precipitation (hydropower, fossil fuel,
37 nuclear, bioenergy), windiness (wind, wave), and cloudiness (solar) (*high confidence*). Increases in
38 temperature reduce efficiencies of thermal power plants (e.g., fossil fuel and nuclear plants) with air-
39 cooled condensers by 0.4–0.7% °C increase in ambient temperature (Cronin et al. 2018a; Yalaw, S. G.
40 et al. 2020; Simioni and Schaeffer 2019). Potentials and costs for renewable energy technologies are
41 also affected by climate change, though with considerable regional variation and uncertainty (Gernaat
42 et al. 2021). Biofuel yields could increase or decrease depending on the level of warming, changes in
43 precipitation, and the effect of CO₂ fertilization (Calvin et al. 2013; Kyle et al. 2014; Gernaat et al.
44 2021). Coastal energy facilities could potentially be impacted by sea-level rise (Brown et al. 2014).

46 The energy sector uses large volumes of water (Fricko et al. 2016), making it highly vulnerable to
47 climate change (Tan and Zhi 2016) (*high confidence*). Thermoelectric and hydropower sources are the
48 most vulnerable to water stress (van Vliet et al. 2016). Restricted water supply to these power sources
49 can affect grid security and affordable energy access (Koch et al. 2014; Ranzani et al. 2018; Zhang et
50 al. 2018d). The hydropower facilities from high mountain areas of Central Europe, Iceland, Western

1 US/Canada, and Latin America (Hock et al. 2019) as well as Africa and China (Bartos and Chester
2 2015; Eyer and Wichman 2018; Tarroja et al. 2016; Savelsberg et al. 2018; Ranzani et al. 2018;
3 Zhang et al. 2018d; Conway et al. 2017; Zhou et al. 2018; Gaupp et al. 2015; Wang et al. 2019; Byers
4 et al. 2018) have experienced changes in seasonality and availability.

6 **3.7.4.2 Implications of mitigation efforts along pathways**

7 Extending energy access to all in line with SDG7 is compatible with strong mitigation consistent with
8 the Paris agreement (*high confidence*). The Low Energy Demand (LED) scenario projects that these
9 twin goals can be achieved by relying heavily on energy efficiency and rapid social transformations
10 (Grubler et al. 2018). The IEA's Sustainable Development Scenario (IEA 2020a) achieves
11 development outcomes but with higher average energy use, and bottom-up modelling suggests that
12 decent living standards could be provided to all in 2040-2050 with roughly 150 EJ, or 40% of current
13 final energy use (Kikstra et al. 2021b; Millward-Hopkins et al. 2020). The trade-offs between climate
14 mitigation and increasing energy consumption of the world's poorest are negligible (Rao and Min
15 2018; Scherer et al. 2018).

16
17 The additional energy demand to meet the basic cooling requirement in Global South is estimated to
18 be much larger than the electricity needed to provide basic residential energy services universally via
19 clean and affordable energy, as defined by SDG7 (IEA 2019; Mastrucci et al. 2019) (*high*
20 *confidence*). If conventional air conditioning systems are widely deployed to provide cooling, energy
21 use could rise significantly (van Ruijven et al. 2019; Falchetta and Mistry 2021; Bezerra et al. 2021),
22 thus creating a positive feedback further increasing cooling demand. However, the overall emissions
23 are barely altered by the changing energy demand composition with reductions in heating demand
24 occurring simultaneously (Isaac and van Vuuren 2009; Labriet et al. 2015; McFarland et al. 2015;
25 Clarke et al. 2018). Some mitigation scenarios show price increases of clean cooking fuels, slowing
26 the transition to clean cooking fuels (SDG 7.1) and leaving a billion people in 2050 still reliant on
27 solid fuels in South Asia (Cameron et al. 2016).

28
29 In contrast, future energy infrastructure could improve reliability, thus lowering dependence on high-
30 carbon, high-air pollution backup diesel generators (Farquharson et al. 2018) that are often used to
31 cope with unreliable power in developing countries (Maruyama Rentschler et al. 2019). There can be
32 significant reliability issues where mini-grids are used to electrify rural areas (Numminen and Lund
33 2019). A stable, sustainable energy transition policy that considers national sustainable development
34 in the short- and long-term is critical in driving a transition to an energy future that addresses the
35 trilemma of energy security, equity, and sustainability (La Viña et al. 2018).

37 **3.7.5 Health**

38
39 SDG 3 aims to ensure healthy lives and promote well-being for all at all ages. Climate change is
40 increasingly causing injuries, illnesses, malnutrition, threats to mental health and well-being, and
41 deaths (see WGII Chapter 7). Mitigation policies and technologies to reduce GHG emissions are often
42 beneficial for human health on a shorter time scale than benefits in terms of slowing climate change
43 (Limaye et al. 2020). The financial value of health benefits from improved air quality alone is
44 projected to exceed the costs of meeting the goals of the Paris Agreement (Markandya et al. 2018).

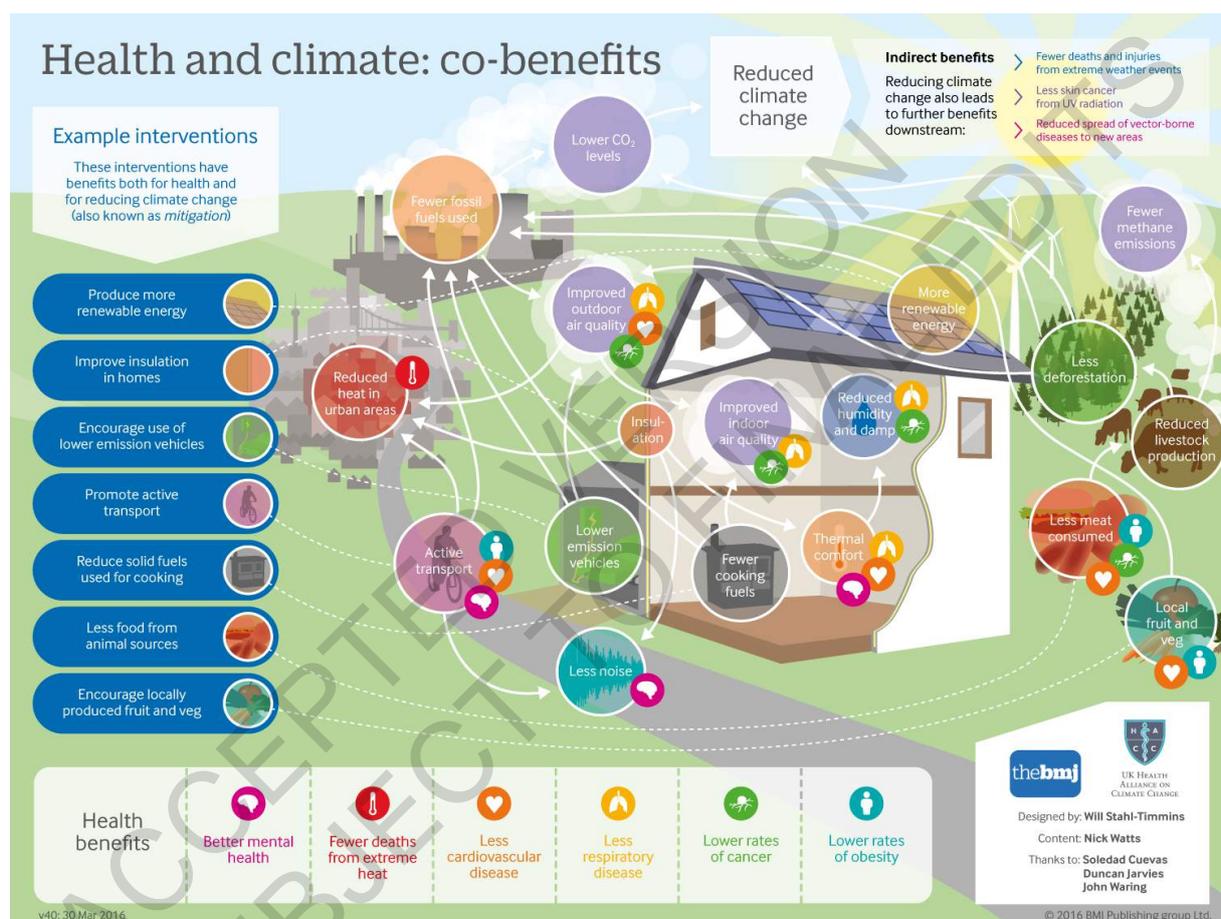

46 **3.7.5.1 Benefits of avoided climate impacts along mitigation pathways**

47
48 The human health chapter of the WGII contribution to the AR6 concluded that climate change is
49 increasingly affecting a growing number of health outcomes, with negative net impacts at the global
50 scale and positive only in a few limited situations. There are few estimates of economic costs of

1 increases in climate-sensitive health outcomes. In the U.S. in 2012, the financial burden in terms of
 2 deaths, hospitalizations, and emergency department visits for ten climate-sensitive events across 11
 3 states were estimated to be USD 10.0 (2.7 – 24.6) billion in 2018 dollars (Limaye et al. 2019).

3.7.5.2 Implications of mitigation efforts along pathways

7 Transitioning toward equitable, low-carbon societies has multiple co-benefits for health and wellbeing
 8 (see WGII Chapter 7). Health benefits can be gained from improvements in air quality through
 9 transitioning to renewable energy and active transport (e.g., walking and cycling); shifting to
 10 affordable low-meat, plant-rich diets; and green buildings and nature-based solutions, such as green
 11 and blue urban infrastructure, as shown in Figure 3.40 (Iacobucci 2016).

14 **Figure 3.40: Diagram showing the co-benefits between health and mitigation (Iacobucci 2016)**

16 The avoided health impacts associated with climate change mitigation can substantially offset
 17 mitigation costs at the societal level (Chang et al. 2017; Ščasný et al. 2015; Schucht et al. 2015;
 18 Markandya et al. 2018). Models of health co-benefits show that a 1.5 C pathway could result in 152
 19 +/- 43 million fewer premature deaths worldwide between 2020 and 2100 in comparison to a
 20 business-as-usual scenario, particularly due to reductions in exposure to PM2.5 (Shindell et al. 2018;
 21 Rauner et al. 2020a; Rafaj et al. 2021). Some of the most substantial health, wellbeing, and equity
 22 benefits associated with climate action derive from investing in basic infrastructure: sanitation, clean
 23 drinking water, clean energy, affordable healthy diets, clean public transport, and improved air quality
 24 from transformative solutions across economic sectors including agriculture, energy, transport and
 25 buildings (Chang et al. 2017).

1
2 The health co-benefits of the NDCs for 2040 were compared for two scenarios, one consistent with
3 the goal of the Paris Agreement and the SDGs and the other also placing health as a central focus of
4 the policies (i.e., health in all climate policies scenario) (Hamilton et al. 2021), for Brazil, China,
5 Germany, India, Indonesia, Nigeria, South Africa, the UK, and the USA. Modelling of the energy,
6 food and agriculture, and transport sectors, and associated risk factors related to mortality, suggested
7 the sustainable pathways scenario could result in annual reductions of 1.18 million air pollution-
8 related deaths, 5.86 million diet-related deaths, and 1.15 million deaths due to physical inactivity.
9 Adopting the more ambitious health in all climate policies scenario could result in further reductions
10 of 462,000 annual deaths attributable to air pollution, 572,000 annual deaths attributable to diet, and
11 943,000 annual deaths attributable to physical inactivity. These benefits were attributable to the
12 mitigation of direct greenhouse gas emissions and the commensurate actions that reduce exposure to
13 harmful pollutants, as well as improved diets and safe physical activity.
14

15 Cost-benefit analyses for climate mitigation in urban settings that do not account for health may
16 underestimate the potential cost savings and benefits (Hess et al. 2020). The net health benefits of
17 controlling air pollution as part of climate mitigation efforts could reach trillions of dollars annually,
18 depending on the air quality policies adopted globally (Markandya et al. 2018; Scovronick et al.
19 2019b). Air pollution reductions resulting from meeting the Paris Agreement targets were estimated to
20 provide health co-benefits-to-mitigation ratios of between 1.4 and 2.5 (Markandya et al. 2018). In
21 Asia, the benefit of air pollution reduction through mitigation measures were estimated to reduce
22 premature mortality by 0.79 million, with an associated health benefit of USD2.8 trillion versus
23 mitigation costs of USD840 billion, equating to 6% and 2% of GDP, respectively (Xie et al. 2018).
24 Similarly, stabilizing radiative forcing to 3.4 W/m² in South Korea could cost USD1.3-8.5 billion in
25 2050 and could lead to a USD23.5 billion cost reduction from the combined benefits of avoided
26 premature mortality, health expenditures, and lost work hours (Kim et al. 2020). The health co-
27 benefits related to physical exercise and reduced air pollution largely offset the costs of implementing
28 low CO₂ emitting urban mobility strategies in three Austrian cities (Wolkingner et al. 2018).
29

30 Just in the United States of America, over the next 50 years, a 2°C pathway could prevent roughly 4.5
31 million premature deaths, about 3.5 million hospitalizations and emergency room visits, and
32 approximately 300 million lost workdays (Shindell 2020). The estimated yearly benefits of USD700
33 billion were more than the estimated cost of the energy transition.
34

35 **3.7.6 Biodiversity (land and water)**

36
37 Biodiversity covers Life Below Water (SDG 14) and Life On Land (SDG 15). Ecosystem services are
38 relevant to the goals of Zero Hunger (SDG 2), Good Health and Well Being (SDG 3), Clean Water
39 and Sanitation (SDG 6) and Responsible Consumption and Production (SDG 12), as well as being
40 essential to human existence (Díaz et al. 2019).
41

42 **3.7.6.1 Benefits of avoided climate impacts along mitigation pathways**

43 **3.7.6.1.1 Terrestrial and freshwater aquatic ecosystems**

44 Climate change is a major driver of species extinction and terrestrial and freshwater ecosystems
45 destruction (see WGII Chapter 2) (*high confidence*). Analysis shows that approximately half of all
46 species with long-term records have shifted their ranges in elevation and about two thirds have
47 advanced their timing of spring events (Parmesan and Hanley 2015). Under 3.2 °C warming, 49% of
48 insects, 44% of plants and 26% of vertebrates are projected to be at risk of extinction. At 2°C, this
49 falls to 18% of insects, 16% of plants and 8% of vertebrates and at 1.5°C, to 6% of insects, 8% of
50

1 plants and 4% of vertebrates (Warren et al. 2018). Incidents of migration of invasive species,
2 including pests and diseases, are also attributable to climate change, with negative impacts on food
3 security and vector-borne diseases. Moreover, if climate change reduces crop yields, cropland may
4 expand – a primary driver of biodiversity loss – in order to meet food demand (Molotoks et al. 2020).
5 Land restoration and halting land degradation under all mitigation scenarios has the potential for
6 synergy between mitigation and adaptation.
7

8 *3.7.6.1.2 Marine and coastal ecosystems*

9 Marine ecosystems are being affected by climate change and growing non-climate pressures including
10 temperature change, acidification, land-sourced pollution, sedimentation, resource extraction and
11 habitat destruction (*high confidence*) (IPCC 2019b; Bindoff et al. 2019). The impacts of climate
12 drivers and their combinations vary across taxa (WGII Chapter 3). The danger of warming and
13 acidification to coral reefs, rocky shores and kelp forests is well established (*high confidence*) (WGII
14 Chapter 3). Migration towards optimal thermal and chemical conditions (Burrows et al. 2019)
15 contributes to large scale redistribution of fish and invertebrate populations, and major impacts on
16 global marine biomass production and maximum sustainable yield (Bindoff et al. 2019).
17

18 *3.7.6.2 Implications of mitigation efforts along pathways*

19 Mitigation measures have the potential to reduce the progress of negative impacts on ecosystems,
20 although it is unlikely that all impacts can be mitigated (*high confidence*) (Ohashi et al. 2019). The
21 specifics of mitigation achievement are crucial, since large-scale deployment of some climate
22 mitigation and land-based CDR measures could have deleterious impacts on biodiversity (Santangeli
23 et al. 2016; Hof et al. 2018).

24 Climate change mitigation actions to reduce or slow negative impacts on ecosystems are likely to
25 support the achievement of SDGs 2, 3, 6, 12, 14 and 15. Some studies show that stringent and
26 constant GHG mitigation practices bring a net benefit to global biodiversity even if land-based
27 mitigation measures are also adopted (Ohashi et al. 2019), as opposed to delayed action which would
28 require much more widespread use of BECCS. Scenarios based on demand reductions of energy and
29 land-based production are expected to avoid many such consequences, due to their minimized reliance
30 on BECCS (Grubler et al. 2018; Conijn et al. 2018; Bowles et al. 2019; Soergel et al. 2021a).
31 Stringent mitigation that includes reductions in demand for animal-based foods and food-waste could
32 also relieve pressures on land-use and biodiversity (*high confidence*), both directly by reducing
33 agricultural land requirements (Leclère et al. 2020) and indirectly by reducing the need for land-based
34 CDR (van Vuuren et al. 2018).
35

36 As environmental conservation and sustainable use of the earth's terrestrial species and ecosystems
37 are strongly related, recent studies have evaluated interconnections among key aspects of land and
38 show pathway to the global sustainable future of land (Erb et al. 2016; Humpenöder et al. 2018; Popp
39 et al. 2014; Obersteiner et al. 2016). Most studies agree that many biophysical options exist to achieve
40 global climate mitigation and sustainable land-use in future. Conserving local biodiversity requires
41 careful policy design in conjunction with land-use regulations and societal transformation in order to
42 minimize the conversion of natural habitats.
43

44 **3.7.7 Cities and infrastructure**

45 This subsection focuses upon SDG9, Industry, Innovation and Infrastructure and SDG11, Sustainable
46 Cities and Communities.
47

48 *3.7.7.1 Benefits of avoided climate impacts along mitigation pathways*

49 By 2100, urban population will be almost double and more urban areas will be built (Jiang and
50 O'Neill 2017), although Covid-19 may modify these trends (Kii 2021). Urbanization will amplify

1 projected air temperature changes in cities, including amplifying heat waves (see WGI Chapter 10,
2 Box 10.3). Benefits of climate mitigation in urban areas include reducing heat, air pollution and
3 flooding. Industrial infrastructure and production-consumption supply networks also benefit from
4 avoided impacts.

6 **3.7.7.2 Implications of mitigation efforts along pathways**

7 Many co-benefits to urban mitigation actions (see Chapter 8, Section 8.2.1) that improve the
8 liveability of cities and contribute to achieving SDG11. In particular, compact, urban form, efficient
9 technologies and infrastructure can play a valuable role in mitigation by reducing energy demand
10 (Güneralp et al. 2017; Creutzig et al. 2016), thus averting carbon lock-in, while reducing land sprawl
11 and hence increasing carbon storage and biodiversity (D'Amour et al. 2017). Benefits of mitigation
12 include air quality improvements from decreased traffic and congestion when private vehicles are
13 displaced by other modes; health benefits from increases in active travel; and lowered urban heat
14 island effects from green-blue infrastructures (section 8.2.1).

15
16 However, increasing urban density or enlarging urban green spaces can increase property prices and
17 reduce affordability (Section 8.2.1). Raising living conditions for slum dwellers & people living in
18 informal settlements will require significant materials and energy; however, regeneration can be
19 conducted in ways that avoid carbon-intense infrastructure lock-in (see Chapter 8 & 9). Cities affect
20 other regions through supply chains (Marinova et al. 2020).

21
22 Sustainable production, consumption and management of natural resources are consistent with, and
23 necessary for, mitigation (Chapters 5 & 11). Demand-side measures can lower requirements for
24 upstream material and energy use (Chapter 5). In terms of industrial production, transformational
25 changes across sectors will be necessary for mitigation (Chapter 11, sections 11.3 and 11.4).

26
27 Addressing multiple SDG arenas requires new systemic thinking in the areas of governance and
28 policy, such as those proposed by (Sachs et al. 2019).

30 **3.8 Feasibility of socio/techno/economic transitions**

31 The objective of this section is to discuss concepts of feasibility in the context of the low carbon
32 transition and pathways. We aim to identify drivers of low carbon scenarios feasibility and to
33 highlight enabling conditions which can ameliorate feasibility concerns.

35 **3.8.1 Feasibility frameworks for the low carbon transition and scenarios**

36 Effectively responding to climate change and achieving sustainable development requires overcoming
37 a series of challenges to transition away from fossil-based economies. Feasibility can be defined in
38 many ways (see also Chapter 1). The political science literature (Majone 1975a,b; Gilabert and
39 Lawford-Smith 2012) distinguishes the feasibility of ‘what’ (i.e. emission reduction strategies), ‘when
40 and where’ (i.e. in the year 2050, globally) and “whom” (i.e. cities). It distinguishes desirability from
41 political feasibility (von Stechow et al. 2015): the former represents a normative assessments of the
42 compatibility with societal goals (i.e. SDGs) while the latter evaluate the plausibility of what can be
43 attained given the prevailing context of transformation (Nielsen et al. 2020). Feasibility concerns are
44 context and time dependent and malleable: enabling conditions can help overcome them. For
45 example, public support for carbon taxes has been hard to secure but appropriate policy design and
46 household rebates can help dissipate opposition (Carattini et al. 2019; Murray and Rivers 2015).

47
48 Regarding scenarios, the feasibility ‘what’ question is the one most commonly dealt with in the
49 literature, though most of the studies have focused on expanding low carbon system, and yet political

1 constraints might arise mostly from phasing out fossil fuel-based ones (Spencer et al. 2018; Fattouh et
2 al. 2019). The ‘when and where’ dimension can also be related to the scenario assessment, but only
3 insofar the models generating them can differentiate time and geographical contextual factors.
4 Distinguishing mitigation potential by regional institutional capacity has a significant influence on the
5 costs of stabilizing climate (Iyer et al. 2015c). The ‘whom’ question is the most difficult to capture by
6 scenarios, given the multitude of actors involved as well as their complex interactions. The focus of
7 socio-technical transition sciences on the co-evolutionary processes can shed light on the dynamics of
8 feasibility (Nielsen et al. 2020).

9
10 The when-where-whom distinction allows depicting a feasibility frontier beyond which
11 implementation challenges prevent mitigation action (Jewell and Cherp 2020). Even if the current
12 feasibility frontier appears restraining in some jurisdictions, it is context-dependent and dynamic as
13 innovation proceeds and institutional capacity builds up (Nielsen et al. 2020). The question is whether
14 the feasibility frontier can move faster than the pace at which the carbon budget is being exhausted.
15 Jewell et al. (2019) show that the emission savings from the pledges of premature retirement of coal
16 plants is 150 times less than globally committed emissions from existing coal power plants. The
17 pledges come from countries with high institutional capacity and relatively low shares of coal in
18 electricity. Other factors currently limiting the capacity to steer transitions at the necessary speed
19 include the electoral market orientation of politicians (Willis 2017), the status quo orientation of
20 senior public officials (Geden 2016), path dependencies created by 'instrument constituencies' (Béland
21 and Howlett 2016), or the benefits of deliberate inconsistencies between talk, decisions and actions in
22 climate policy (Rickards et al. 2014). All in all, a number of different delay mechanisms in both
23 science and policy have been identified to potentially impede climate goal achievement (Karlsson and
24 Gilek 2020) - see also Chapter 13.

25
26 In addition to its contextual and dynamic nature, feasibility is a multi-dimensional concept. The IPCC
27 1.5°C special report distinguishes 6 dimensions of feasibility: geophysical, environmental-ecological,
28 technological, economic, socio-cultural and institutional. At the individual option level, different
29 mitigation strategies face various barriers as well as enablers (see Chapter 6 for the option-level
30 assessment). However, a systemic transformation involves interconnections of a wide range of
31 indicators. Model-based assessments are meant to capture the integrative elements of the transition
32 and of associated feasibility challenges. However, the translation of model-generated pathways into
33 feasibility concerns (Rogelj et al. 2018b) has developed only recently. Furthermore, multiple forms of
34 knowledge can be mobilized to support strategic decision-making and complement scenario analysis
35 (Turnheim and Nykvist 2019). We discuss both approaches next.

37 **3.8.2 Feasibility appraisal of low carbon scenarios**

38 Evaluating the feasibility of low carbon pathways can take different forms. In the narrowest sense,
39 there is feasibility pertaining the reporting of model-generated scenarios: here an infeasible scenario is
40 one which cannot meet the constraints embedded implicitly or explicitly in the models which
41 attempted to generate it. Second, there is a feasibility that relates to specific elements or overall
42 structure characterizing the low carbon transition compared to some specified benchmark.

43 **3.8.2.1 Model solvability**

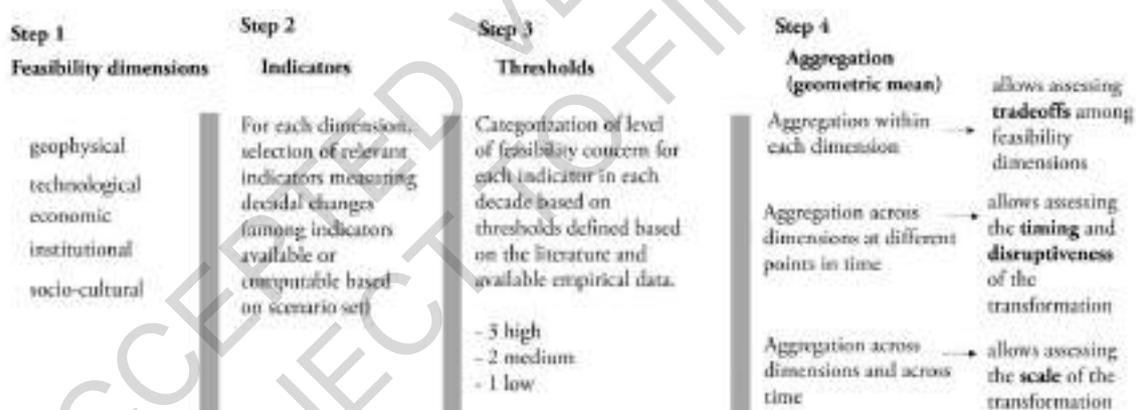

44 In order to be generated, scenarios must be coherent with the constraints and assumptions embedded
45 in the models (i.e., deployment potential of given technologies, physical and geological limits) and in
46 the scenario design (i.e., carbon budget). Sometimes, models cannot solve specific scenarios. This
47 provides a first, coarse indication of feasibility concerns. Specific vetting criteria can be imposed,
48 such as carbon price values above which scenarios should not be reported, as in Clarke et al. (2009).
49 However, model solvability raises issues of aggregation in model ensemble. Since model solving is

1 not a random process, but a function of the characteristics of the models, analysing only reported
2 outcomes leads to statistical biases (Tavoni and Tol 2010).

3
4 Although model-feasibility differs distinctly from feasibility in the real world, it can indicate the
5 relative challenges of low carbon scenarios - primarily when performed in a model ensemble of
6 sufficient size. Riahi et al. (2015) interpreted infeasibility across a large number of models as an
7 indication of increased risk that the transformation may not be attainable due to technical or economic
8 concerns. All models involved in a model comparison of 1.5°C targets (Rogelj et al. 2018b) (Table
9 S1) were able to solve under favourable underlying socio-economic assumptions (SSP1), but none for
10 the more challenging SSP3. This interpretation of feasibility was used to highlight the importance of
11 socio-economic drivers for attaining climate stabilization. Gambhir et al. (2017) constrained the
12 models to historically observed rates of change and found that it would no longer allow to solve for
13 2°C, highlighting the need for rapid technological change.

14 3.8.2.2 Scenario feasibility

15 Evaluating the feasibility of scenarios involves several steps (see Figure 3.41). First, one need to
16 identify which dimensions of feasibility to focus on. Then, for each dimension, one needs to select
17 relevant indicators for which sufficient empirical basis exists and which are an output of models (or at
18 least of a sufficient number of them). Then, thresholds marking different levels of feasibility concerns
19 are defined based on available literature, expert elicitations and empirical analysis based on
20 appropriately chosen historical precedents. Finally, scenario feasibility scores are obtained for each
21 indicator, and where needed aggregated up in time or dimensions, as a way to provide an overall
22 appraisal of feasibility trade-offs, depending on the timing, disruptiveness and scale of transformation.
23
24

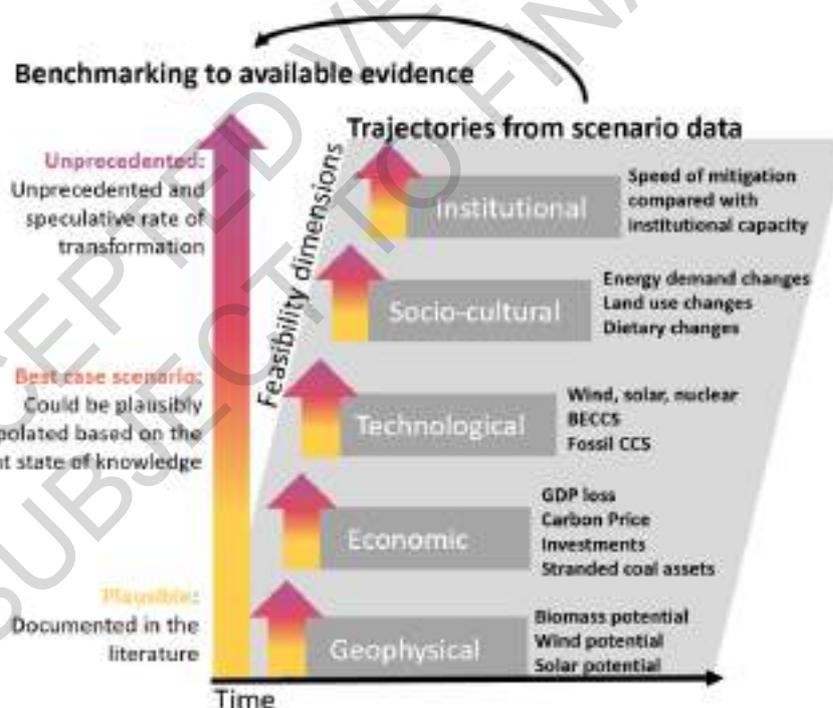

25
26 **Figure 3.41: Steps involved in evaluating the feasibility of scenarios**

27 Most of the existing literature has focused on the technological dimensions, given the technology
28 focus of models and the ease of comparison. The literature points to varied findings. Some suggest
29 that scenarios envision technological progress consistent with historical benchmarks (Loftus et al.
30 2015; Wilson et al. 2013). Others that scenarios exceed historically observed rates of low carbon
31 technology deployment and of energy demand transformation globally (Napp et al. 2017; van der
32 Zwaan et al. 2013; Semieniuk et al. 2021; Cherp et al. 2021), but not for all countries (Cherp et al.
33 2021). The reason for these discrepancies depends on the unit of analysis and the indicators used.
34 Comparing a different kind of historical indicators, (van Sluisveld et al. 2015) find that indicators that
35 look into the absolute change of energy systems remain within the range of historical growth frontiers
36 for the next decade, but increase to unprecedented levels before mid-century. Expert assessments
37 provide another way of benchmarking scenarios, though they have shown to be systematically biased
38 (Wiser et al. 2021) and to underperform empirical methods (Meng et al. 2021). (van Sluisveld et al.
39 2018a) find that scenarios and experts align for baseline scenarios but differ for low carbon ones.

1 Scenarios rely more on conventional technologies based on existing infrastructure (such as nuclear
2 and CCS) than what forecasted by experts. Overall, the technology assessment of the feasibility space
3 highlights that Paris-compliant transformations would have few precedents, but not zero (Cherp et al.
4 2021).

5
6 Recent approaches have addressed multiple dimensions of feasibility, an important advancement since
7 social and institutional aspects are as if not more important than technology ones (Jewell and Cherp
8 2020). Feasibility corridors of scenarios based on their scale, rate of change and disruptiveness have
9 been identified (Kriegler et al. 2018b; Warszawski et al. 2021). The reality check shows that many
10 1.5°C compatible scenarios violate the feasibility corridors. The ones which didn't are associated with
11 a greater coverage of the available mitigation levers (Warszawski et al. 2021).

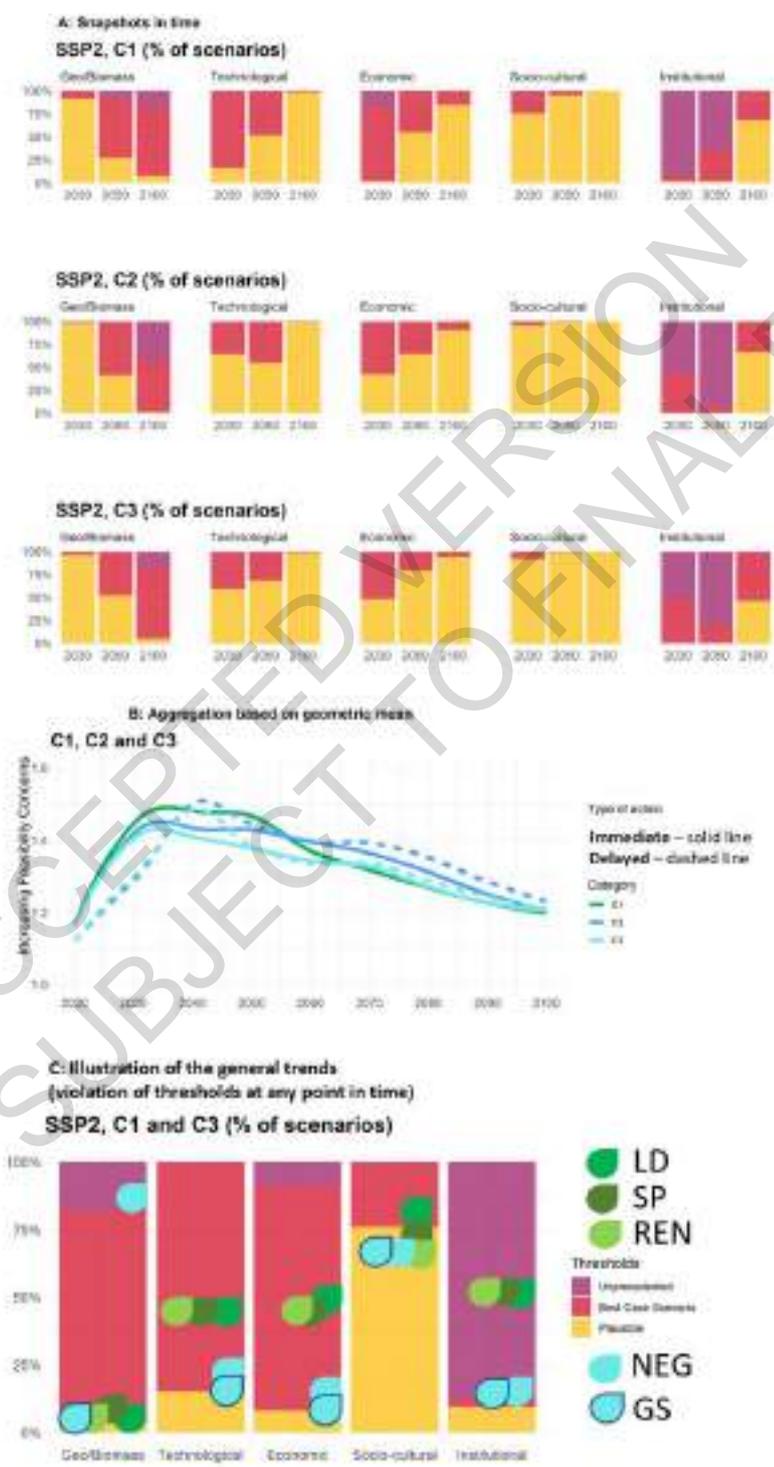

12
13 Brutschin et al. (2021) proposed an operational framework covering all six dimensions of feasibility.
14 They developed a set of multi-dimensional metrics capturing the timing, disruptiveness and the scale
15 of the transformative change within each dimension (as in Kriegler et al. (2018b)). Thresholds of
16 feasibility risks of different intensity are obtained through the review of the relevant literature and
17 empirical analysis of historical data. Novel indicators include governance levels (Andrijevic et al.
18 2020a). The 17 bottom-up indicators are then aggregated up across time and dimension, as way to
19 highlight feasibility trade-offs. Aggregation is done via compensatory approaches such as the
20 geometric mean. This is employed, for instance, for the Human Development Index. A conceptual
21 example of this approach as applied to the IPCC AR6 scenarios database is shown in Figure 3.42 and
22 further described in the Annex.
23

24

28 **concerns are defined based on historical trends and available literature. Details about indicator and**
29 **thresholds values can be found in Annex III**

30 In Figure 3.43, we show the results of applying the methodology of Brutschin et al. (2021) to the AR6
31 scenarios database. The charts highlight the dynamic nature of feasibility risks, which are mostly
32 concentrated in the decades before mid-century except for geophysical risks driven by CO₂ removals

1 later in the century. Different dimensions pose differentiated challenges: for example, institutional
 2 feasibility challenges appear to be the most relevant, in line with the qualitative literature. Thus,
 3 feasibility concerns might be particularly relevant in countries with weaker institutional capacity. The
 4 Figure also highlights the key role of policy and technology, as enabling factors. In particular (Panel
 5 B), internationally coordinated and immediate emission reductions allow to smooth out feasibility
 6 concerns and reduce long term challenges compared to delayed policy action, as a result of a more
 7 gradual transition and lower requirements of CO₂ removals. For the same climate objective, different
 8 illustrative mitigation pathways entail somewhat different degrees and distributions of implementation
 9 challenges (panel C).

11 3.8.3 Feasibility in the light of socio-technical transitions

12 The limitations associated with quantitative low-carbon transition pathways stem from a predominant
 13 reliance on techno-economic considerations with a simplified or non-existent representation of the
 14 socio-political and institutional agreement. Accompanying the required deployment of low carbon
 15 technologies will be the formation of new socio-technical systems (Bergek et al. 2008). With a socio-
 16 technical system being defined as a cluster of elements comprising of technology, regulation, user
 17 practices and markets, cultural meaning, infrastructure, maintenance networks, and supply networks
 18 (Geels and Geels 2005; Hofman et al. 2004); the interrelationship between technological systems and
 19 social systems must be comprehensively understood. It is of vital importance that the pro-cess of
 20 technical change must considered in its institutional and social context so as to ascertain potential
 21 transition barriers which in turn provide an indication of pathway feasibility. In order to address the
 22 multitudinous challenges associated with low-carbon transition feasibility and governance, it has been
 23 opined that the robustness of evaluating pathways may be improved by the bridging of differing
 24 quantitative-qualitative analytical approaches (Haxeltine et al. 2008; Foxon et al. 2010; Hughes 2013;
 25 Wangel et al. 2013; Li et al. 2015; Turnheim et al. 2015; Geels et al. 2016a,b, 2018; Moallemi et al.
 26 2017; De Cian et al. 2018; Li and Strachan 2019). The rationale for such analytical bridging is to
 27 rectify the issue that in isolation each disciplinary approach only can generate a fragmented
 28 comprehension of the transition pathway with the consequence being an incomplete identification of
 29 associated challenges in terms of feasibility. Concerning low-carbon transition pathways generated by
 30 IAMs, it has been argued that a comprehensive analysis should include social scientific enquiry
 31 (Geels et al. 2016a, 2018; van Sluisveld et al. 2018b). The normative analysis of IAM pathways
 32 assists in the generation of a vision or the formulation of a general plan with this being complemented
 33 by socio-technical transition theory (Geels et al. 2016a). Such an approach thereby allowing for the
 34 socio-political feasibility and the social acceptance and legitimacy of low-carbon options to be
 35 considered. Combining computer models and the multi-level perspective can help identify ‘transition
 36 bottlenecks’ (Geels et al. 2018). Similarly, increased resolution of integrated assessment models’
 37 actors has led to more realistic narratives of transition in terms of granularity and behaviour
 38 (McCollum et al. 2017; van Sluisveld et al. 2018b). Increased data availability of actual behaviour
 39 from smart technology lowers the barriers to representing behavioural change in computer
 40 simulations, and thus better represent crucial demand side transformations (Creutzig et al. 2018).
 41 Increasing the model resolution is a meaningful way forward. However, integrating a much broader
 42 combination of real-life aspects and dynamics into models could lead to an increased complexity that
 43 could restrict them to smaller fields of applications (De Cian et al. 2018).

44
 45 Other elements of feasibility relate to social justice, which could be essential to enhance the political
 46 and public acceptability of the low carbon transition. Reviewing the literature, one study finds that
 47 employing social justice as an orienting principle can increase the political feasibility of low carbon
 48 policies (Patterson et al. 2018). Three elements are identified as key: i) protecting vulnerable people
 49 from climate change impacts, ii), protecting people from disruptions of transformation, iii), enhancing
 50 the process of envisioning and implementing an equitable post-carbon society.

3.8.4 Enabling factors

There is strong agreement that the climate policy institutional framework as well as technological progress have a profound impact on the attainability of low carbon pathways. Delaying international cooperation reduces the available carbon budget and locks into carbon intensive infrastructure exacerbating implementation challenges (Clarke et al. 2009; Bosetti et al. 2009; Krey and Riahi 2009; Boucher et al. 2009; Keppo and Rao 2007; van Vliet et al. 2009; Knopf et al. 2011; Luderer et al. 2013; Jakob et al. 2012; Aboumahboub et al. 2014; Bertram et al. 2021; Popp et al. 2014; Rogelj et al. 2013a; Riahi et al. 2015; Kriegler et al. 2014a; Gambhir et al. 2017). Similarly, technological availability influences the feasibility of climate stabilization, though differently for different technologies (Iyer et al. 2015a; Kriegler et al. 2014a; Riahi et al. 2015).

One of the most relevant factors affecting mitigation pathways and their feasibility is the rate and kind of socio-economic development. For example, certain socio-economic trends and assumptions about policy effectiveness preclude achieving stringent mitigation futures (Rogelj et al. 2018b). The risk of failure increases markedly in high growth, unequal and/or energy-intensive worlds - such as those characterized by the shared socio-economic pathways SSP3, SSP4 and SSP5. On the other hand, socio-economic development conducive to mitigation relieves the energy sector transformation from relying on large scale technology development: for example, the amount of biomass with CCS in SSP1 is one third of that in SSP5. The reason why socio-economic trends matter so much is that they both affect the CO₂ emissions in counterfactual scenarios as well as the mitigation capacity (Riahi et al. 2017; Rogelj et al. 2018b). Economic growth assumptions are the most important determinant of scenario emissions (Marangoni et al. 2017). De- and post-growth scenarios have been suggested as valuable alternatives to be considered (Hickel et al. 2021; Keyßer and Lenzen 2021), though substantial challenges remain regarding political feasibility (Keyßer and Lenzen 2021).

The type of policy instrument assumed to drive the decarbonization process also play a vital role for determining feasibility. The majority of scenarios exploring climate stabilization pathways in the past have focused on uniform carbon pricing as the most efficient instrument to regulate emissions. However, carbon taxation raises political challenges (Beiser-McGrath and Bernauer 2019), see also Chapter 13 and 14. Carbon pricing will transfer economic surplus from consumers and producers to the government. Losses for producers will be highly concentrated in those industries possessing fixed or durable assets with “high asset specificity” (Murphy 2002; Dolphin et al. 2020). These sectors have opposed climate jurisdictions (Jenkins 2014). Citizens are sensitive to rising energy prices, though revenue recycling can be used to increase support (Carattini et al. 2019). A recent model comparison project confirms findings from the extant literature: using revenues to reduce pre-existing capital or, to a lesser extent, labour taxes, reduces policy costs and eases distributional concerns (Mcfarland et al. 2018; Barron et al. 2018).

Nonetheless, winning support will require a mix of policies which go beyond carbon pricing, and include subsidies, mandates and feebates (Rozenberg et al. 2018; Jenkins 2014). More recent scenarios take into account a more comprehensive range of policies and regional heterogeneity in the near to medium term (Roelfsema et al. 2020). Regulatory policies complementing carbon prices could reduce the implementation challenges by increasing short term emission reduction, though they could eventually reduce economic efficiency (Bertram et al. 2015b; Kriegler et al. 2018a). Innovation policies such as subsidies to R&D have been shown to be desirable due to innovation market failures, and also address the dynamic nature of political feasibility (Bosetti et al. 2011).

3.9 Methods of assessment and gaps in knowledge and data

3.9.1 AR6 mitigation pathways

The analysis in this chapter relies on the available literature as well as an assessment of the scenarios contained in the AR6 scenarios database. Scenarios were submitted by research and other institutions following an open call (see Annex III Part II). The scenarios included in the AR6 scenarios database are an unstructured ensemble, as they are from multiple underlying studies and depend on which institutions chose to submit scenarios to the database. As noted in Section 3.2, they do not represent the full scenario literature or the complete set of possible scenarios. For example, scenarios that include climate change impacts or economic degrowth are not fully represented, as these scenarios, with a few exceptions, were not submitted to the database. Additionally, sensitivity studies, which could help elucidate model behaviour and drivers of change, are mostly absent from the database - though examples exist in the literature (Marangoni et al. 2017).

The AR6 scenarios database contains 3131 scenarios of which 2425 with global scope were considered by this chapter, generated by almost 100 different model versions, from more than 50 model families. Of the 1686 vetted scenarios, 1202 provided sufficient information for a climate categorization. Around 46% of the pathways are consistent with an end of century temperature of at least likely limiting warming to below 2°C. There are many ways of constructing scenarios that limit warming to a particular level and the choice of scenario construction has implications for the timing of both net zero CO₂ and GHG emissions and the deployment of CDR (Emmerling et al. 2019; Rogelj et al. 2019b; Johansson et al. 2020). The AR6 scenarios database includes scenarios where temperature is temporarily exceeded (40% of all scenarios in the database have median temperature in 2100 that is 0.1°C lower than median peak temperature). Climate stabilization scenarios are typically implemented by assuming a carbon price rising at a particular rate per year, though that rate varies across model, scenario, and time period. Standard scenarios assume a global single carbon price to minimize policy costs. Cost minimizing pathways can be reconciled with equity considerations through posterior international transfers. Many scenarios extrapolate current policies and include non-market, regulatory instruments such as technology mandates.

Scenarios are not independent of each other and not representative of all possible outcomes, nor of the underlying scenario generation process; thus, the statistical power of the database is limited. Dependencies in the data generation process originate from various sources. Certain model groups, and types, are over-represented. For example, 8 model teams contributed with 90% of scenarios. Second, not all models can generate all scenarios, and these differences are not random, thereby creating selection bias (Tavoni and Tol 2010). Third, there are strong model dependencies: the modelling scientific community shares code and data, and several IAMs are open source.

3.9.2 Models assessed in this chapter

The models assessed in this chapter differ in their sectoral coverage and the level of complexity in each sector. Models tend to have more detail in their representation of energy supply and transportation, than they do for industry (Section 3.4; Annex III). Some models include detailed land use models, while others exclude land models entirely and use supply curves to represent bioenergy potential (Bauer et al. 2018a). IAMs do not include all mitigation options available in the literature (Rogelj et al. 2018b; Smith et al. 2019). For example, most IAM pathways exclude many granular demand-side mitigation options and land-based mitigation options found in more detailed sectoral models; additionally, only a few pathways include CDR options beyond afforestation/reforestation and BECCS. Section 3.4 and Chapter 12 include some results and comparisons to non-IAM models (e.g., bottom-up studies and detailed sectoral models). These sectoral studies often include a more complete set of mitigation options but exclude feedbacks and linkages across sectors which may alter

1 the mitigation potential of a given sector. There is an increasing focus in IAM studies on SDGs
2 (Section 3.7), with some studies reporting the implications of mitigation pathways on SDGs (e.g.,
3 Bennich et al. (2020)) and others using achieving SDGs as a constraint on the scenario itself (van
4 Vuuren et al. 2015; Soergel et al. 2021a). However, IAMs are still limited in the SDGs they represent,
5 often focusing on energy, water, air pollution and land. On the economic side, the majority of the
6 models report information on marginal costs (i.e., carbon price). Only a subset provides full economic
7 implications measured by either economic activity or welfare. Also often missing, is detail about
8 economic inequality within countries or large aggregate regions.

9
10 For further details about the models and scenarios, see Annex III.

13 **Frequently Asked Questions (FAQs)**

14 **FAQ 3.1 – Is it possible to stabilize warming without net negative CO₂ and GHG emissions?**

15 Yes. Achieving net zero CO₂ emissions and sustaining them into the future is sufficient to stabilize
16 the CO₂-induced warming signal which scales with the cumulative net amount of CO₂ emissions. At
17 the same time, the warming signal of non-CO₂ GHGs can be stabilized or reduced by declining
18 emissions that lead to stable or slightly declining concentrations in the atmosphere. For short-lived
19 GHGs with atmospheric lifetimes of less than 20 years, this is achieved when residual emissions are
20 reduced to levels that are lower than the natural removal of these gases in the atmosphere. Taken
21 together, mitigation pathways that bring CO₂ emissions to net zero and sustain it, while strongly
22 reducing non-CO₂ GHGs to levels that stabilize or decline their aggregate warming contribution, will
23 stabilize warming without using net negative CO₂ emissions and with positive overall GHG emissions
24 when aggregated using GWP100. A considerable fraction of pathways limiting warming to 1.5°C
25 with no or limited overshoot and likely limiting warming to 2°C, respectively, do not or only
26 marginally (<10 GtCO₂ cumulative until 2100) deploy net negative CO₂ emissions (26% and 46%,
27 respectively) and do not reach net zero GHG emissions by the end of the century (48% and 70%,
28 respectively). This is no longer the case in pathways that return warming to 1.5°C after a high
29 overshoot (typically > 0.1°C). All of these pathways deploy net negative emissions on the order of
30 330 (26-623 GtCO₂) (median and 5th-95th percentile) and 87% achieve net negative GHGs emissions
31 in AR6 GWP-100 before the end of the century. Hence, global net negative CO₂ emissions, and net
32 zero or net negative GHG emissions, are only needed to decline, not to stabilize global warming. The
33 deployment of carbon dioxide removal (CDR) is distinct from the deployment of net negative CO₂
34 emissions, because it is also used to neutralize residual CO₂ emissions to achieve and sustain net zero
35 CO₂ emissions. CDR deployment can be considerable in pathways without net negative emissions and
36 all pathways limiting warming to 1.5°C use it to some extent.

38 **FAQ 3.2 – How can net zero emissions be achieved and what are the implications of net zero 39 emissions for the climate?**

40 Halting global warming in the long term requires, at a minimum, that no additional CO₂ emissions
41 from human activities are added to the atmosphere (i.e., CO₂ emissions must reach “net” zero). Given
42 that CO₂ emissions constitute the dominant human influence on global climate, global net zero CO₂
43 emissions are a prerequisite for stabilizing warming at any level. However, CO₂ is not the only
44 greenhouse gas that contributes to global warming and reducing emissions of other greenhouse gases
45 alongside CO₂ towards net zero emissions of all GHGs would lower the level at which global
46 temperature would peak. The temperature implications of net zero GHG emissions depend on the
47 bundle of gases that is being considered, and the emissions metric used to calculate aggregated GHG
48 emissions and removals. If reached and sustained, global net zero GHG emissions using the 100-year
49 Global Warming Potential (GWP-100) will lead to gradually declining global temperature.

1 Not all emissions can be avoided. Achieving net zero CO₂ emissions globally therefore requires deep
2 emissions cuts across all sectors and regions, along with active removal of CO₂ from the atmosphere
3 to balance remaining emissions that may be too difficult, too costly or impossible to abate at that time.
4 Achieving global net zero GHG emissions would require, in addition, deep reductions of non-CO₂
5 emissions and additional CO₂ removals to balance remaining non-CO₂ emissions.

6 Not all regions and sectors must reach net zero CO₂ or GHG emissions individually to achieve global
7 net zero CO₂ or GHG emissions, respectively; instead, positive emissions in one sector or region can
8 be compensated by net negative emissions from another sector or region. The time each sector or
9 region reaches net zero CO₂ or GHG emissions depends on the mitigation options available, the cost
10 of those options, and the policies implemented (including any consideration of equity or fairness).
11 Most modelled pathways that likely limit warming to 2°C above pre-industrial levels and below use
12 land-based CO₂ removal such as afforestation/reforestation and BECCS to achieve net zero CO₂ and
13 net zero GHG emissions even while some CO₂ and non-CO₂ emissions continue to occur. Pathways
14 with more demand-side interventions that limit the amount of energy we use, or where the diet that we
15 consume is changed, can achieve net zero CO₂, or net zero GHG emissions with less carbon dioxide
16 removal. All available studies require at least some kind of carbon dioxide removal to reach net zero;
17 that is, there are no studies where absolute zero GHG or even CO₂ emissions are reached by deep
18 emissions reductions alone.

19 Total GHG emissions are greater than emissions of CO₂ only; reaching net zero CO₂ emissions
20 therefore occurs earlier, by up to several decades, than net zero GHG emissions in all modelled
21 pathways. In most modelled pathways that likely limit warming to 2°C above pre-industrial levels and
22 below in the most cost-effective way, the AFOLU and energy supply sectors reach net zero CO₂
23 emissions several decades earlier than other sectors; however, many pathways show much reduced,
24 but still positive net GHG emissions in the AFOLU sector in 2100.

25 26 **FAQ 3.3 – How plausible are high emissions scenarios, and how do they inform policy?**

27 IAMs are used to develop a wide range of scenarios describing future trajectories for greenhouse gas
28 emissions based on a wide set of assumptions regarding socio-economic development, technological
29 changes, political development and climate policy. Typically, the IAM-based scenarios can be divided
30 into a) reference scenarios (describing possible trajectories in the absence of new stringent climate
31 policies) and b) mitigation scenarios (describing the impact of various climate policy assumptions).
32 Reference scenarios typically result in high emissions and, subsequently, high levels of climate
33 change (in the order of 2.5-4 °C during the 21st century). The purpose of such reference scenarios is
34 to explore the consequences of climate change and act as a reference for mitigation scenarios. The
35 possible emission levels for reference scenarios diverge from stabilising and even slowly declining
36 emissions (e.g., for current policy scenarios or SSP1) to very high emission levels (e.g., SSP5 and
37 RCP8.5). The latter leads to nearly 5 °C of warming by the end of the century for medium climate
38 sensitivity. Hausfather and Peters (2020) pointed out that since 2011, the rapid development of
39 renewable energy technologies and emerging climate policy have made it considerably less likely that
40 emissions could end up as high as RCP8.5. This means that reaching emissions levels as high as
41 RCP8.5 has become less likely. Still, high emissions cannot be ruled out for many reasons, including
42 political factors and, for instance, higher than anticipated population and economic growth. Climate
43 projections of RCP8.5 can also result from strong feedbacks of climate change on (natural) emission
44 sources and high climate sensitivity (see WGI Chapter 7). Therefore, their median climate impacts
45 might also materialise while following a lower emission path (e.g., Hausfather and Betts (2020)). All-
46 in-all, this means that high-end scenarios have become considerably less likely since AR5 but cannot
47 be ruled out. High-end scenarios (like RCP8.5) can be very useful to explore high-end risks of climate
48 change but are not typical ‘business-as-usual’ projections and should therefore not be presented as
49 such.

Table of Contents

Chapter 4: Mitigation and development pathways in the near- to mid-term	4-1
Executive summary	4-3
4.1 Introduction	4-7
4.2 Accelerating mitigation actions across scales.....	4-9
4.2.1 Mitigation targets and measures in nationally determined contributions.....	4-9
4.2.2 Aggregate effects of NDCs and other mitigation efforts relative to long-term mitigation pathways 4-11	
Cross-Chapter Box 4 Comparison of NDCs and current policies with the 2030 GHG emissions from long-term temperature pathways	4-22
4.2.3 Mitigation efforts in subnational and non-state action plans and policies	4-25
4.2.4 Mid-century low-emission strategies at the national level.....	4-32
4.2.5 What is to be done to accelerate mitigation?	4-39
4.2.6 Implications of accelerated mitigation for national development objectives.....	4-51
4.2.7 Obstacles to accelerated mitigation and how overcoming them amounts to shifts in development pathways.....	4-58
4.3 Shifting Development pathways.....	4-61
4.3.1 Framing of development pathways	4-61
4.3.2 Implications of development pathways for mitigation and mitigative capacity	4-65
4.3.3 Examples of shifts in development pathways and of supporting policies.....	4-72
Cross-Chapter Box 5 Shifting development paths to increase sustainability and broaden mitigation options 4-74	
4.4 How to shift development pathways and accelerate the pace and scale of mitigation	4-79
4.4.1 Approaches, enabling conditions and examples	4-79
4.4.2 Adaptation, development pathways and mitigation	4-92
4.4.3 Risks and uncertainties.....	4-97
4.5 Equity, including just transitions	4-99
4.6 Knowledge gaps	4-104
Frequently asked questions	4-105
References.....	4-107

1 **Executive summary**

2 This chapter focuses on accelerating mitigation and on shifting development pathways to increased
3 sustainability, based on literature particularly at national scale. While previous WGIII assessments have
4 discussed mitigation pathways, focus on development pathways is more recent. The timeframe is the
5 near-term (now up to 2030) to mid-term (2030 to 2050), complementing Chapter 3 on the long-term
6 (from 2050 onward).

7 **An emissions gap persists, exacerbated by an implementation gap, despite mitigation efforts**
8 **including those in near-universal nationally determined contributions (NDCs).** The “emissions
9 gap” is understood as the difference between the emissions with NDCs in 2030, and mitigation
10 pathways consistent with the temperature goals. In general, the term “implementation gap” refers to the
11 difference between goals on paper and how they are achieved in practice. In this report, the term refers
12 to the gap between mitigation pledges contained in national determined contributions, and the expected
13 outcome of existing policies. There is considerable literature on country-level mitigation pathways,
