5 30@30 scenario show that the demand for these materials would increase by 30 times for lithium and
6 around 25 times for cobalt. While there are efforts to move away from expensive materials such as
7 cobalt (IEA 2019a, 2021a), dependence on lithium will remain, which may be a cause of concern
8 (Olivetti et al. 2017; You and Manthiram 2018). A more detailed discussion on resource constraints for
9 lithium is provided in Box 10.6 on critical materials.

10 Externalities from resource extraction are another concern, though current volumes of lithium are much
11 smaller than other metals (steel, aluminium). As a result, lithium was not even mentioned in the global
12 resource outlook of UNEP (IRP 2019). Nonetheless, it is essential to manage demand and limit
13 externalities since the demand for lithium is going to increase many times in the future. Reuse of LIBs
14 used in EVs for stationary energy applications can help in reducing the demand for LIBs. However, the
15 main challenges are the difficulty in accessing the information on the health of batteries to be recycled
16 and technical problems in remanufacturing the batteries for their second life (Ahmadi et al. 2017).
17 Recycling lithium from used batteries could be another possible supply source (Winslow et al. 2018).
18 While further R&D is required for commercialisation (Ling et al., 2018), recent efforts at recycling
19 LIBs are very encouraging (Ma et al. 2021). The standardisation of battery modules and packaging
20 within and across vehicle platforms, increased focus on design for recyclability, and supportive
21 regulation are important to enable higher recycling rates for LIBs (Harper et al. 2019).

22 Several next-generation battery chemistries are often referred to as post-LIBs (Placke et al. 2017). These
23 chemistries include metal-sulphur, metal-air, metal-ion (besides Li) and all-solid-state batteries
24 (ASSB). The long development cycles of the automotive industry (Cano et al. 2018) and the advantages
25 of LIBs in terms of energy density and cycle life (Table 6.5, Chapter 6) mean that it is unlikely that
26 post-LIB technologies will replace LIBs in the next decade. However, lithium-sulphur, lithium-air, and
27 zinc-air have emerged as potential alternatives for LIBs. These emerging chemistries may also be used
28 to supplement LIBs in dual-battery configurations, to extend the driving range at lower costs or with
29 higher energy density (Cano et al. 2018). Lithium-sulphur (Li-S) batteries have a lithium metal anode
30 with a higher theoretical capacity than lithium-ion anodes and much lower cost sulphur cathodes relative
31 to typical Li-ion insertion cathodes (Manthiram et al. 2014). As a result, Li-S batteries are much cheaper
32 than LIB to manufacture and have a higher energy density (Table 6.5, Chapter 6). Conversely, these
33 batteries face challenges from sulphur cathodes, such as low conductivity of the sulphur and lithium
34 sulphide phases, and the relatively high solubility of sulphur species in common lithium battery
35 electrolytes, leading to low cycle life (Cano et al. 2018). Lithium-air batteries offer a further
36 improvement in specific energy and energy density above Li-S batteries owing to their use of
37 atmospheric oxygen as a cathode in place of sulphur. However, their demonstrated cycle-life is much
38 lower (Table 6.5, Chapter 6). Lithium-air batteries also have low specific power. Therefore, lithium-air
39 require an extra battery for practical applications (Cano et al. 2018). Finally, zinc-air batteries could
40 more likely be used in future EVs because of their more advanced technology status and higher
41 practically achievable energy density (Fu et al. 2017). Like Li-air batteries, their poor specific power
42 and energy efficiency will probably prevent zinc-air batteries from being used as a primary energy
43 source for EVs. Still, they could be promising when used in a dual-battery configuration (Cano et al.
44 2018).

45 The technological readiness of batteries is a crucial parameter in the advancement of EVs (Manzetti
46 and Mariasiu 2015). Energy density, power density, cycle life, calendar life, and the cost per kWh are
47 the pertinent parameters for comparing the technological readiness of various battery technologies
48 (Manzetti and Mariasiu 2015; Andwari et al. 2017; Lajunen et al. 2018). Table 6.5 in Chapter 6 provides

1 a summary of the values of these parameters for alternative battery technologies. LIBs comprehensively
2 dominate the other battery types and are at a readiness level where they can be applied for land transport
3 applications (cars, scooters, electrically assisted cycles) and at battery pack costs below 150 USD per
4 kWh, making EVs cost-competitive with conventional vehicles (Nykqvist et al. 2019). In 2020 the stock
5 of battery-electric LDVs had crossed the 10 million mark (IEA 2021a). (Schmidt et al. 2017) project
6 that the cost of a battery pack for LIBs will reach 100 USD per kWh by 2030, but more recent trends
7 show this could happen much earlier. For example, according to IEA, battery pack costs could be as
8 low as 80 USD per kWh by 2030 (IEA 2019a). In addition, there are clear trends that now vehicle
9 manufacturers are offering vehicles with bigger batteries, greater driving ranges, higher top speeds,
10 faster acceleration, and all size categories (Nykqvist et al. 2019). In 2020 there were over 600,000
11 battery-electric buses and over 31,000 battery-electric trucks operating globally (IEA 2021a).

12 LIBs are not currently envisaged to be suitable for long-haul transport. However, several battery
13 technologies are under development (Table 6.5, Chapter 6), which could further enhance the
14 competitiveness of EVs and expand their applicability to very short-haul aviation and ships, especially
15 smaller vehicles. Li-S, Li-air, and Zn-air hold the highest potential for these segments (Cano et al.
16 2018). All three of these technologies rely on making use of relatively inexpensive elements, which can
17 help bring down battery costs (Cano et al. 2018). The main challenge these technologies face is in terms
18 of the cycle life. Out of the three, Li-S has already been used for applications in unmanned aerial
19 vehicles (Fotouhi et al., 2017) due to relatively high specific energy (almost double the state of art
20 LIBs). However, even with low cycle life, Li-air and Zn-air hold good prospects for commercialisation
21 as range extender batteries for long-range road transport and with vehicles that are typically used for
22 city driving (Cano et al. 2018).

23 *Alternative electricity storage technologies for heavy-duty transport:* While LIBs described in the
24 previous section are driving the electrification of LDVs, their application to railways, aviation, ships,
25 and large vehicles faces challenges due to the higher power requirements of these applications. The use
26 of a capacitor with a higher power density than LIBs could be suitable for the electrification of such
27 vehicles. It is one of the solutions for regenerating large and instantaneous energy from regenerative
28 brakes. Classical capacitors generally show more attractive characteristics in power density (8,000-
29 10,000 W/kg) than batteries. However, the energy density is poor (1-4 Wh/kg) compared to batteries,
30 and there is an issue of self-discharge (González et al. 2016; Poonam et al. 2019). To improve the energy
31 density, electrochemical double layer capacitors (EDLCs; supercapacitor) and hybrid capacitors (10-24
32 Wh/kg, 900-9000 W/kg in the product-level) such as Li-ion capacitors (LICs) have been developed.
33 The highest energy density of the LIC system (100-140 Wh/kg in the research stage) are approaching
34 that of the Li-ion battery systems (80-240 Wh/kg in the product stage) (Naoi et al. 2012; Panja et al.
35 2020). Examples of effective use of capacitors include a 12 tonne truck with a capacitor-based kinetic
36 energy recovery system (KERS) that has been reported to save up to 32% of the fuel use of standard
37 truck (Kamdar 2017). Similarly, an EDLC bank applied to electric railway systems has been shown to
38 result in a 10% reduction in power consumption per day (Takahashi et al. 2017). Finally, systems in
39 which capacitors are mounted on an electric bus for charging at a stop have been put into practical use,
40 e.g., Trackless Tram (Newman et al. 2019). At the bus stop, the capacitor is charged at 600 kW for 10
41 ~ 40 seconds, which provides enough power for 5 ~ 10 km (Newman et al. 2019). In addition, more
42 durable capacitors can achieve a longer life than LIB systems (ADB 2018).

43 Hybrid energy storage (HES) systems, which combine a capacitor and a battery, achieve both high
44 power and high energy, solving problems such as capacity loss of the battery and self-discharge of the
45 capacitor. In these systems, the capacitor absorbs the steeper power, while the LIB handles the steady
46 power, thereby reducing the power loss of the EV to half. Furthermore, since the in-rush current of the
47 battery is suppressed, there is an improvement in the reliability of the LIB (Noumi et al., 2014). In a
48 hybrid diesel train, 8.2% of the regenerative energy is lost due to batteries' limited charge-discharge

1 performance; however, using an EDLC with batteries can save this energy (Takahashi et al. 2017;
2 Mayrink et al. 2020)

3 The development of power storage devices and advanced integrated system approaches, including
4 power electronics circuits such as HES and their control technologies, are important for the
5 electrification of mobility. These technologies are solutions that could promote the electrification of
6 systems, reduce costs, and contribute to the social environment through multiple outcomes in the
7 decarbonisation agenda.

8

9 **10.3.3 Fuel cell technologies**

10 In harder-to-electrify transport segments, such as heavy-duty vehicles, shipping, and aviation,
11 Hydrogen holds significant promise for delivering emissions reductions if it is produced using low-
12 carbon energy sources. In particular, Hydrogen fuel cells are seen as an emerging option to power larger
13 vehicles for land-based transport (Tokimatsu et al. 2016; IPCC 2018; IEA 2019b). Despite this
14 potential, further advancements in technological and economic maturity will be required in order for
15 Hydrogen fuel cells to play a greater role. While this section focuses primarily on Hydrogen fuel cells,
16 Ammonia and Methanol fuel cells may also emerge as options for low power applications.

17 During the last decade, Hydrogen fuel cell vehicles (HFCVs) have attracted growing attention, with
18 fuel cell technology improving through research and development. Fuel cell systems cost 80 to 95 per
19 cent less than they did in the early 2000s, at approximately \$50 per kW for light-duty (80 kW) and \$100
20 per kW for medium-heavy duty (160 kW). These costs are approaching the US Department of Energy's
21 (US DOE) goal of \$40 per kW in 2025 at a production target of 500,000 systems per year (IEA 2019c).
22 In addition to cost reductions, the power density of fuel cell stacks has now reached around 3.0 kW/L,
23 and average durability has improved to approximately 2,000-3,000 hours (Jouin et al. 2016; Kurtz et al.
24 2019). Despite these improvements, fuel cell systems are not yet mature for many commercial
25 applications. For example, the US DOE has outlined that for Hydrogen fuel cell articulated trucks (semi-
26 trailers) to compete with diesel vehicles, fuel cell durability will need to reach 30,000 hours (US DOE
27 2019). While some fuel cell buses have demonstrated durability close to these targets (Eudy and Post
28 2018a), another review of light fuel cell vehicles found maximum durability of 4,000 hours (Kurtz et
29 al. 2019). As more fuel cell vehicles are trialled, it is expected that further real-world data will become
30 available to track ongoing fuel cell durability improvements.

31 Ammonia and Methanol fuel cells are considered to be less mature than Hydrogen fuel cells. However,
32 they offer the benefit of using a more easily transported fuel that can be directly used without converting
33 to Hydrogen (Zhao et al. 2019). Conversely, both Methanol and Ammonia are toxic, and in the case of
34 Methanol fuel cells, carbon dioxide is released as a by-product of generating electricity with the fuel
35 cell (Zhao et al. 2019). Due to the lower power output, Methanol and Ammonia fuel cells are also not
36 well-suited to heavy duty vehicles (Jeerh et al. 2021). They are therefore unlikely to compete with
37 Hydrogen fuel cells. However, Ammonia and Methanol could be converted at refuelling stations to
38 Hydrogen as an alternative to being directly used in fuel cells (Zhao et al. 2019).

39 Several FCV-related technologies are fully ready for demonstration and early market deployment,
40 however, further research and development will be required to achieve full-scale commercialisation,
41 likely from 2030 onwards (Staffell et al. 2019; Energy Transitions Commission 2020; IEA 2021b).
42 Some reports argue that it may be possible to achieve serial production of fuel cell heavy-duty trucks
43 in the late 2020s, with comparable costs to diesel vehicles achieved after 2030 (Jordbakker et al. 2018).
44 Over the next decade or so, Hydrogen FCVs could become cost-competitive for various transport
45 applications, potentially including long-haul trucks, marine ships, and aviation (FCHEA 2019; FCHJU
46 2019; BloombergNEF 2020; Hydrogen Council 2017, 2020). The speed of fuel cell system cost
47 reduction is a key factor for achieving widespread uptake. Yet, experts disagree on the relationship

1 between the scale of fuel cell demand, cost, and performance improvements (Cano et al. 2018). Costs
2 of light-, medium-, and heavy-duty fuel cell powertrains have decreased by orders of magnitude with
3 further reductions of a factor of two expected with continued technological progress (Whiston et al.
4 2019). For example, the costs of platinum for fuel cell stacks have decreased by an order of magnitude
5 (Staffell et al. 2019); current generation FCVs use approximately 0.25 g/kW Pt and a further reduction
6 of 50-80% is expected by 2030 (Hao et al. 2019).

7 Hydrogen is likely to take diverse roles in the future energy system: as a fuel in industry and buildings,
8 as well as transport, and as energy storage for variable renewable electricity. Further research is required
9 to understand better how a Hydrogen transport fuel supply system fits within the larger Hydrogen
10 energy system, especially in terms of integration within existing infrastructure, such as the electricity
11 grid and the natural gas pipeline system (IEA 2015).

12 Strong and durable policies would be needed to enable widespread use of Hydrogen as a transport fuel
13 and to sustain momentum during a multi-decade transition period for Hydrogen FCVs to become cost-
14 competitive with electric vehicles (IEA 2019c; FCHEA 2019; FCHJU 2019; BNEF 2020; Hydrogen
15 Council 2017, 2020). The analysis suggests that Hydrogen is likely to have strategic and niche roles in
16 transport, particularly in long-haul shipping and aviation. With continuing improvements, Hydrogen
17 and electrification will likely play a role in decarbonising heavy-duty road and rail vehicles.

18 19 **10.3.4 Refuelling and charging infrastructure**

20 The transport sector relies on liquid gasoline, and diesel for land-based transport, jet fuel for aviation,
21 and heavy fuel oil for shipping. Extensive infrastructure for refuelling liquid fossil fuels already exists.
22 Ammonia, synthetic fuels, and biofuels have emerged as alternative fuels for powering combustion
23 engines and turbines used in land, shipping, and aviation (Figure 10.2). Synthetic fuels such as e-
24 Methanol and Fischer-Tropsch liquids have similar physical properties and could be used with existing
25 fossil fuel infrastructure (Soler, 2019). Similarly, biofuels have been used in several countries together
26 with fossil fuels (Panoutsou et al. 2021). Ammonia is a liquid, but only under pressure, and therefore
27 will not be compatible with liquid fossil fuel refuelling infrastructure. Ammonia is, however, widely
28 used as a fertiliser and chemical raw material and 10% of annual Ammonia production is transported
29 via sea (Gallucci 2021). As such, a number of port facilities include Ammonia storage and transport
30 infrastructure and the shipping industry has experience in handling Ammonia (Gallucci 2021). This
31 infrastructure would likely need to be extended in order to support the use of Ammonia as a fuel for
32 shipping and therefore ports are likely to be the primary sites for these new refuelling facilities.

33 EVs and HFCV require separate infrastructure than liquid fuels. The successful diffusion of new vehicle
34 technologies is dependent on the preceding deployment of infrastructure (Leibowicz 2018), so that the
35 deployment of new charging and refuelling infrastructure will be critical for supporting the uptake of
36 emerging transport technologies like EVs and HFCVs, where it makes sense for each to be deployed.
37 As a result, there is likely a need for the simultaneous investment in both infrastructure and vehicle
38 technologies to accelerate decarbonisation of the transport sector.

39 *Charging infrastructure:* Charging infrastructure is important for a number of key reasons. From a
40 consumer perspective, robust and reliable charging infrastructure networks are required to build
41 confidence in the technology and overcome the often-cited barrier of 'range anxiety' (She et al. 2017).
42 Range anxiety is where consumers do not have confidence that an EV will meet their driving range
43 requirements. For LDVs, the majority of charging (75-90%) has been reported to take place at or near
44 homes (Figenbaum 2017; Webb et al. 2019; Wenig et al. 2019). Charging at home is a particularly
45 significant factor in the adoption of EVs as consumers are less willing to purchase an EV without home
46 charging (Berkeley et al. 2017; Funke and Plötz 2017; Nicholas et al. 2017). However, home charging
47 may not be an option for all consumers. For example, apartment dwellers may face specific challenges

1 in installing charging infrastructure (Hall and Lutsey 2020). Thus, the provision of public charging
2 infrastructure is another avenue for alleviating range anxiety, facilitating longer distance travel in EVs,
3 and in turn, encouraging adoption (Hall and Lutsey 2017; Melliger et al. 2018; Narassimhan and
4 Johnson 2018; Melton et al. 2020). Currently, approximately 10% of charging occurs at public
5 locations, roughly split equally between AC (slower) and DC (fast) charging (Figenbaum 2017; Webb
6 et al. 2019; Wenig et al. 2019). Deploying charging infrastructure at workplaces and commuter car
7 parks is also important, particularly as these vehicles are parked at these locations for many hours.
8 Indeed, around 15-30% of EV charging currently occurs at these locations (Figenbaum 2017; Webb et
9 al. 2019; Wenig et al. 2019). It has been suggested that automakers and utilities could provide support
10 for the installation of home charging infrastructure (Hardman et al. 2018), while policy-makers can
11 provide support for public charging. Such support could come via supportive planning policy, building
12 regulations, and financial support. Policy support could also incentivise the deployment of charging
13 stations at workplaces and commuter car parks. Charging at these locations would have the added
14 benefit of using excess solar energy generated during the day (Hardman et al. 2018; Webb et al. 2019).

15 While charging infrastructure is of high importance for the electrification of light-duty vehicles,
16 arguably, it is even more important for heavy-duty vehicles given the costs of high-power charging
17 infrastructure. It is estimated that the installed cost of fast-charging hardware can vary between
18 approximately USD 45,000 to 200,000 per charger, depending on the charging rate, the number of
19 chargers per site, and other site conditions (Nicholas 2019; Hall and Lutsey 2019; Nelder and Rogers
20 2019). Deployment of shared charging infrastructure at key transport hubs, such as bus and truck depots,
21 freight distribution centres, marine shipping ports and airports, can encourage a transition to electric
22 vehicles across the heavy transport segments. Furthermore, if charging infrastructure sites are designed
23 to cater for both light and heavy-duty vehicles, infrastructure costs could decrease by increasing
24 utilisation across multiple applications and/or fleets (Nelder and Rogers 2019).

25 There are two types of charging infrastructure for electric vehicles: conductive charging involving a
26 physical connection and wireless/induction charging. The majority of charging infrastructure deployed
27 today for light and heavy-duty vehicles is conductive. However, wireless charging technologies are
28 beginning to emerge – particularly for applications like bus rapid transit – with vehicles able to charge
29 autonomously while parked and/or in motion (IRENA 2019). For road vehicles, electric road systems,
30 or road electrification, is also emerging as an alternative form of conductive charging infrastructure that
31 replaces a physical plug (Ainalis et al. 2020; Hill et al. 2020). This type of charging infrastructure is
32 particularly relevant for road freight where load demand is higher. Road electrification can take the
33 form of a charging rail built into the road pavement, run along the side of the road, through overhead
34 catenary power lines - similar to electrical infrastructure used for rail - or at recharging facilities at
35 stations along the route. This infrastructure can also be used to directly power other electrified
36 powertrains, such as hybrid and HFCV (Hardman et al. 2018; Hill et al. 2020).

37 Charging infrastructure also varies in terms of the level of charging power. For light vehicles, charging
38 infrastructure is generally up to 350 kW, which provide approximately 350 kilometres for every 10
39 minutes of charging. For larger vehicles, like buses and trucks, charging infrastructure is generally up
40 to 600 kW, providing around 50-100 km for every 10 minutes of charging (depending on the size of the
41 bus/truck). Finally, even higher power charging infrastructure is currently being developed at rates
42 greater than 1 MW, particularly for long-haul trucks and for short-haul marine shipping and aviation.
43 For example, one of the largest electric ferries in the world, currently operating in Denmark, uses a 4.4
44 MW charger (Heinemann et al. 2020).

45 Finally, there are several different charging standards, varying across transport segments and across
46 geographical locations. Like electrical appliances, different EV charging connectors and sockets have
47 emerged in different regions, e.g. CCS2 in Europe (ECA 2021), GB/T in China (Hove and Sandalow
48 2019). Achieving interoperability between charging stations is seen as another important issue for

1 policy-makers to address to provide transparent data to the market on where EV chargers are located
2 and a consistent approach to paying for charging sessions (van der Kam and Bekkers 2020).
3 Interoperability could also play an important role in enabling smart charging infrastructure (Neimeh
4 and Andersen 2020).

5 *Smart charging - electric vehicle-grid integration strategies:* EVs provide several opportunities for
6 supporting electricity grids if appropriately integrated. Conversely, a lack of integration could
7 negatively affect the grid, particularly if several vehicles are charged in parallel at higher charging rates
8 during peak demand periods (Webb et al. 2019; Jochem et al. 2021). There are three primary approaches
9 to EV charging. In unmanaged charging, EVs are charged ad-hoc, whenever connected, regardless of
10 conditions on the broader electricity grid (Webb et al. 2019; Jochem et al. 2021). Second, in managed
11 charging, EVs are charged during periods beneficial to the grid, e.g. high renewable generation and/or
12 low demand periods. Managed charging also allows utilities to regulate the rate of charge and can thus
13 provide frequency and regulation services to the grid (Weis et al. 2014). Finally, in bidirectional
14 charging or vehicle-to-grid (V2G), EVs are generally subject to managed charging, but an extension
15 provides the ability to export electricity from the vehicle's battery back to the building and/or wider
16 electricity grid (Ercan et al. 2016; Noel et al. 2019; Jochem et al. 2021). The term 'smart charging' has
17 become an umbrella term to encompass both managed charging (often referred to as a V1G) and
18 vehicle-to-grid (V2G). For electric utilities, smart charging strategies can provide backup power,
19 support load balancing, reduce peak loads (Zhuk et al. 2016; Noel et al. 2019; Jochem et al. 2021),
20 reduce the uncertainty in forecasts of daily and hourly electrical loads (Peng et al. 2012), and allow
21 greater utilisation of generation capacity (Hajimiragha et al. 2010; Madzharov et al. 2014).

22 Smart charging strategies can also enhance the climate benefits of EVs (Yuan et al. 2021). Controlled
23 charging can help avoid high carbon electricity sources, decarbonisation of the ancillary service
24 markets, or peak shaving of high carbon electricity sources (Jochem et al. 2021). V2G-capable EVs can
25 result in even lower total emissions, particularly when compared to other alternatives (Reddy et al.
26 2016). Noel et al.(2019) analysed V2G pathways in Denmark and noted that at a penetration rate of
27 75% by 2030, \$34 billion in social benefits could be accrued (through things like displaced pollution).
28 These social benefits translate to \$1,200 per vehicle. V2G-capable EVs were found to have the potential
29 to reduce carbon emissions compared to a conventional gasoline vehicle by up to 59%, assuming
30 optimised charging schedules (Hoehne and Chester 2016).

31 Projections of energy storage suggest smart charging strategies will come to play a significant role in
32 future energy systems. Assessment of different energy storage technologies for Europe showed that
33 V2G offered the most storage potential compared to other options and could account for 200 GW of
34 installed capacity by 2060, whereas utility-scale batteries and pumped hydro storage could provide 160
35 GW of storage capacity (Després et al., 2017). Another study found that EVs with controlled charging
36 (V1G) could provide similar services to stationary storage but at a far lower cost (Coignard et al. 2018).
37 While most deployments of smart charging strategies are still at the pilot stage, the number of projects
38 continues to expand, with the V2G Hub documenting at least 90 V2G projects across 22 countries in
39 2021 (Vehicle to Grid (VG) 2021). Policymakers have an important role in facilitating collaboration
40 between vehicle manufacturers, electricity utilities, infrastructure providers, and consumers to enable
41 smart charging strategies and ensure EVs can support grid stability and the uptake of renewable energy.
42 This is a critical part of decarbonising transport.

43 *Hydrogen infrastructure:* HFCVs are reliant on the development of widespread and convenient
44 Hydrogen refuelling stations (FCHEA 2019; IEA 2019c; BNEF 2020). Globally, there are around 540
45 Hydrogen refuelling stations, with the majority located in North America, Europe, Japan, and China
46 (IEA 2021a). Approximately 70% of these refuelling stations are open to the public (Coignard et al.
47 2018). Typical refuelling stations currently have a refuelling capacity of 100 to 350 kg/day (CARB

1 2019, 2020; H2 Tools 2020; AFDC 2021). At most, current Hydrogen refuelling stations have daily
2 capacities under 500 kg/day (Liu et al. 2020b).

3 The design of Hydrogen refuelling stations depends on the choice of methods for Hydrogen supply and
4 delivery, compression and storage, and the dispensing strategy. Hydrogen supply could happen via on-
5 site production or via transport and delivery of Hydrogen produced off-site. At the compression stage,
6 Hydrogen is compressed to achieve the pressure needed for economic stationery and vehicle storage.
7 This pressure depends on the storage strategy. Hydrogen can be stored as a liquid or a gas. Hydrogen
8 can also be dispensed to the vehicles as a gas or a liquid, depending on the design of the vehicles (though
9 it tests the extremes of temperature range and storage capacity for an industrial product). The
10 technological and economic development of each of these components continues to be researched.

11 If Hydrogen is produced off site in a large centralised plant, it must be stored and delivered to refuelling
12 stations. The cost of Hydrogen delivery depends on the amount of Hydrogen delivered, the delivery
13 distance, the storage method (compressed gas or cryogenic liquid), and the delivery mode (truck vs.
14 pipeline). Table 10.6 describes the three primary options for Hydrogen delivery. Most Hydrogen
15 refuelling stations today are supplied by trucks and, very occasionally, Hydrogen pipelines. Gaseous
16 tube trailers could also be used to deliver Hydrogen in the near term, or over shorter distances, due to
17 the low fixed cost (although the variable cost is high). Both liquefied truck trailers and pipelines are
18 recognised as options in the medium to long-term as they have higher capacities and lower costs over
19 longer distances (FCHJU 2019; Li et al. 2020; EU 2021). Alternatively, Hydrogen can be produced on
20 site using a small-scale onsite electrolyser or steam methane reforming unit combined with CCS.
21 Hydrogen is generally dispensed to vehicles as a compressed gas at pressures 350 or 700 bar, or as
22 liquified Hydrogen at -253°C (Hydrogen Council 2020).

23

24 **Table 10.6 Overview of three transport technologies for Hydrogen delivery in the transport sector**
25 **showing relative differences. Source: (IEA 2019c)**

	<i>Capacity</i>	<i>Delivery distance</i>	<i>Energy loss</i>	<i>Fixed costs</i>	<i>Variable costs</i>	<i>Deployment phase</i>
Gaseous tube trailers	Low	Low	Low	Low	High	Near term
Liquefied truck trailers	Medium	High	High	Medium	Medium	Medium to long term
Hydrogen pipelines	High	High	Low	High	Low	Medium to long term

26

27 The costs for Hydrogen refuelling stations vary widely and remain uncertain for the future (IEA 2019c).
28 The IEA reports that the investment cost for one Hydrogen refuelling station ranges between USD 0.6–
29 2 million for Hydrogen at a pressure of 700 bar and a delivery capacity of 1,300 kg per day. The
30 investment cost of Hydrogen refuelling stations with lower refuelling capacities (~50 kg H₂ per day)
31 delivered at lower pressure (350 bar) range between USD 0.15–1.6 million. A separate estimate by the
32 International Council for Clean Transport suggests that at a capacity of 600 kg of Hydrogen per day,
33 the capital cost of a single refuelling station would be approximately USD 1.8 million (ICCT 2017).
34 Given the high investment costs for Hydrogen refuelling stations, low utilisation can translate into a
35 high price for delivered Hydrogen. In Europe, most pumps operate at less than 10% capacity. For small
36 refuelling stations with a capacity of 50 kg H₂ per day, this utilisation rate translates to a high price of
37 around USD 15–25 per kg H₂ – in line with current retail prices (IEA 2019c). The dispensed cost of

1 Hydrogen is also highly correlated with the cost of electricity, when H₂ is produced using electrolysis,
2 which is required to produce low-carbon Hydrogen.

3

4 **10.4 Decarbonisation of land-based transport**

5 **10.4.1 Light-duty vehicles for passenger transport**

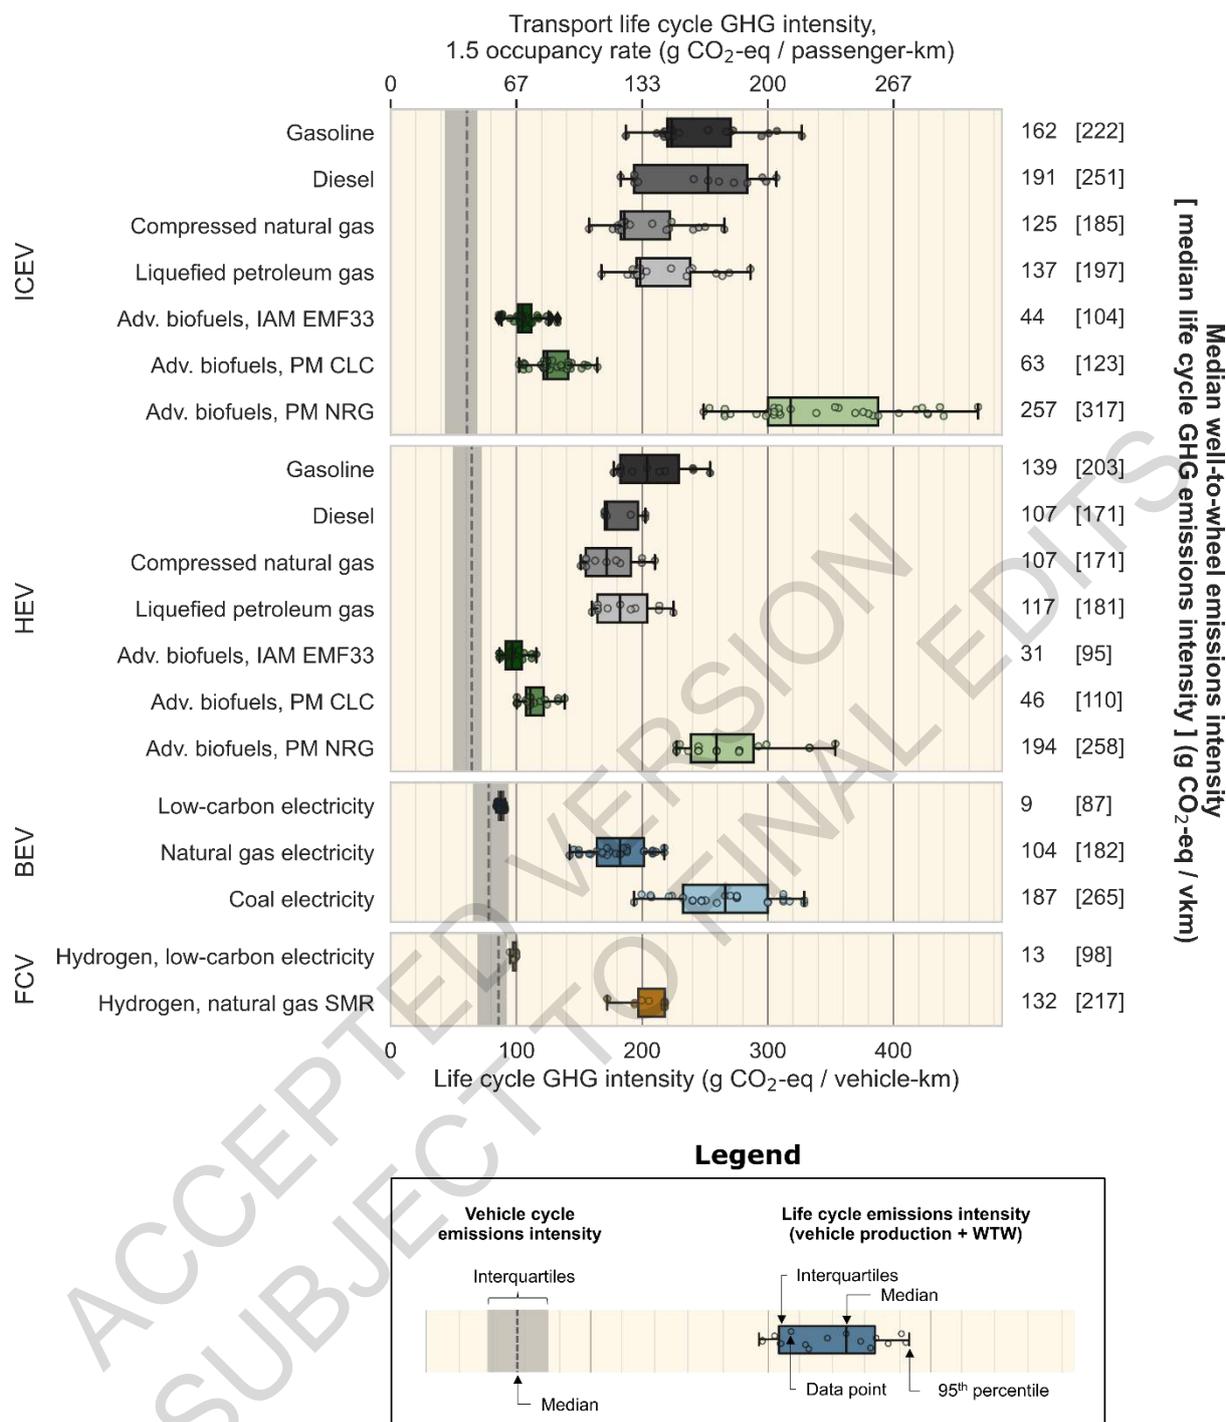

6 LDVs represent the main mode of transport for private citizens (ITF 2019) and currently represent the
7 largest share of transport emissions globally (IEA 2019d). Currently, powertrains depending on gasoline
8 and diesel fuels remain the dominant technology in the LDV segment (IEA 2019d). HEVs, and fully
9 battery electric vehicles (BEVs), however, have become increasingly popular in recent years (IEA
10 2021a). Correspondingly, the number of life cycle assessment (LCA) studies investigating HEVs,
11 BEVs, and fuel cell vehicles have increased. While historically the focus has been on the tailpipe
12 emissions of LDVs, LCA studies demonstrate the importance of including emissions from the entire
13 vehicle value chain, particularly for alternative powertrain technologies.

14 Figure 10.4 presents the cumulative life cycle emissions for selected powertrain technologies and fuel
15 chain combinations for compact and mid-sized LDV. This figure summarizes the harmonized findings
16 from the academic literature reviewed and the data submitted through an IPCC data collection effort,
17 as described in Appendix 10.1 (Cusenza et al. 2019; Hawkins et al. 2013; Tong et al. 2015b; Bauer et
18 al. 2015; Gao et al. 2016; Ellingsen et al. 2016; Kim and Wallington 2016; Cai et al. 2017; Ke et al.
19 2017; Lombardi et al. 2017; Miotti et al. 2017; Evangelisti et al. 2017; Valente et al. 2017; de Souza et
20 al. 2018; Elgowainy et al. 2018; Luk et al. 2018; Bekel and Pauliuk 2019; Messagie et al. 2014; Hoque
21 et al. 2019; IEA 2019a; Rosenfeld et al. 2019; Shen et al. 2019; Wang et al. 2019; Wu et al. 2019;
22 Benajes et al. 2020; Ambrose et al. 2020; Hill et al. 2020; Knobloch et al. 2020; JEC 2020; Qiao et al.
23 2020; Cox et al. 2018; Sacchi 2021; Zheng et al. 2020; Wolfram et al. 2020; Valente et al. 2021). The
24 values in the figure (and the remaining figures in this section) depend on the 100-year GWP used in
25 each study, which may differ from the recent GWP updates from WGI. However, it is unlikely that the
26 qualitative insights gained from the figures in this section would change using the update 100-year
27 GWP values.

28 Furthermore, note that the carbon footprint of biofuels used in Figure 10.4 are aggregate numbers not
29 specific to any individual value chain or fuel type. They are derived by combining land use-related
30 carbon emissions from Chapter 7 with conversion efficiencies and emissions as described in Section
31 10.3. Specifically, land use footprints derived from the three modelling approaches employed here are:
32 1) Integrated Assessment Models – Energy Modelling Forum 33 (IAM EMF33); 2) Partial models
33 assuming constant land cover (CLC), and, 3) Partial models using natural regrowth (NRG). The
34 emissions factors used here correspond to scenarios where global production of biomass for energy
35 purposes are 100 EJ/year, with lower emissions factors expected at lower levels of consumption and
36 vice-versa. Further details are available in Box 10.2 and Chapter 7.

37

38

1
2 **Figure 10.4** Life cycle GHG emissions intensities for mid-sized light-duty vehicle and fuel technologies
3 from the literature. The primary x-axis reports units in g CO₂-eq vkm⁻¹, assuming a vehicle life of 180,000
4 km. The secondary x-axis uses units of g CO₂-eq pkm⁻¹, assuming a 1.5 occupancy rate. The values in the
5 figure rely on the 100-year GWP value embedded in the source data, which may differ slightly with the
6 updated 100-year GWP values from WGI. The shaded area represents the interquartile range for
7 combined vehicle manufacturing and end-of-life phases. The length of the box and whiskers represent the
8 interquartile range of the operation phase for different fuel chains, while their placement on the x-axis
9 represents the absolute life cycle climate intensity, that is, includes manufacturing and end-of-life phases.
10 Each individual marker indicates a data point. ‘Adv. Biofuels’ i.e., advanced biofuels, refers to the use of

1 **second-generation biofuels and their respective conversion and cultivation emission factors. ‘IAM**
2 **EMF33’ refers to emissions factors for advanced biofuels derived from simulation results from the**
3 **integrated assessment models EMF33 scenarios. ‘PM’ refers to partial models, where ‘CLC’ is with**
4 **constant land cover and ‘NRG’ is with natural regrowth. ‘Hydrogen, low-carbon electricity’ is produced**
5 **via electrolysis using low-carbon electricity. ‘Hydrogen, natural gas SMR’ refers to fuels produced via**
6 **steam methane reforming of natural gas.**

7
8 The tailpipe emissions and fuel consumption reported in the literature generally do not use empirical
9 emissions data. Rather, they tend to report fuel efficiency using driving cycles such as New European
10 Driving Cycle (NEDC) or the US EPA Federal Test Procedure. As a result, depending on the driving
11 cycle used, operating emissions reported in literature are possibly underestimated by as much as 15-
12 38%, in comparison to actual real driving emissions (Fontaras et al. 2017; Tsiakmakis et al. 2017;
13 Triantafyllopoulos et al. 2019). The extent of these underestimations, however, vary between
14 powertrain types, engine sizes, driving behaviour and environment.

15 Current average life cycle impacts of mid-size ICEVs span from approximately 65 g CO₂-eq pkm⁻¹ to
16 210 g CO₂-eq pkm⁻¹, with both values stemming from ICEVs running on biofuels. Between this range
17 of values, the current reference technologies are found, with diesel-powered ICEVs having total median
18 life cycle impacts of 130 g CO₂-eq pkm⁻¹ and gasoline-fuelled vehicles with 160 g CO₂-eq pkm⁻¹. Fuel
19 consumption dominates the life cycle emissions of ICEVs, with approximately 75% of these emissions
20 arising from the tailpipe and fuel chain.

21 HEVs and plug-in HEVs (PHEVs) vary in terms of degree of powertrain electrification. HEVs mainly
22 rely on regenerative braking for charging the battery. PHEVs combine regenerative braking with
23 external power sources for charging the battery. Operating emissions intensity is highly dependent on
24 the degree to which electrified driving is performed, which in turn is user- and route-dependent. For
25 PHEVs, emissions intensity is also dependent on the source of the electricity for charging. HEV and
26 PHEV production impacts are comparable to the emissions generated for producing ICEVs as the
27 batteries are generally small compared to those of BEVs. Current HEVs may reduce emissions
28 compared to ICEVs by up to 30%, depending on the fuel, yielding median life cycle intensities varying
29 between 60 g CO₂-eq pkm⁻¹ (biofuels, EMF33) and 165-170 g CO₂-eq pkm⁻¹ (biofuels, partial models
30 NRG). Within this wide range, all the combinations of electric/fossil driving can be found, as well as
31 the life cycle intensity for driving 100% on fossil fuel. Because HEVs rely on combustion as the main
32 energy conversion process, they offer limited mitigation opportunities. However, HEVs represent a
33 suitable temporary solution, yielding a moderate mitigation potential, in areas where the electricity mix
34 is currently so carbon intensive that the use of PHEVs and BEVs is not an effective mitigation solution
35 (Wolfram and Wiedmann 2017; Wu et al. 2019).

36 In contrast to HEVs, PHEVs may provide greater opportunities for use-phase emissions reductions for
37 LDVs. These increased potential benefits are due to the ability to charge the battery with low-carbon
38 electricity and the longer full-electric range in comparison to HEVs (Laberteaux et al. 2019). Consumer
39 behaviour (e.g., utility factor (UF) and charging patterns), manufacturer settings, and access to
40 renewable electricity for charging strongly influence the total operational impacts (Wu et al, 2019). The
41 UF is a weighting of the percentage of distance covered using the electric charge (charge depleting (CD)
42 stage) versus the distance covered using the internal combustion engine (charge sustaining (CS) stage)
43 (Paffumi et al. 2018). When the PHEV operates in CS mode, the internal combustion engine is used for
44 propulsion and to maintain the state of charge of the battery within a certain range, together with
45 regenerative braking (Plötz et al. 2018; Raghavan and Tal 2020). When running in CS mode, PHEVs
46 have a reduced mitigation potential and have impacts comparable to those of HEVs. On the other hand,
47 when the PHEV operates in CD mode, the battery alone provides the required propulsion energy (Plötz
48 et al. 2018; Raghavan and Tal 2020). Thus, in CD mode, PHEVs hold potential for higher mitigation

1 potential, due to the possibility of charging the battery with low carbon electricity sources.
2 Consequently, the UF greatly influences the life cycle emissions of PHEVs. The current peer-reviewed
3 literature presents a wide range of UFs mainly due to varying testing protocols applied for estimating
4 the fuel efficiency and user behaviour (Pavlovic et al. 2017; Paffumi et al. 2018; Plötz et al. 2018, 2020;
5 Raghavan and Tal 2020; Hao et al. 2021). These factors make it difficult to harmonize and compare
6 impacts across PHEV studies. Due to the low number of appropriate PHEV studies relative to the other
7 LDV technologies and the complications in harmonizing available PHEV results, this technology is
8 omitted from Figure 10.4. However, due to the dual operating nature of PHEV vehicles, one can expect
9 that the life cycle GHG emissions intensities for these vehicles will lie between those of their ICEV and
10 BEV counterparts of similar size and performance.

11 Currently, BEVs have higher manufacturing emissions than equivalently sized ICEVs, with median
12 emissions of 14 t CO₂-eq/vehicle against approximately 10 t CO₂-eq/vehicle of their mid-sized fossil-
13 fuelled counterparts. These higher production emissions of BEVs are largely attributed to the battery
14 pack manufacturing and to the additional power electronics required. As manufacturing technology and
15 capacity utilization improve and globalizes to regions with low-carbon electricity, battery
16 manufacturing emissions will likely decrease. Due to the higher energy efficiency of the electric
17 powertrain, BEVs may compensate for these higher production emissions in the driving phase.
18 However, the mitigation ability of this technology relative to ICEVs is highly dependent on the
19 electricity mix used to charge the vehicle. As a consequence of the variety of energy sources available
20 today, current BEVs have a wide range of potential average life cycle impacts, ranging between 60 and
21 180 g CO₂-eq pkm⁻¹ with electricity generated from wind and coal, respectively. The ability to achieve
22 large carbon reductions via vehicle electrification is thus highly dependent on the generation of low-
23 carbon electricity, with the greatest mitigation effects achieved when charging the battery with low-
24 carbon electricity. The literature suggests that current BEVs, if manufactured on low carbon electricity
25 as well as operated on low carbon electricity would have footprints as low 22 g CO₂-eq pkm⁻¹ for a
26 compact sized car (Ellingsen et al. 2014, 2016). This value suggests a reduction potential of around
27 85% compared to similarly sized fossil fuel vehicles (median values). Furthermore, BEVs have a co-
28 benefit of reducing local air pollutants that are responsible for human health complications, particularly
29 in densely populated areas (Hawkins et al. 2013; Ke et al. 2017).

30 As with BEVs, current HFCVs have higher production emissions than similarly sized ICEVs and BEVs,
31 generating on average approximately 15 t CO₂-eq/vehicle. As with BEVs, the life cycle impacts of
32 FCVs are highly dependent on the fuel chain. To date, the most common method of Hydrogen
33 production is steam methane reforming from natural gas (Khojasteh Salkuyeh et al. 2017), which is
34 relatively carbon intensive, resulting in life cycle emissions of approximately 88 g CO₂-eq pkm⁻¹.
35 Current literature covering life cycle impacts of the FCVs show that vehicles fuelled with Hydrogen
36 produced from steam methane reforming through natural gas offer little or no mitigation potential over
37 ICEVs. Other available Hydrogen fuel chains vary widely in carbon intensity, depending on the
38 synthesis method and the energy source used (electrolysis or steam methane reforming; fossil fuels vs.
39 renewables). The least carbon-intensive Hydrogen pathways rely on electrolysis powered by low-
40 carbon electricity. Compared to ICEVs and BEVs, FCVs for LDVs are at a lower technology readiness
41 level as discussed in section 10.3.

42

43 **START BOX HERE**

44

45

Box 10.3 – Vehicle size trends and implications on the fuel efficiency of LDVs

46 *Vehicle size trends:* On a global scale, SUV sales have been constantly growing in the last decade, with
47 39% of the vehicles sold in 2018 being SUVs (IEA 2019d). If the trend towards increasing vehicle size
48 and engine power continues, it may result in higher overall emissions from the LDV fleet (relatively to

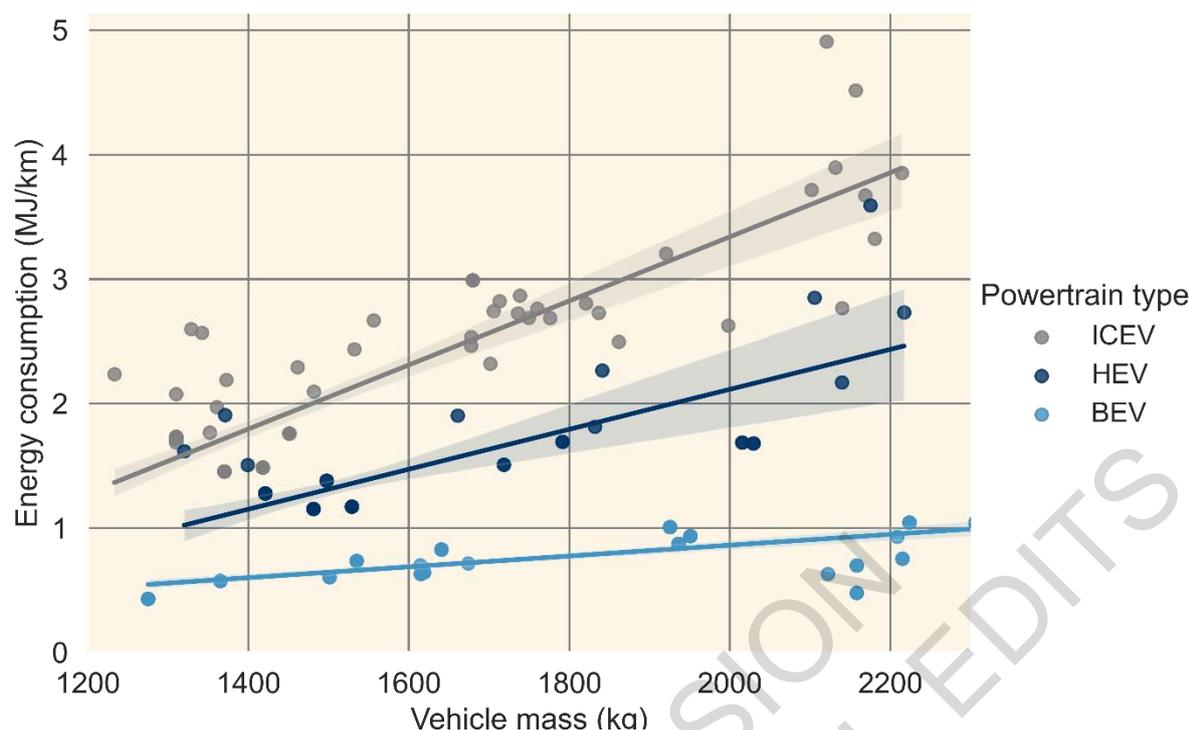

1 smaller vehicles with the same powertrain technology). The magnitude of the influence vehicle mass
2 has on fuel efficiency varies with the powertrain, which have different efficiencies. Box 10.3 Figure 1
3 highlights this relationship using data from the same literature used to create Figure 10.4. Higher
4 powertrain efficiency results in lower energy losses in operation, and thus requires less energy input to
5 move a given mass than a powertrain of lower efficiency. This pattern is illustrated by the more gradual
6 slope of BEVs in Box 10.3 Figure 1. The trend towards bigger and heavier vehicles with consequently
7 higher use phase emissions can be somewhat offset by improvements in powertrain design, fuel
8 efficiency, light weighting, and aerodynamics (Gargoloff et al. 2018; Wolfram et al. 2020). The
9 potential improvements provided by these strategies are case-specific and not thoroughly evaluated in
10 the literature, either individually or as a combination of multiple strategies.

11 *Light weighting:* There is an increasing use of advanced materials such as high-strength steel,
12 aluminium, carbon fibre, and polymer composites for vehicle light weighting (Hottle et al. 2017). These
13 materials reduce the mass of the vehicle and thereby also reduce the fuel or energy required to drive.
14 Light-weighted components often have higher production emissions than the components they replace
15 due to the advanced materials used (Kim and Wallington 2016). Despite these higher production
16 emissions, some studies suggest that the reduced fuel consumption over the lifetime of the light-
17 weighted vehicle may provide a net mitigation effect in comparison to the non-light-weighted vehicle
18 (Hottle et al. 2017; Kim and Wallington 2013; Upadhyayula et al. 2019; Milovanoff et al. 2019;
19 Wolfram et al. 2020). However, multiple recent publications have found that in some cases, depending
20 on, for example, vehicle size and carbon intensity of the light weighting materials employed, the GHG
21 emissions avoided due to improved fuel efficiency do not offset the higher manufacturing emissions of
22 the vehicle (Luk et al. 2018; Wu et al. 2019). In addition, these advanced materials may be challenging
23 to recycle in a way that retains their high technical performance (Meng et al. 2017).

24 *Co-effects on particulate matter:* Light weighting may also alleviate the particulate matter (PM)
25 emissions arising from road and brake wear. BEVs are generally heavier than their ICEV counterparts,
26 which may potentially cause higher stress on the road surfaces and tires, with consequently higher PM
27 emissions per kilometre driven (Timmers and Achten 2016). Regenerative braking in HEVs, BEVs and
28 FCVs, however, reduces the mechanical braking required, and therefore may compensate for the higher
29 brake wear emissions from these heavier vehicle types. In addition, BEVs have no tailpipe emissions,
30 which further offsets the increased PM emissions from road and tire wear. Therefore, light-weighting
31 strategies may offer a carbon and particulates mitigation effect; however, in some cases, other
32 technological options may reduce CO₂ emissions even further.

33

34

1
2 **Box 10.3, Figure 1 Illustration of energy consumption as a function of vehicle size (using mass as a proxy)**
3 **and powertrain technology. FCVs omitted due to lacking data.**

4
5 **END BOX HERE**

6 Two-wheelers, consisting mainly of lower-powered mopeds and higher-powered motorcycles, are
7 popular for personal transport in densely populated cities, especially in developing countries. LCA
8 studies for this class of vehicle are relatively uncommon compared to four-wheeled LDVs. In the
9 available results, however, two-wheelers exhibit similar trends for the different powertrain technologies
10 as the LDVs, with electric powertrains having higher production emissions, but usually lower operating
11 emissions. The life cycle emissions intensity for two-wheelers is also generally lower than four-wheeled
12 LDVs on a vehicle-kilometre basis. However, two-wheelers generally cannot carry as many passengers
13 as four-wheeled LDVs. Thus, on a passenger-kilometre basis, a fully occupied passenger vehicle may
14 still have lower emissions than a fully occupied two-wheeler. However, today, most passenger vehicles
15 have relatively low occupancy and thus have a correspondingly high emissions intensity on a pkm basis.
16 This points to the importance of utilization of passenger vehicles at higher occupancies to reduce the
17 life cycle intensity of LDVs on a pkm basis. For example, the median emissions intensity of a gasoline
18 passenger vehicle is 222 g CO₂-eq vkm⁻¹, and 160 g CO₂-eq vkm⁻¹ for a gasoline two-wheeler (Cox and
19 Mutel 2018). At a maximum occupancy factor of four and two passengers, respectively, the transport
20 emissions intensity for these vehicles are 55 and 80 g CO₂-eq pkm⁻¹. Under the same occupancy rates
21 assumption, BEV two-wheelers recharged on the average European electricity mix, achieve lower life
22 cycle GHG intensities than BEV four-wheeled LDVs. On the other hand, FCV two-wheelers with
23 Hydrogen produced via steam methane reforming present higher GHG intensity than their four-wheeled
24 counterparts, when compared on a pkm basis at high occupancy rates.

25 ICEV, HEV, and PHEV technologies, which are powered using combustion engines, have limited
26 potential for deep reduction of GHG emissions. Biofuels offer good mitigation potential if low land use
27 change emissions are incurred (e.g., the IAM EMF33 and partial models, CLC biofuels pathways shown
28 in Figure 10.4). The literature shows large variability, depending on the method of calculating

1 associated land use changes. Resolving these apparent methodological differences is important to
2 consolidating the role biofuels may play in mitigation, as well as the issues raised in Chapter 7 about
3 the conflicts over land use. The mitigation potential of battery and fuel cell vehicles is strongly
4 dependent on the carbon intensity of their production and the energy carriers used in operation.
5 However, these technologies likely offer the highest potential for reducing emissions from LDVs. Prior
6 work on the diffusion dynamics of transport technologies suggests that “the diffusion of infrastructure
7 precedes the adoption of vehicles, which precedes the expansion of travel” (Leibowicz 2018). These
8 dynamics reinforce the argument for strong investments in both the energy infrastructure and the vehicle
9 technologies.

10 To successfully transition towards LDVs utilizing low-carbon fuels or energy sources, the technologies
11 need to be accessible to as many people as possible, which requires competitive costs compared to
12 conventional diesel and gasoline vehicles. The life cycle costs (LCCs) of LDVs depend on the
13 purchasing costs of the vehicles, their efficiency, the fuel costs, and the discount rate. Figure 10.5 shows
14 the results of a parametric analysis of LCC for diesel LDVs, BEVs, and FCVs. The range of vehicle
15 efficiencies captured in Figure 10.5 are the same as the ranges used for Figure 10.4, while the ranges
16 for fuel costs and vehicle purchase prices come from the literature. The assumed discount rate for this
17 parametric analysis is 3%. Appendix 10.2 includes the details about the method and underlying data
18 used to create this figure.

19

20

ACCEPTED VERSION
SUBJECT TO FINAL EDITING

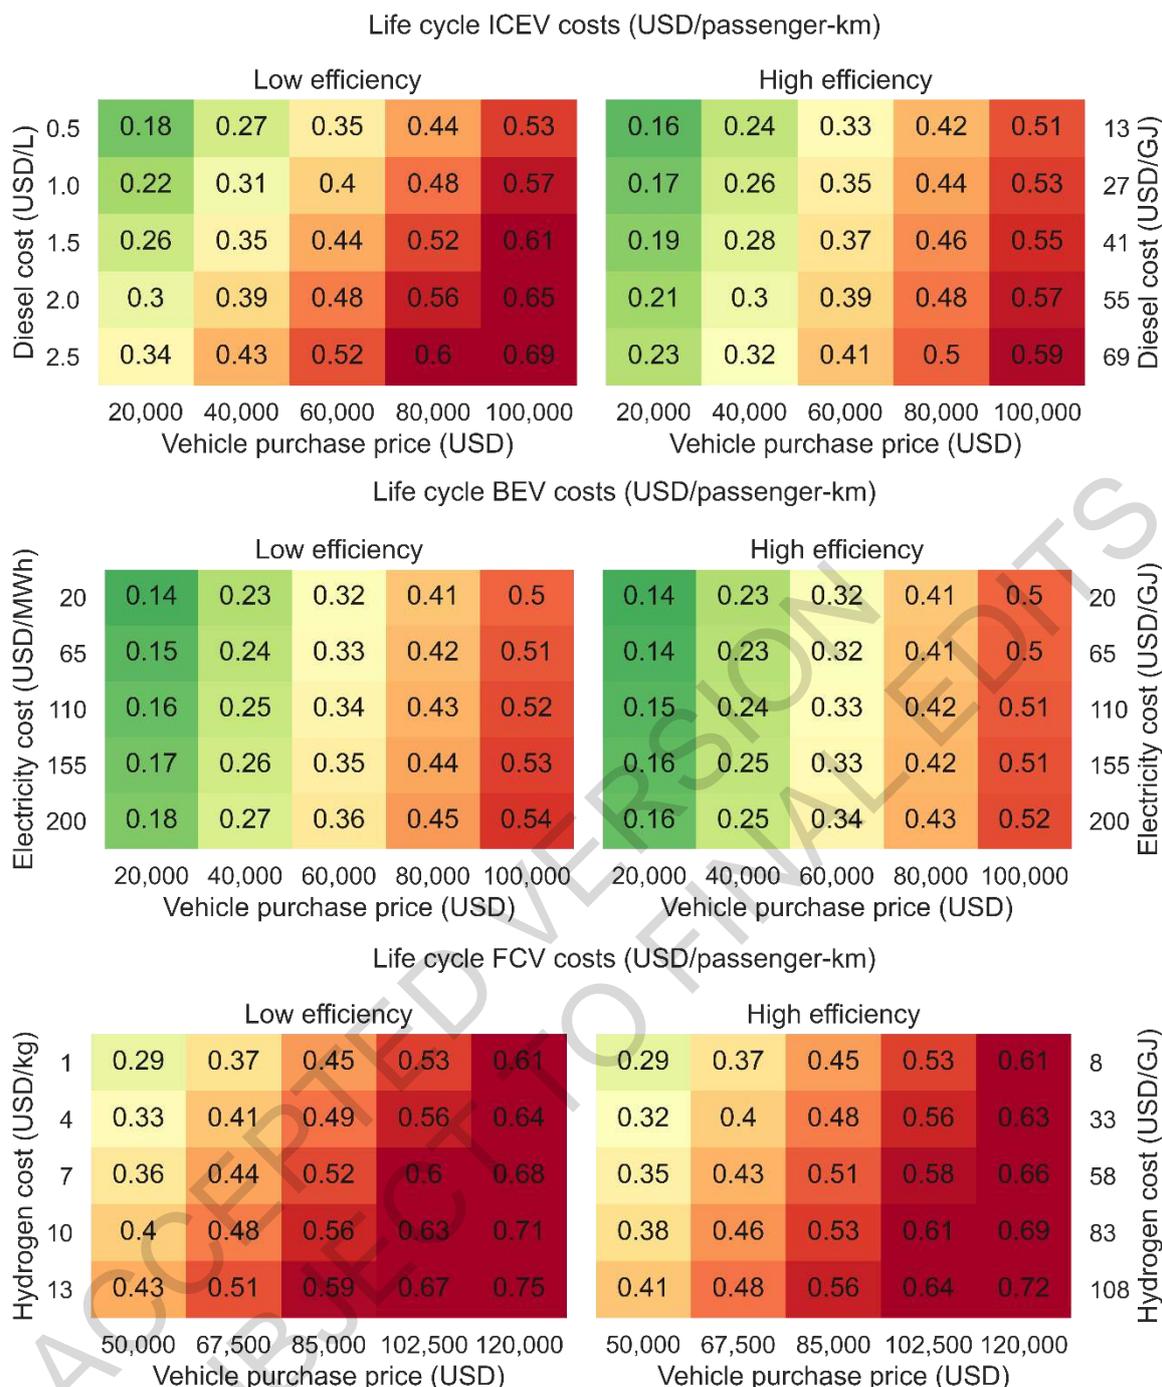

Figure 10.5 LCC for light-duty ICEVs, BEVs, and HFCVs. The results for ICEVs represent the LCC of a vehicle running on gasoline. However, these values are also representative for ICEVs running on diesel as the costs ranges in the literature for these two solutions are similar. The secondary y-axis depicts the cost of the different of the energy carriers normalized in USD/GJ for easier cross-comparability.

Figure 10.5 shows the range of LCC, in USD per pkm, for different powertrain technologies, and the influence of vehicle efficiency (low or high), vehicle purchase price, and fuel/electricity cost on the overall LCC. For consistency with Figure 10.4, an occupancy rate of 1.5 is assumed. Mid-sized ICEVs have a purchase price of USD 20,000-40,000, and average fuel costs are in the range of 1-1.5 USD/L. With these conditions, the LCC of fossil-fuelled LDVs span between 0.22-0.35 USD per pkm or between 0.17-0.28 USD per pkm, for low and high efficiency ICEVs respectively (Figure 10.5).

1 BEVs have higher purchase prices than ICEVs, though a sharp decline has been observed since AR5.
2 Due to the rapid development of the lithium-ion battery technology over the years (Schmidt et al. 2017)
3 and the introduction of subsidies in several countries, BEVs are quickly reaching cost parity with
4 ICEVs. Mid-sized BEVs average purchase prices are in the range of USD 30,000-50,000 but the
5 levelised cost of electricity shows a larger spread (65-200 USD/MWh) depending on the geographical
6 location and the technology (see Chapter 6). Therefore, assuming purchase price parity between ICEVs
7 and BEVs, BEVs show lower LCC (Figure 10.5) due to higher efficiency and the lower cost of
8 electricity compared to fossil fuels on a per-GJ basis (secondary y-axis on Figure 10.5).

9 FCVs represent the most expensive solution for LDV, mainly due to the currently higher purchase price
10 of the vehicle itself. However, given the lower technology readiness level of FCVs and the current
11 efforts in the research and development of this technology, FCVs could become a viable technology for
12 LDVs in the coming years. The issues regarding the extra energy involved in creating the Hydrogen
13 and its delivery to refuelling sites remain, however. The levelized cost of Hydrogen on a per GJ basis
14 is lower than conventional fossil fuels but higher than electricity. In addition, within the levelized cost
15 of Hydrogen, there are significant cost differences between the Hydrogen producing technologies.
16 Conventional technologies such as coal gasification and steam methane reforming from natural gas,
17 both with and without carbon capture and storage, represent the cheapest options (Bekel and Pauliuk
18 2019; Parkinson et al. 2019; Khzouz et al. 2020; Al-Qahtani et al. 2021). Hydrogen produced via
19 electrolysis is currently the most expensive technology, but with significant potential cost reductions
20 due to the current technology readiness level.

21 22 **10.4.2 Transit technologies for passenger transport**

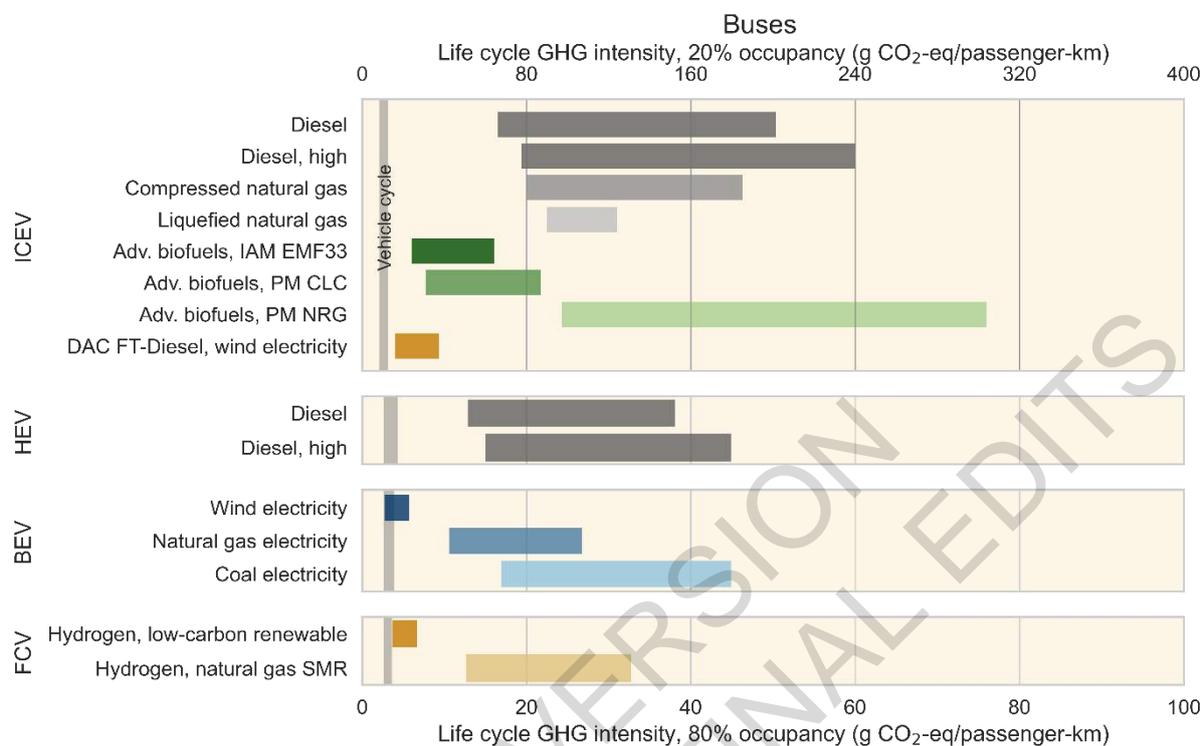

23 Buses provide urban and peri-urban transport services to millions of people around the world and a
24 growing number of transport agencies are exploring alternative-fuelled buses. Alternative technologies
25 to conventional diesel-powered buses include buses powered with CNG, LNG, synthetic fuels, and
26 biofuels (e.g., biodiesel, renewable diesel, dimethyl ether); diesel hybrid-electric buses; battery electric
27 buses; electric catenary buses, and Hydrogen fuel cell buses. Rail is an alternative mode of transit that
28 could support decarbonisation of land-based passenger mobility. Electric rail systems can provide urban
29 services (light rail and metro systems), as well as longer distance transport. Indeed, many cities of the
30 world already have extensive metro systems, and regions like China, Japan and Europe have a robust
31 high-speed inter-city railway network. Intercity rail transport can be powered with electricity; however,
32 fossil fuels are still prevalent for long-distance rail passenger transport in some regions. Battery electric
33 long-distance trains may be a future option for these areas.

34 Figure 10.6 shows the life cycle GHG emissions from different powertrain and fuel technologies for
35 buses and passenger rail. The data in each panel came from a number of relevant scientific studies (IEA
36 2019e; Tong et al. 2015a; Dimoula et al. 2016; de Bortoli et al. 2017; Meynerts et al. 2018; Cai et al.
37 2015; de Bortoli and Christoforou 2020; Hill et al. 2020; Liu et al. 2020a; Valente et al. 2021, 2017).
38 The width of the bar represents the variability in available estimates, which is primarily driven by
39 variability in reported vehicle efficiency, size, or drive cycle. While some bars overlap, the figure may
40 not fully capture correlations between results. For example, low efficiency associated with aggressive
41 drive cycles may drive the upper end of the emission ranges for multiple technologies; thus, an overlap
42 does not necessarily suggest uncertainty regarding which vehicle type would have lower emissions for
43 a comparable trip. Additionally, reported life cycle emissions do not include embodied GHG emissions
44 associated with infrastructure construction and maintenance. These embodied emissions are potentially
45 a larger fraction of life cycle emissions for rail than for other transport modes (Chester and Horvath
46 2012; Chester et al. 2013). One study reported values ranging from 10-25 g CO₂ per passenger-
47 kilometre (International Union of Railways 2016), although embodied emissions from rail are known
48 to vary widely across case studies (Olugbenga et al. 2019). These caveats are also applicable to the

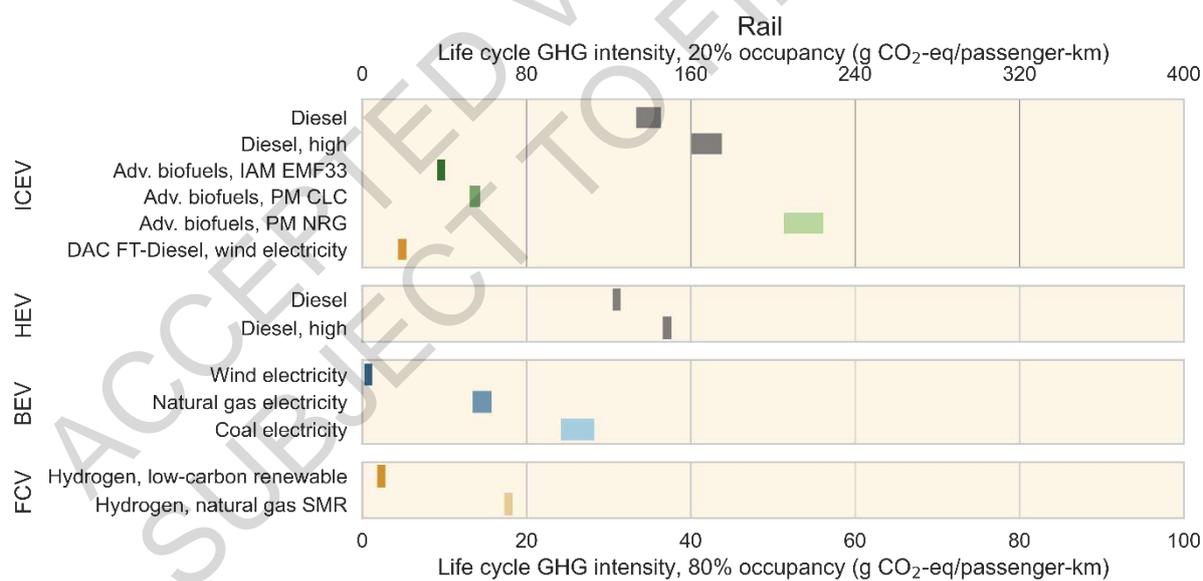

1 other figures in this section.

2

3

4

5

6

7 **Figure 10.6 Life cycle GHG intensity of land-based bus and rail technologies.** Each bar represents the
 8 range of the life cycle estimates, bounded by minimum and maximum energy use per pkm, as reported
 9 for each fuel/powertrain combination. The ranges are driven by differences in vehicle characteristics and
 10 operating efficiency. For energy sources with highly variable upstream emissions low, medium and/or
 11 high representative values are shown as separate rows. The primary x-axis shows life cycle GHG
 12 emissions, in g CO₂-eq per pkm, assuming 80% occupancy; the secondary x-axis assumes 20%
 13 occupancy. The values in the figure rely on the 100-year GWP value embedded in the source data, which
 14 may differ slightly with the updated 100-year GWP values from WGI. For buses, the main bars show full

1 life cycle, with vertical bars disaggregating the vehicle cycle. ‘Diesel, high’ references emissions factors for
2 diesel from oil sands. ‘Adv. Biofuels’ i.e., advanced biofuels, refers to the use of second-generation
3 biofuels and their respective conversion and cultivation emission factors. ‘IAM EMF33’ refers to
4 emissions factors for advanced biofuels derived from simulation results from the integrated assessment
5 models EMF33 scenarios. ‘PM’ refers to partial models, where ‘CLC’ is with constant land cover and
6 ‘NRG’ is with natural regrowth. ‘DAC FT-Diesel, wind electricity’ refers to Fischer-Tropsch diesel
7 produced via a CO₂ direct air capture process that uses wind electricity. ‘Hydrogen, low-carbon
8 renewable’ refers to fuels produced via electrolysis using low-carbon electricity. ‘Hydrogen, natural gas
9 SMR’ refers to fuels produced via steam methane reforming of natural gas. Results for ICEVs with ‘high
10 emissions DAC FT-Diesel from natural gas’ are not included here since the life cycle emissions are
11 estimated to be substantially higher than petroleum diesel ICEVs.

12
13 Figure 10.6 highlights that BEV and FCV buses and passenger rail powered with low carbon electricity
14 or low carbon Hydrogen, could offer reductions in GHG emissions compared to diesel-powered buses
15 or diesel-powered passenger rail. However, and not surprisingly, these technologies would offer only
16 little emissions reductions if power generation and Hydrogen production rely on fossil fuels. While
17 buses powered with CNG and LNG could offer some reductions compared to diesel-powered buses,
18 these reductions are unlikely to be sufficient to contribute to deep decarbonisation of the transport sector
19 and they may slow down conversion to low or zero-carbon options already commercially available.
20 Biodiesel and renewable diesel fuels (from sources with low upstream emissions and low risk of induced
21 land use change) could offer important near-term reductions for buses and passenger rail, as these fuels
22 can often be used with existing vehicle infrastructure. They could also be used for long haul trucks and
23 trains, shipping and aviation as discussed below and in later sections.

24 There has been growing interest in the production of synthetic fuels from CO₂ produced by direct air
25 capture (DAC) processes. Figure 10.6 includes the life cycle GHG emissions from buses and passenger
26 rail powered with synthetic diesel produced through a DAC system paired with a Fischer-Tropsch (FT)
27 process based on (Liu et al. 2020a). This process requires the use of Hydrogen (as shown in Figure 10.2
28 in section 10.3), so the emissions factors of the resulting fuel depend on the emissions intensity of
29 Hydrogen production. An electricity emissions factor less than 140 g CO₂-eq kWh⁻¹ would be required
30 for this pathway to achieve lower emissions than petroleum diesel (Liu et al. 2020a); e.g., this would
31 be equivalent to 75% wind and 25% natural gas electricity mix (see Appendix 10.1). If the process
32 relied on steam methane reforming for Hydrogen production or fossil-based power generation, synthetic
33 diesel from the DAC-FT process would not provide GHG emissions reductions compared to
34 conventional diesel. DAC-FT from low-carbon energy sources appears to be promising from an
35 emissions standpoint and could warrant the R&D and demonstration attention outlined in the rest of the
36 chapter, but it cannot be contemplated as a decarbonisation strategy without the availability of low-
37 carbon Hydrogen.

38 At high occupancy, both bus and rail transport offer substantial GHG reduction potential per pkm, even
39 compared with the lowest-emitting private vehicle options. Even at 20% occupancy, bus and rail may
40 still offer emission reductions compared to passenger cars, especially notable when comparing BEVs
41 with low-carbon electricity (the lowest emission option for all technologies) across the three modes.
42 Only when comparing a fossil fuel-powered bus at low occupancy with a low-carbon powered car at
43 high occupancy is this conclusion reversed. Use of public transit systems, especially those that rely on
44 buses and passenger rail fuelled with the low carbon fuels previously described would thus support
45 efforts to decarbonise the transport sector. Use of these public transit systems will depend on urban
46 design and consumer preferences (as described in Section 10.2 and Chapters 5 and 8), which in turn
47 depend on time, costs, and behavioural choices.

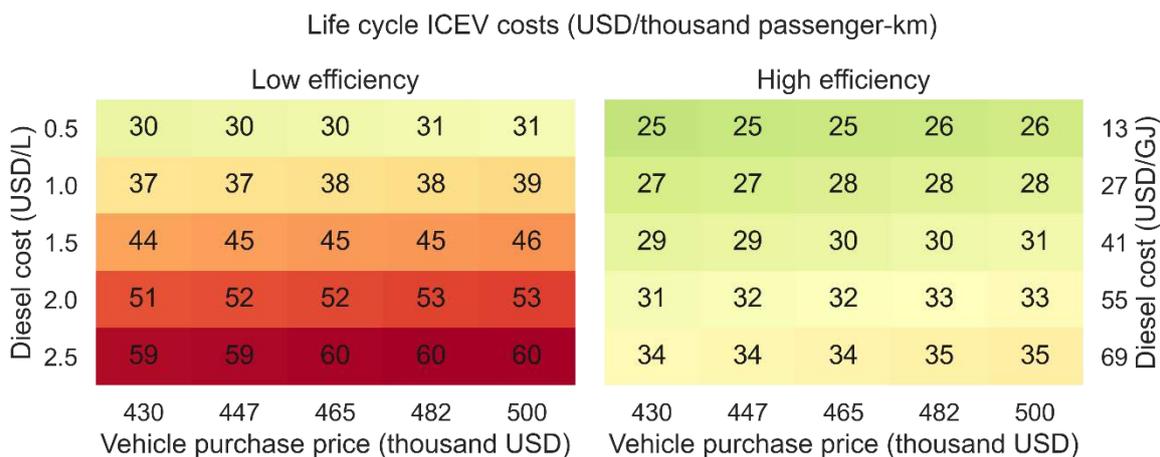

48 Figure 10.7 shows the results of a parametric analysis of the LCCs of transit technologies with the
49 highest potential for GHG emissions reductions. As with Figure 10.5, the vehicle efficiency ranges are

1 the same as those from the LCA estimates (80% occupancy). Vehicle, fuel, and maintenance costs
2 represent ranges in the literature (Eudy and Post 2018b; IEA 2019e; Argonne National Laboratory 2020;
3 BNEF 2020; Eudy and Post 2020; Hydrogen Council 2020; IEA 2020b,c; IRENA 2020; Johnson et al.
4 2020; Burnham et al. 2021; IEA 2021c,d; U.S. Energy Information Administration 2021), and the
5 discount rate is 3% where applicable. Appendix 10.2 of the chapter provides the details behind these
6 estimates. The panels for the ICEV can represent buses and passenger trains powered with any form of
7 diesel, whether derived from petroleum, synthetic hydrocarbons, or biofuels. For reference, global
8 average automotive diesel prices from 2015-2020 fluctuated around 1 USD/L, and the 2019 world
9 average industrial electricity price was approximately 100 USD/MWh (IEA 2021d). Retail Hydrogen
10 prices in excess of 13 USD/kg have been observed (Eudy and Post 2018a; Argonne National Laboratory
11 2020; Burnham et al. 2021) though current production cost estimates for Hydrogen produced from
12 electrolysis are far lower ((IRENA 2020), and as reported in Chapter 6), at around 5-7 USD/kg with
13 future forecasts as low as 1 USD/kg ((IRENA 2020; BNEF 2020; Hydrogen Council 2020), and as
14 reported in Chapter 6).

15 Under most parameter combinations, rail is the most cost-effective option, followed by buses, both of
16 which are an order of magnitude cheaper than passenger vehicles. Note that costs per pkm are strongly
17 influenced by occupancy assumptions; at low occupancy (e.g., <20% for buses and <10% for rail), the
18 cost of transit approaches the LCC for passenger cars. For diesel rail and buses, cost ranges are driven
19 by fuel costs, whereas vehicle are both important drivers for electric or Hydrogen modes due to high
20 costs (but also large projected improvements) associated with batteries and fuel cell stacks. Whereas
21 the current state of ICEV technologies is best represented by cheap vehicles and low fuel costs for diesel
22 (top left of each panel), these costs are likely to rise in future due to stronger emission/efficiency
23 regulations and rising crude oil prices. On the contrary, the current status of alternative fuels is better
24 represented by high capital costs and mid-to-high fuel costs (right side of each panel; mid-to-bottom
25 rows), but technology costs are anticipated to fall with increasing experience, research, and
26 development. Thus, while electric rail is already competitive with diesel rail, and electric buses are
27 competitive with diesel buses in the low efficiency case, improvements are still required in battery costs
28 to compete against modern diesel buses on high efficiency routes, at current diesel costs. Similarly,
29 improvements to both vehicle cost and fuel costs are required for Hydrogen vehicles to become cost
30 effective compared to their diesel or electric counterparts. At either the upper end of the diesel cost
31 range (bottom row of ICEV panels), or within the 2030-2050 projections for battery costs, fuel cell
32 costs and Hydrogen costs (top left of BEV and FCV panels) – both battery and Hydrogen powered
33 vehicles become financially attractive.

Figure 10.7 Life cycle costs for internal combustion engine vehicles ICEV, BEV, and HFCV for buses and passenger rail. The range of efficiencies for each vehicle type are consistent with the range of efficiencies in Figure 10.6 (80% occupancy). The results for the ICEV can be used to evaluate the life cycle costs of ICE buses and passenger rail operated with any form of diesel, whether from petroleum, synthetic hydrocarbons, or biofuel, as the range of efficiencies of vehicles operating with all these fuels is similar. The secondary y-axis depicts the cost of the different energy carriers normalized in USD/GJ for easier cross-comparability.

12

1 **10.4.3 Land-based freight transport**

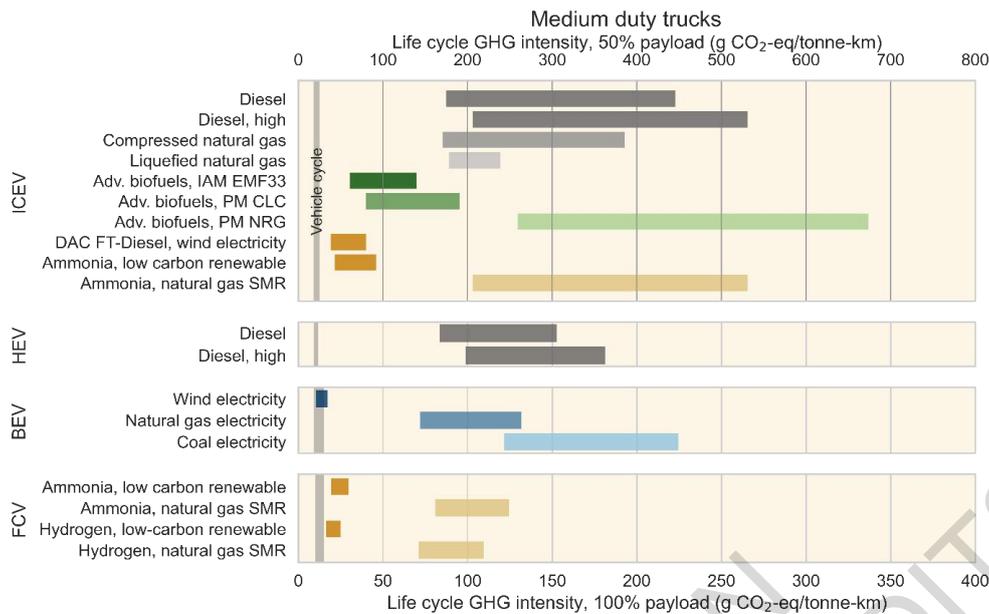

2 As is the case with passenger transport, there is growing interest in alternative fuels that could reduce
3 GHG emissions from freight transport. Natural gas-based fuels (e.g., CNG, LNG) are an example,
4 however these may not lead to drastic reductions in GHG emissions compared to diesel. Natural gas-
5 powered vehicles have been discussed as a means to mitigate air quality impacts (Khan et al. 2015; Pan
6 et al. 2020; Cai et al. 2017) but those impacts are not the focus of this review. Decarbonisation of
7 medium and heavy-duty trucks would likely require the use of low-carbon electricity in battery-electric
8 trucks, low-carbon Hydrogen or Ammonia in fuel-cell trucks, or bio-based fuels (from sources with low
9 upstream emissions and low risk of induced land use change) used in ICE trucks.

10 Freight rail is also a major mode for the inland movement of goods. Trains are more energy efficient
11 (per tkmm) than trucks, so expanded use of rail systems (particularly in developing countries where
12 demand for goods could grow exponentially) could provide carbon abatement opportunities. While
13 diesel-based locomotives are still a major propulsion used in freight rail, interest in low-carbon
14 propulsion technologies is growing. Electricity already powers freight rail in many European countries
15 using overhead catenaries. Other low-carbon technologies for rail may include advanced storage
16 technologies, biofuels, synthetic fuels, Ammonia, or Hydrogen.

4 **Figure 10.8 Life cycle GHG intensity of land-based freight technologies and fuel types. Each bar**
 5 **represents the range of the life cycle estimates, bounded by minimum and maximum energy use per tkm,**
 6 **as reported for each fuel/powertrain combination. The ranges are driven by differences in vehicle**
 7 **characteristics and operating efficiency. For energy sources with highly variable upstream emissions, low,**
 8 **medium and/or high representative values are shown as separate rows. For trucks, the primary x-axis**

1 shows life cycle GHG emissions, in g CO₂-eq per tkm, assuming 100% payload; the secondary x-axis
2 assumes 50% payload. The values in the figure rely on the 100-year GWP value embedded in the source
3 data, which may differ slightly with the updated 100-year GWP values from WGI. For rail, values
4 represent average payloads. For trucks, main bars show full life cycle, with vertical bars disaggregating
5 the vehicle cycle. ‘Diesel, high’ references emissions factors for diesel from oil sands. ‘Adv. Biofuels’
6 refers to the use of second-generation biofuels and their respective conversion and cultivation emission
7 factors. ‘IAM EMF33’ refers to emissions factors for advanced biofuels derived from simulation results
8 from the EMF33 scenarios. ‘PM’ refers to partial models, where ‘CLC’ is with constant land cover and
9 ‘NRG’ is with natural regrowth. DAC FT-Diesel, wind electricity refers to Fischer-Tropsch diesel
10 produced via a CO₂ direct air capture process that uses wind electricity. ‘Ammonia and Hydrogen, low-
11 carbon renewable’ refers to fuels produced via electrolysis using low-carbon electricity. ‘Ammonia and
12 Hydrogen, natural gas SMR’ refers to fuels produced via steam methane reforming of natural gas.

13
14 Figure 10.8 presents a review of life cycle GHG emissions from land-based freight technologies (heavy
15 and medium-duty trucks, and rail). Each panel within the figure represents data in GHG emissions per
16 tkm of freight transported by different technology and/or fuel types, as indicated by the labels to the
17 left. The data in each panel came from a number of relevant scientific studies (Merchan et al. 2020;
18 Frattini et al. 2016; Zhao et al. 2016; CE Delft 2017; Isaac and Fulton 2017; Song et al. 2017; Cooper
19 and Balcombe 2019; S. Mojtaba et al. 2019; Nahlik et al. 2016; Prussi et al. 2020; Hill et al. 2020; Liu
20 et al. 2020a; Valente et al. 2021; Gray et al. 2021; Valente et al. 2017; Tong et al. 2015a). Similar to
21 the results for buses, technologies that offer substantial emission reductions for freight include: ICEV
22 trucks powered with the low carbon variants for biofuels, Ammonia or synthetic diesel; BEVs charged
23 with low carbon electricity; and FCVs powered with renewable-based electrolytic Hydrogen, or
24 Ammonia. Since Ammonia and Fischer-Tropsch diesel are produced from Hydrogen, their emissions
25 are higher than the source Hydrogen, but their logistical advantages over Hydrogen are also a
26 consideration (as discussed in Section 10.3).

27 Trucks exhibit economies of scale in fuel consumption, with heavy duty trucks generally showing lower
28 emissions per tkm than medium duty trucks. Comparing the life cycle GHG emissions from trucks and
29 rail, it is clear that rail using internal combustion engines is more carbon efficient than using internal
30 combustion trucks. Note that the rail emissions are reported for an average representative payload, while
31 the trucks are presented at 50% and 100% payload, based on available data. The comparison between
32 trucks and rail powered with electricity or Hydrogen is less clear – especially considering that these
33 values omit embodied GHG from infrastructure construction. One study reported embodied rail
34 infrastructure emissions of 15 g CO₂ per tonne-kilometre for rail (International Union of Railways
35 2016), although such embodied emissions from rail are known to vary widely across case studies
36 (Olugbenga et al. 2019). Regardless, trucks and rail with low carbon electricity or low-carbon Hydrogen
37 have substantially lower emissions than incumbent technologies.

38 For trucks, Figure 10.8 includes two x-axes representing two different assumptions about their payload,
39 which substantially influence emissions per tonne-kilometre. These results highlight the importance of
40 truckload planning as an emissions reduction mechanism, for example, as also shown in (Kaack et al.
41 2018). Several studies also point to improvements in vehicle efficiency as an important mechanism to
42 reduce emissions from freight transport (Taptich et al. 2016; Kaack et al. 2018). However, projections
43 for diesel vehicles using such efficiencies beyond 2030 are promising, but still far higher emitting than
44 vehicles powered with low carbon sources.

45 Figure 10.9 shows the results of a parametric analysis of the LCC of trucks and freight rail technologies
46 with the highest potential for deep GHG reductions. As with Figure 10.8, the vehicle efficiency ranges
47 are the same as those from the LCA estimates (80% payload for trucks; effective payload as reported
48 by original studies for rail). Vehicle, fuel and maintenance costs represent ranges in the literature
49 (Moultak et al. 2017; Eudy and Post 2018b; IEA 2019e; Argonne National Laboratory 2020; BNEF

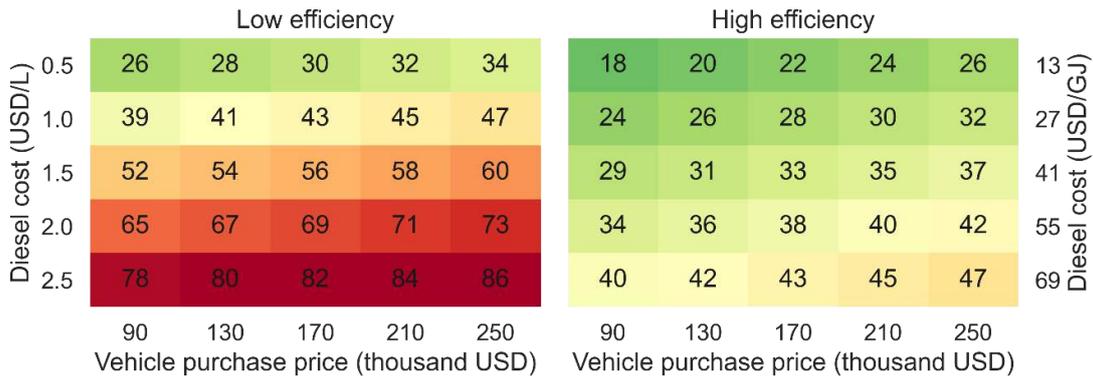

1 2020; IRENA 2020; Burnham et al. 2021; IEA 2021c), and the discount rate is 3% where applicable
2 (details are in Appendix 10.2). The panels for the ICEV can represent trucks and freight trains powered
3 with any form of diesel, whether derived from petroleum, synthetic hydrocarbons, or biofuels. See
4 discussion preceding Figure 10.7 for additional details about current global fuel costs. Under most
5 parameter combinations, rail is the more cost-effective option, but the high efficiency case for trucks
6 (representing fuel efficient vehicles, favourable drive cycles and high payload) can be more cost-
7 effective than the low efficiency case for rail (representing systems with higher fuel consumption and
8 lower payload). For BEV trucks, cost ranges are driven by vehicle purchase price due to the large
9 batteries required and the associated wide range between their current high costs and anticipated future
10 cost reductions. For all other truck and rail technologies, fuel cost ranges play a larger role. Similar to
11 transit technologies, the current state of freight ICEV technologies is best represented by cheap vehicles
12 and low fuel costs for diesel (top left of each panel), and the current status of alternative fuels is better
13 represented by high capital costs and mid-to-high fuel costs (right side of each panel; mid-to-bottom
14 rows), with expected future increases in ICEV LCC and decreases in alternative fuel vehicle LCC.
15 Electric and Hydrogen freight rail are potentially already competitive with diesel rail (especially electric
16 catenary (IEA 2019e)), but low data availability (especially for Hydrogen efficiency ranges) and wide
17 ranges for reported diesel rail efficiency (likely encompassing low capacity utilization) makes this
18 comparison challenging. Alternative fuel trucks are currently more expensive than diesel trucks, but
19 future increases in diesel costs or a respective decrease in Hydrogen costs or in BEV capital costs
20 (especially the battery) would enable either alternative fuel technology to become financially attractive.
21 These results are largely consistent with raw results reported in existing literature, which suggest
22 ambiguity over whether BEV trucks are already competitive, but more consistency that Hydrogen is
23 not yet competitive, but could be in future (Zhao et al. 2016; White and Sintov 2017; Moulak et al.
24 2017; Sen et al. 2017; Zhou et al. 2017; Mareev et al. 2018; Yang et al. 2018a; El Hannach et al. 2019;
25 S. Mojtaba et al. 2019; Tanco et al. 2019; Burke and Sinha 2020; Jones et al. 2020). There is limited
26 data available on the LCC for freight rail, but at least one study IEA (2019g) suggests that electric
27 catenary rail is likely to have similar costs as diesel rail, while battery electric trains remain more
28 expensive and Hydrogen rail could become cheaper under forward-looking cost reduction scenarios.

1 10.5 Decarbonisation of aviation

2 This section addresses the potential for reducing GHG emissions from aviation. The overriding
3 constraint on developments in technology and energy efficiency for this sector is safety. Governance is
4 complex in that international aviation comes under the International Civil Aviation Organization
5 (ICAO), a specialised UN agency. The measures to reduce GHG emissions that are considered include
6 both in-sector (technology, operations, fuels) and out of sector (market-based measures, high-speed rail
7 modal shift/substitution). Demand management is not explicitly considered in this section, as it was
8 discussed in 10.2. A limited range of scenarios to 2050 and beyond are available and assessed at the
9 end of the section.

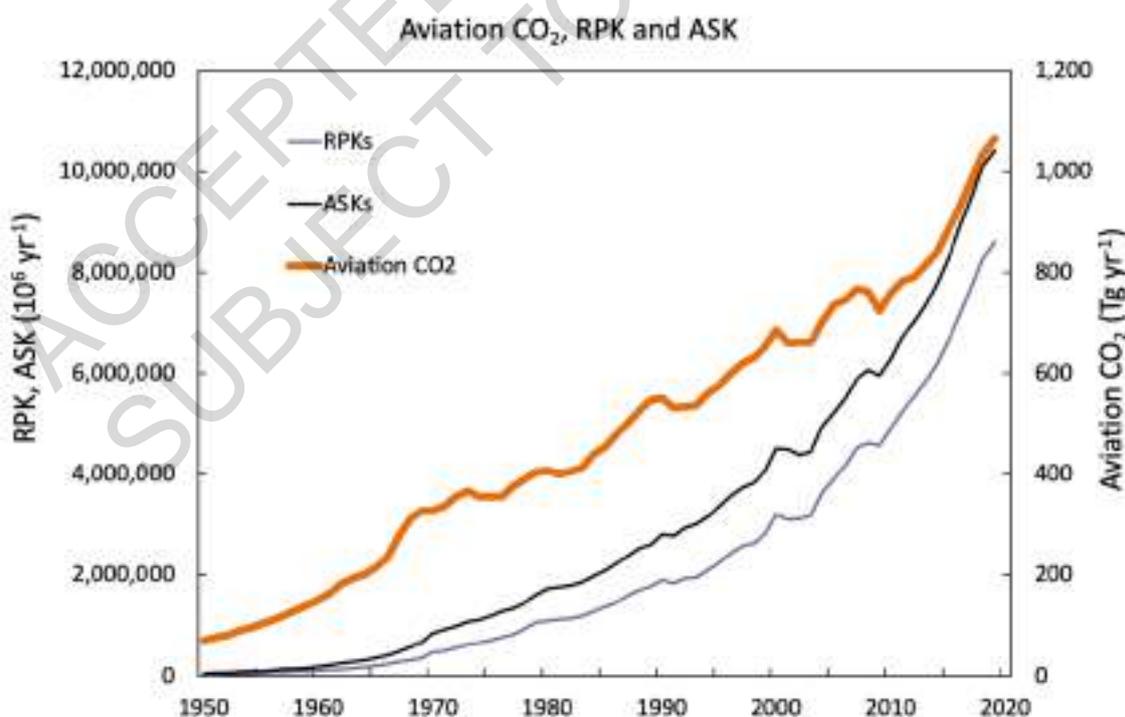

10

11 10.5.1 Historical and current emissions from aviation

12 Aviation is widely recognised as a ‘hard-to-decarbonise’ sector (Gota et al. 2019) having a strong
13 dependency on liquid fossil fuels and an infrastructure that has long ‘lock-in’ timescales, resulting in
14 slow fleet turnover times. The principal GHG emitted is CO₂ from the combustion of fossil fuel aviation
15 kerosene (‘JET-A’), although its non-CO₂ emissions can also affect climate (see section 10.5.2).
16 International emissions of CO₂ are about 65% of the total emissions from aviation (Fleming and de
17 Lépinay 2019), which totalled approximately 1 Gt of CO₂ in 2018. Emissions from this segment of the
18 transport sector have been steadily increasing at rates of around 2.5% per year over the last two decades
19 (see Figure 10.10), although for the period 2010 to 2018 the rate increased to roughly 4% per year. The
20 latest available data (2018) indicate that aviation is responsible for approximately 2.4% of total
21 anthropogenic emissions of CO₂ (including land use change) on an annual basis (using IEA data, IATA
22 data and global emissions data of Le Quéré et al., 2018).

23

24

(2021) using IEA and other data

28

1
2

10.5.2 Short lived climate forcers and aviation

3 Aviation's net warming effect results from its historical and current emissions of CO₂, and non-CO₂
4 emissions of water vapour, soot, sulphur dioxide (from sulphur in the fuel), and nitrogen oxides (NO_x,
5 = NO + NO₂) (Penner et al. 1999; Lee et al. 2021; Naik et al. 2021). Although the effective radiative
6 forcing (ERF) of CO₂ from historic aviation emissions is not currently the largest forcing term, it is
7 difficult to address because of the sector's current dependency on fossil-based hydrocarbon fuels and
8 the longevity of CO₂. A residual of emissions of CO₂ today will still have a warming effect in many
9 thousands of years (Archer et al. 2009; Canadell et al. 2021) whereas water vapour, soot, and NO_x
10 emissions will have long ceased to contribute to warming after some decades. As a result, CO₂
11 mitigation of aviation to 'net zero' levels, as required in 1.5 °C emission scenarios, requires fundamental
12 shifts in technology, fuel types, or changes of behaviour or demand.

13 The non-CO₂ effects of aviation on climate fall into the category of short-lived climate forcers (SLCFs).
14 Emissions of NO_x currently result in net positive warming from the formation of short-term ozone
15 (warming) and the destruction of ambient methane (cooling). If the conditions are suitable, emissions
16 of soot and water vapour can trigger the formation of contrails (Kärcher 2018), which can spread to
17 form extensive contrail-cirrus cloud coverage. Such cloud coverage is estimated to have a combined
18 ERF that is ~57% of the current net ERF of global aviation (Lee et al. 2021), although a comparison of
19 cirrus cloud observations under pre- and post-COVID-19 pandemic conditions suggest that this forcing
20 could be smaller (Digby et al. 2021). Additional effects from aviation from aerosol-cloud interactions
21 on high-level ice clouds through soot (Chen and Gettelman 2013; Zhou and Penner 2014; Penner et al.
22 2018), and lower-level warm clouds through Sulphur (Righi et al. 2013; Kapadia et al. 2016) are highly
23 uncertain, with no best estimates available (Lee et al. 2021). In total, the net ERF from aviation's non-
24 CO₂ SLCFs is estimated to be approximately 66% of aviation's current total forcing. It is important to
25 note that the fraction of non-CO₂ forcing to total forcing is not a fixed quantity and is dependent on the
26 recent history of growth (or otherwise) of CO₂ emissions (Klöwer et al. 2021) The non-CO₂ effects
27 from aviation are the subject of discussion for mitigation options (e.g., (Arrowsmith et al. 2020)).
28 However, the issues are complex, potentially involving technological and operational trade-offs with
29 CO₂.

30

31 10.5.3 Mitigation potential of fuels, operations, energy efficiency, and market-based 32 measures

33 *Technology options for engine and airframe:* For every kg of jet fuel combusted, 3.16 kg CO₂ is emitted.
34 Engine and airframe manufacturers' primary objective, after safety issues, is to reduce direct operating
35 costs, which are highly dependent on fuel burn. Large investments have gone into engine technology
36 and aircraft aerodynamics to improve fuel burn per km (Cumpsty et al. 2019). There have been major
37 step changes in engine technology over time, from early turbojet engines, to larger turbofan engines.
38 However, the basic configuration of an aircraft has remained more or less the same for decades and will
39 likely remain at least to 2037 (Cumpsty et al. 2019). Airframes performance has improved over the
40 years with better wing design, but large incremental gains have become much harder as the technology
41 has matured. For twin-aisle aircraft, generally used for long ranges, fuel-burn is a pressing concern and
42 there have been several all-new aircraft designs with improvements in their lift-to-drag ratio (Cumpsty
43 et al. 2019). The principal opportunities for fuel reduction come from improvements in aerodynamic
44 efficiency, aircraft mass reduction, and propulsion system improvements. In the future, Cumpsty et al.
45 (2019) suggest that the highest rate of fuel burn reduction achievable for new aircraft is likely to be no
46 more than about 1.3% per year, which is well short of ICAO's aspirational goal of 2% global annual
47 average fuel efficiency improvement. Radically different aircraft shapes, like the blended wing body

1 (where the wings are not distinct from the fuselage) are likely to use about 10% less fuel than future
2 advanced aircraft of conventional form (Cumpsty et al. 2019). Such improvements would be “one-off”
3 gains, do not compensate for growth in emissions of CO₂ expected to be in excess of 2% per annum,
4 and would take a decade or more to penetrate the fleet completely. Thus, the literature does not support
5 the idea that there are large improvements to be made in the energy efficiency of aviation that keep pace
6 with the projected growth in air transport.

7 *Operational improvements for navigation:* From a global perspective, aircraft navigation is relatively
8 efficient, with many long-haul routes travelling close to great circle trajectories, and avoiding
9 headwinds that increase fuel consumption. The ICAO estimates that flight inefficiencies on a global
10 basis are currently of the order 2–6% (ICAO 2019), while (Fleming and de Lépinay 2019) project
11 operational improvements (air traffic management) of up to 13% on a regional basis by 2050.
12 ‘Intermediate stop operations’ have been suggested, whereby longer-distance travel is broken into flight
13 legs, obviating the need to carry fuel for the whole mission. (Linke et al. 2017) modelled this operational
14 behaviour on a global basis and calculated a fuel savings of 4.8% over a base case in which normal fuel
15 loads were carried. However, this approach increases the number of landing/take-off cycles at airports.
16 ‘Formation flying’, which has the potential to reduce fuel burn on feasible routes has also been proposed
17 (Xu et al. 2014; Marks et al. 2021).

18 *Alternative biofuels, synthetic fuels, and liquid Hydrogen:* As noted above, the scope for reducing CO₂
19 emissions from aviation through improved airplane technology or operations is limited and unable to
20 keep up with the projected growth, let alone reduce beyond the present emission rate at projected levels
21 of demand (assuming post-pandemic recovery of traffic). Thus, the literature outlined here suggests that
22 the only way for demand for aviation to continue to grow without increasing CO₂ emissions is to employ
23 alternative lower-carbon bio- or synthetic aviation fuels (Klöwer et al. 2021). For shorter ranges, flights
24 of light planes carrying up to 50 passengers may be able to use electric power (Sahoo et al. 2020) but
25 these planes are a small proportion of the global aviation fleet (Epstein and O’Flarity 2019; Langford
26 and Hall 2020) and account for less than 12% of current aviation CO₂ emissions. Alternative lower-
27 carbon footprint fuels have been certified for use over recent years, principally from bio-feedstocks, but
28 are not yet widely available at economic prices (Kandaramath Hari et al. 2015; Capaz et al. 2021a). In
29 addition, alternative fuels from bio-feedstocks have variable carbon footprints because of different life
30 cycle emissions associated with various production methods and associated land-use change (de Jong
31 et al. 2017; Staples et al. 2018; Capaz et al. 2021b; Zhao et al. 2021).

32 The development of ‘sustainable aviation fuels’ (referred to as ‘SAFs’) that can reduce aviation’s carbon
33 footprint is a growing area of interest and research. Alternative aviation fuels to replace fossil-based
34 kerosene have to be certified to an equivalent standard as Jet-A for a variety of parameters associated
35 with safety issues. Currently, the organisation responsible for aviation fuel standards, ASTM
36 International, has certified seven different types of sustainable aviation fuels with maximum blends
37 ranging from 10% to 50% (Chiaromonti 2019). Effectively, these blend requirements limit the amount
38 of non-hydrocarbon fuel (e.g., Methanol) that can be added at present. While there currently is a
39 minimum level of aromatic hydrocarbon contained in jet fuel to prevent ‘O-ring’ shrinkage in the fuel
40 seals (Khandelwal et al. 2018), this minimum level can likely be lower in the medium- to long- term,
41 with the added benefits of reduced soot formation and reduced contrail cirrus formation (Bier et al.
42 2017; Bier and Burkhardt 2019).

43 Bio-based fuels can be produced using a variety of feedstocks including cultivated feedstock crops, crop
44 residues, municipal solid waste, waste fats, oils and greases, wood products and forestry residues
45 (Staples et al. 2018). Each of these different sources can have different associated life cycle emissions,
46 such that they are not net zero-CO₂ emissions but have associated emissions of CO₂ or other GHGs
47 from their production and distribution (see Section 10.3 and Box 10.2). In addition, associated land use
48 change emissions of CO₂ represent a constraint in climate change mitigation potential with biofuel

1 (Staples et al. 2017) and has inherent large uncertainties (Plevin et al. 2010). Other sustainability issues
2 include food vs. fuel arguments, water resource use, and impacts on biodiversity. Cost-effective
3 production, feedstock availability, and certification costs are also relevant (Kandaramath Hari et al.
4 2015). Nonetheless, bio-based SAFs have been estimated to achieve life cycle emissions reductions
5 ranging between approximately 2% and 70% under a wide range of scenarios (Staples et al. 2018). For
6 a set of European aviation demand scenarios, Kousoulidou and Lonza (2016) estimated that the fuel
7 demand in 2030 would be ~100 Mtoe and biokerosene (HEFA/HVO) penetration would provide around
8 2% of the total fuel demand at that date. Several issues limit the expansion of biokerosene for aviation,
9 the primary one being the current cost of fossil fuel compared to the costs SAF production (Capaz et al.
10 2021a). Other hybrid pathways e.g., the Hydrogenation of biofuels (the Hydrogen assumed to be
11 generated with low carbon energy), could increase the output and improve the economic feasibility of
12 bio-based SAF (Hannula 2016; Albrecht et al. 2017).

13 Costs remain a major barrier for bio-SAF, which cost around three times the price of kerosene by
14 (Kandaramath Hari et al. 2015). Clearly, for SAFs to be economically competitive, large adjustments
15 in prices of fossil fuels or the introduction of policies is required. Staples et al. (2018) estimated that in
16 order to introduce bio-SAFs that reduce life cycle GHG emissions by at least 50% by 2050, prices and
17 policies were necessary for incentivization. They estimate the need for 268 new biorefineries per year
18 and capital investments of approximately USD 22 to 88 billion (2015 prices) per year between 2020
19 and 2050. Wise et al. (2017) suggest that carbon prices would help leverage production and availability.

20 Various pathways have been discussed for the production of non-bio SAFs such as power-to-liquid
21 pathways (Schmidt et al. 2018), sometimes termed ‘electro-fuels’ (Goldmann et al. 2018), or more
22 generalised power to ‘x’ pathways (Kober and Bauer 2019). This process would involve the use of low
23 carbon energy electricity, CO₂, and water to synthesise jet fuel through the Fischer-Tropsch process or
24 Methanol synthesis. Hydrogen would be produced via an electrochemical process, powered by low
25 carbon energy and combined with CO₂ captured directly from the atmosphere or through BECCS. The
26 energy requirement from photovoltaics has been estimated to be of the order 14 – 20 EJ to phase out
27 aviation fossil fuel by 2050 (Gössling et al. 2021a). These synthetic fuels have potential for large life
28 cycle emission reductions (Schmidt et al. 2016). In comparison to bio-SAF production, the
29 implementation of the processes is in its infancy. However, assuming availability of low carbon energy
30 electricity, these fuels have much smaller land and water requirements than bio-SAF. Low carbon
31 energy supply, scalable technology, and therefore costs represent barriers. (Scheelhaase et al. 2019)
32 review current estimates of costs, which are estimated to be approximately 4 to 6 times the price of
33 fossil kerosene.

34 Liquid Hydrogen (LH₂) as a fuel has been discussed for aeronautical applications since the 1950s
35 (Brewer 1991) and a few experimental aircraft have flown using such a fuel. Experimental, small
36 aircraft have also flown using Hydrogen fuel cells. Although the fuel has an energy density per unit
37 mass about 3 times greater than kerosene, it has a much lower energy density per unit volume
38 (approximately factor 4, (McKinsey 2020)). The increased volume requirement makes the fuel less
39 attractive for aviation since it would require the wings to be thickened or else fuel to take up space in
40 the fuselage. Bicer and Dincer (2017) found that LH₂-powered aircraft compared favourably to
41 conventional kerosene-powered aircraft on a life cycle basis, providing that the LH₂ was generated from
42 low carbon energy sources (0.014 kg CO₂ per tonne km *cf* 1.03 kg CO₂ per tonne km, unspecified
43 passenger aircraft). However, Ramos Pereira et al. (2014) also made a life cycle comparison and found
44 much smaller benefits of LH₂-powered aircraft (manufactured from low carbon energy) compared with
45 conventional fossil-kerosene. The two studies expose the sensitivities of boundaries and assumptions
46 in the analyses. (Shreyas Harsha 2014; Rondinelli et al. 2017) conclude that there are many
47 infrastructural barriers but that the environmental benefits of low carbon-based LH₂ could be
48 considerable. Khandelwal et al. (2013) take a more optimistic view of the prospect of LH₂-powered

1 aircraft but envisage them within a Hydrogen-oriented energy economy. A recently commissioned
2 study by the European Union (EU)'s 'Clean Sky' (McKinsey 2020) addresses many of the aspects of
3 the opportunities and obstacles in developing LH₂ powered aircrafts. The report provides an optimistic
4 view of the feasibility of developing such aircraft for short to medium haul but makes clear that new
5 aircraft designs (such as blended-wing body aircraft) would be needed for longer distances.

6 The non-CO₂ impacts of LH₂-powered aircrafts remain poorly understood. The emission index of water
7 vapour would be much larger (estimated to be 2.6 times greater by Ström and Gierens (2002)) than for
8 conventional fuels, and the occurrence of contrails may increase but have lower ERF because of the
9 lower optical depth (Marquart et al. 2005). Moreover, contrails primarily form on soot particles from
10 kerosene-powered aircraft, which would be absent from LH₂ exhaust (Kärcher 2018). The overall effect
11 is currently unknown as there are no measurements. Potentially, NO_x emissions could be lower with
12 combustor redesign (Khandelwal et al. 2013).

13 In conclusion, there are favourable arguments for LH₂-powered aircraft both on an efficiency basis
14 (Verstraete 2013) and an overall reduction in GHG emissions, even on an life cycle basis. However,
15 LH₂ requires redesign of the aircraft, particularly for long-haul operations. Similarly, there would be a
16 need for expanded infrastructure for fuel manufacture, storage, and distribution at airports, which is
17 likely to be more easily overcome if there is a more general move towards a Hydrogen-based energy
18 economy.

19 *Technological and operational trade-offs between CO₂ and non-CO₂ effects:* Since aviation has
20 additional non-CO₂ warming effects, there has been some discussion as to whether these can be
21 addressed by either technological or operational means. For example, improved fuel efficiency has
22 resulted from high overall pressure ratio engines with large bypass ratios. This improvement has
23 increased pressure and temperature at the combustor inlet, with a resultant tendency to increase thermal
24 NO_x formation in the combustor. Combustor technology aims to reduce this increase, but it represents
25 a potential technology trade-off whereby NO_x control may be at the expense of extra fuel efficiency.
26 Estimating the benefits or disbenefits of CO₂ (proportional to fuel burned) vs. NO_x in terms of climate
27 is complex (Freeman et al. 2018).

28 Any GWP/GTP type emissions equivalency calculation always involves the user selection of a time
29 horizon over which the calculation is made, which is a *subjective* choice (Fuglestvedt et al. 2010). In
30 general, the longer the time horizon, the more important CO₂ becomes in comparison with a short-lived
31 climate forcing agent. So, for example, a net (overall) aviation GWP for a 20-year time horizon is 4.0
32 times that of CO₂ alone, but only 1.7 over a 100-year time horizon. Correspondingly, a GTP for a 20-
33 year time horizon is 1.3, but it is 1.1 for 100 years (Lee et al. 2021).

34 A widely discussed opportunity mitigation of non-CO₂ emissions from aviation is the avoidance of
35 persistent contrails that can form contrail cirrus. Contrails only form in ice-supersaturated air below a
36 critical temperature threshold (Kärcher 2018). It is therefore feasible to alter flight trajectories to avoid
37 such areas conducive to contrail formation, since ice-supersaturated areas tend to be 10s to 100s of km
38 in the horizontal and only a few 100 metres in the vertical extent (Gierens et al. 1997). Theoretical
39 approaches show that avoidance is possible on a flight-by-flight basis (Matthes et al. 2017; Teoh et al.
40 2020). Case studies have shown that flight planning according to trajectories with minimal climate
41 impact can substantially (up to 50%) reduce the aircraft net climate impacts despite small additional
42 CO₂ emissions (e.g., (Niklaß et al. 2019)). However, any estimate of the net benefit or disbenefit
43 depends firstly on the assumed magnitude of the contrail cirrus ERF effect (itself rather uncertain,
44 assessed with a low confidence level;) and upon the choice of metric and time-horizon applied. While
45 this is a potentially feasible mitigation option, notwithstanding the CO₂ percontrail trade-off question,
46 meteorological models cannot currently predict the formation of persistent contrails with sufficient
47 accuracy in time and space (Gierens et al. 2020) such that this mitigation option is speculated to take of
48 the order of up to a decade to mature (Arrowsmith et al. 2020)

1 *Market-based offsetting measures:* The EU introduced aviation into its CO₂ emissions trading scheme
2 (ETS) in 2012. Currently, the EU-ETS for aviation includes all flights within the EU as well as to and
3 from EEA states. Globally, ICAO agreed in 2016 to commence, in 2020, the ‘Carbon Offsetting and
4 Reduction Scheme for International Aviation’ (CORSIA). The pandemic subsequently resulted in the
5 baseline being changed to 2019.

6 CORSIA has a phased implementation, with an initial pilot phase (2021–2023) and a first phase (2024–
7 2026) in which states will participate voluntarily. The second phase will then start in 2026–2035, and
8 all states will participate unless exempted. States may be exempted if they have lower aviation activity
9 levels or based on their UN development status. As of September 2021, 109 ICAO Member States will
10 voluntarily be participating in CORSIA starting in 2022. In terms of routes, only those where both States
11 are participating are included. There will be a special review of CORSIA by the end of 2032 to
12 determine the termination of the scheme, its extension, or any other changes to the scheme beyond
13 2035.

14 By its nature, CORSIA does not lead to a reduction in in-sector emissions from aviation since the
15 program deals mostly in approved offsets. At its best, CORSIA is a transition arrangement to allow
16 aviation to reduce its impact in a more meaningful way later. From 2021 onwards, operators can reduce
17 their CORSIA offsetting requirements by claiming emissions reductions from ‘CORSIA Eligible Fuels’
18 that have demonstrably reduced life cycle emissions. These fuels are currently available at greater costs
19 than the offsets (Capaz et al. 2021a). As a result, most currently approved CORSIA offsets are avoided
20 emissions, which raises the issue of additionality (Warnecke et al. 2019) The nature of ‘avoided
21 emissions’ is to prevent an emission that was otherwise considered to be going to occur, e.g. prevented
22 deforestation. Avoided emissions are ‘reductions’ (over a counterfactual) and purchased from other
23 sectors that withhold from an intended emission (Becken and Mackey 2017), such that if additionality
24 were established, a maximum of 50% of the intended emissions are avoided. Some researchers suggest
25 that avoided deforestation offsets are not a meaningful reduction, since deforestation continues to be a
26 net source of CO₂ emissions (Mackey et al. 2013; Friedlingstein et al. 2020).

27 *Modal shift to High-Speed Rail:* Due to the limitations of the current suite of aviation mitigation
28 strategies, the potential for high-speed rail (HSR) is of increasing interest (Givoni and Banister 2006;
29 Chen 2017; Bi et al. 2019). The IEA’s Net Zero by 2050 roadmap suggests significant behavioural
30 change with more regional flights shifting to HSR in the NZE pathway (IEA 2021e). For HSR services
31 to be highly competitive with air travel, the optimal distance between the departure and arrival points
32 has been found to be in the approximate range of 400-800 km (Bows et al. 2008; Rothengatter 2010),
33 although in the case of China’s HSR operations, this range can be extended out to 1,000 km with
34 corresponding air services having experienced significant demand reduction upon HSR service
35 commencement (Lawrence et al. 2019). In some instances, negative effects on air traffic, air fare, and
36 flight frequency have occurred at medium-haul distances such as HSR services in China on the Wuhan-
37 Guangzhou route (1,069 km) and the Beijing-Shanghai route (1,318 km) (Fu et al. 2015; Zhang and
38 Zhang 2016; Chen 2017; Li et al. 2019; Ma et al. 2019). This competition at medium-haul distances is
39 contrary to that which has been experienced in European and other markets and may be attributable to
40 China having developed a comprehensive network with hub stations, higher average speeds, and an
41 integrated domestic market with strong patronage (Zhang et al. 2019a).

42 The LCA literature suggests that the GHG emissions associated with HSR vary depending on spatial,
43 temporal, and operational specifics (Åkerman 2011; Baron et al. 2011; Chester and Horvath 2012; Yue
44 et al. 2015; Hoyos et al. 2016; Jones et al. 2017; Robertson 2016, 2018; Lin et al. 2019). These studies
45 found a wide range of approximately 10 - 110 grams CO₂ per pkm for HSR. This range is principally
46 attributable to the sensitivity of operational parameters such as the HSR passenger seating capacity,
47 load factor, composition of renewable and non-renewable energy sources in electricity production,
48 rolling stock energy efficiency and patronage (i.e. ridership both actual and forecast), and line-haul

1 infrastructure specifics (e.g. tunnelling and aerial structure requirements for a particular corridor)
2 (Åkerman 2011; Chester and Horvath 2012; Yue et al. 2015; Newman et al. 2018; Robertson 2018) The
3 prospect for HSR services providing freight carriage (especially on-line purchases) is also growing
4 rapidly (Strale 2016; Bi et al. 2019; Liang and Tan 2019) with a demonstrated emission reduction
5 potential from such operations (Hoffrichter et al. 2012). However, additional supportive policies will
6 most likely be required (Strale 2016; Watson et al. 2019). Limiting emissions avoidance assessments
7 for HSR modal substitution to account only for CO₂ emissions ignores aviation's non-CO₂ effects (see
8 Section 10.5.2), and likely results in an under-representation of the climate benefits of HSR replacing
9 flights.

10 HSR modal substitution can generate a contra-effect if the air traffic departure and arrival slots that
11 become available as the result of the modal shift are simply reallocated to additional air services (Givoni
12 and Banister 2006; Givoni and Dobruszkes 2013; Jiang and Zhang 2016; Cornet et al. 2018; Zhang et
13 al. 2019a). Furthermore, HSR services have the potential to increase air traffic at a hub airport through
14 improved networks but this effect can vary based on the distance of the HSR stations to airports (Jiang
15 and Zhang 2014; Xia and Zhang 2016; Zhang et al. 2019b; Liu et al. 2019). Such rebound effects could
16 be managed through policy interventions. For example, in 2021 the French government regulated that
17 all airlines operating in France suspend domestic airline flights on routes if a direct rail alternative with
18 a travel time of less than 2.5 hours is available. Other air travel demand reduction measures that have
19 been proposed include regulations to ban frequent flyer reward schemes, mandates that all marketing
20 of air travel declare flight emissions information to the prospective consumer (i.e., the carbon footprint
21 of the nominated flight), the introduction of a progressive 'Air Miles Levy' as well as the inclusion of
22 all taxes and duties that are presently exempt from air ticketing (Carmichael 2019). Moreover, China
23 has the highest use of HSR in the world in part due to its network and competitive speeds and in part
24 due to heavy regulation of the airline industry, in particular restrictions imposed on low-cost air carrier
25 entry and subsidisation of HSR (Li et al. 2019). These air travel demand reduction strategies in addition
26 to stimulating HSR ridership may induce shifts to other alternative modes.

27 Despite the risk of a rebound effect, and due to the probable reality of an incremental adoption of
28 sustainable aviation fuel technology in the coming decades, the commencement of appropriate HSR
29 services has the potential to provide, particularly in the short to medium-term, additional means of
30 aviation emissions mitigation.

31 **10.5.4 Assessment of aviation-specific projections and scenarios**

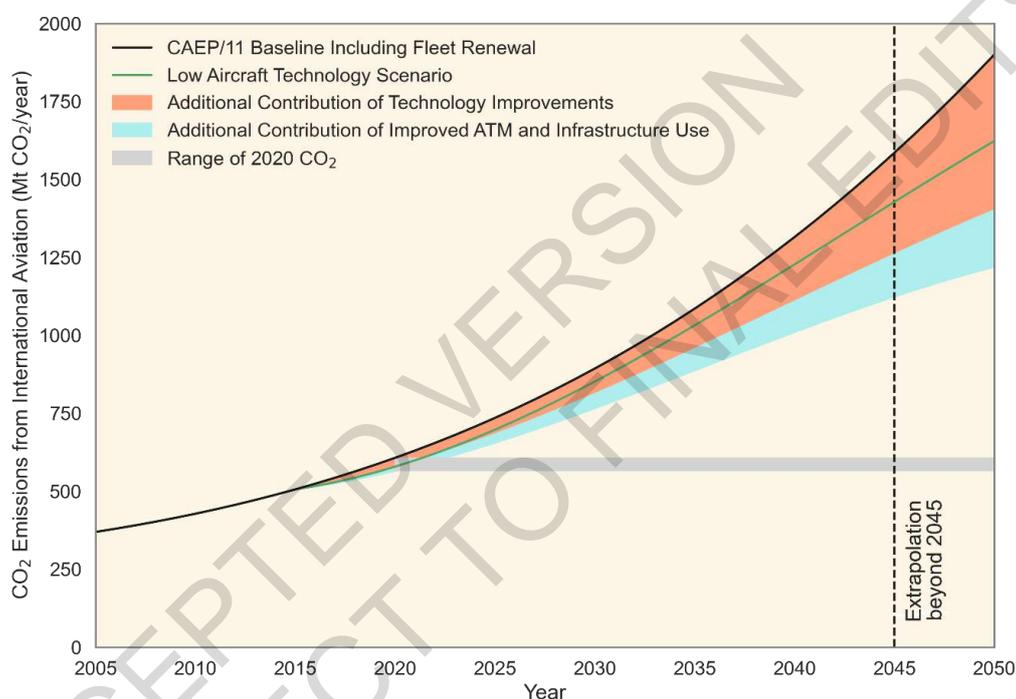

32 The most recent projection from ICAO (prior to the COVID-19 pandemic) for international traffic (mid-
33 range growth) is shown in Figure 10.11 (Fleming and de Lépinay 2019). This projection shows the
34 different contributions of mitigation measures from two levels of improved technology, as well as
35 improvements in air traffic management (ATM) and infrastructure use. The projections indicate an
36 increase of CO₂ emissions by a factor of 2.2 in 2050 over 2020 levels for the most optimistic set of
37 mitigation assumptions. The high/low traffic growth assumptions would indicate increases by factors
38 of 2.8 and 1.1, respectively in 2050, over 2020 levels (again, for the most optimistic mitigation
39 assumptions).

40 The International Energy Agency has published several long-term aviation scenarios since the AR5
41 within a broader scope of energy projections. Their first set of aviation scenarios include a 'reference
42 technology scenario' (RTS), a '2° Scenario' (2DS) and a 'Beyond 2° Scenario' (B2DS). The scenarios
43 are simplified in assuming a range of growth rates and technological/operational improvements (IEA
44 2017b) Mitigation measures brought about by policy and regulation are treated in a broad-brush manner,
45 noting possible uses of taxes, carbon pricing, price and regulatory signals to promote innovation.

46 The IEA has more recently presented aviation scenarios to 2070 in their 'Sustainable Development
47 Scenario' that assume some limited reduced post-COVID-19 pandemic demand, and potential

1 technology improvements in addition to direct reductions in fossil kerosene usage from substitution of
 2 biofuels and synthetic fuels (IEA 2021b). There is much uncertainty in how aviation will recover from
 3 the COVID-19 pandemic but, in this scenario, air travel returns to 2019 levels in three years, and then
 4 continues to expand, driven by income. Government policies could dampen demand (12% lower by
 5 2040 than the IEA ‘Stated Policies Scenario,’ which envisages growth at 3.4% per year, which in turn
 6 is lower than ICAO at 4.3%). Mitigation takes place largely by fuel substitution – lower-carbon biofuels
 7 and synthetic fuels, with a smaller contribution from technology. Approximately 85% of the actual
 8 cumulative CO₂ emissions (to 2070) are attributed to use of fuel at their lowest Technology Readiness
 9 Level of ‘Prototype,’ which is largely made up of biofuels and synthetic fuels, as shown in Figure 10.12.
 10 Details of the technological scenarios and the fuel availability/uptake assumptions are given in (IEA
 11 2021b), which also makes clear that the relevant policies are not currently in place to make any such
 12 scenario happen.

3 **States Policies Scenario (‘STEPS’) and composition of the Sustainable Development Scenario**
4 (from (IEA 2021b))

5
6 Within the Coupled Model Intercomparison Project Phase 6 (CMIP6) emissions database, a range of
7 aviation emission scenarios for a range of SSP scenarios are available (see Figure 10.13). This figure
8 suggests that by 2050, direct emissions from aviation could be 1.5 to 6.5 (5-95th percentile) times higher
9 than in the 2020 model year under the scenarios without firm commitments to meet a long-term
10 temperature target (i.e., C7-8 scenarios with temperature change above 2.5°C by 2100). In the C1-2
11 scenario group, which limit temperature change below 1.5°C, aviation emissions could still be up to 2.5
12 times higher in 2050 than emissions in the 2020 model year (95th percentile) but may need to decrease
13 by 10% by 2050 (5th percentile).

15
16 **Figure 10.13 CO₂ emission from AR6 aviation scenarios indexed to 2020 modelled year. Data from the**
17 **AR6 scenario database.**

18
19 The COVID-19 pandemic of 2020 has changed many activities and consequentially, associated
20 emissions quite dramatically (Le Quéré et al. 2018; Friedlingstein et al. 2020; Liu et al. 2020c; UNEP
21 2020). Aviation was particularly affected, with a reduction in commercial flights in April 2020 of ~74%

1 over 2019 levels, with some recovery over the following months, remaining at 42% lower as of October
2 2020 (Petchenik 2021). The industry is considering a range of potential recovery scenarios, with the
3 International Air Transport Association (IATA) speculating that recovery to 2019 levels may take up
4 until 2024 (see Box on COVID-19 and (Early and Newman 2021). Others suggest, however, that the
5 COVID-19 pandemic and increased costs as a result of feed-in quotas or carbon taxes, could slow down
6 the rate of growth of air travel demand, though global demand in 2050 would still grow 57%–187%
7 between 2018 and 2050 (instead of 250% in a baseline recovery scenario) (Gössling et al. 2021a).

9 **10.5.5 Accountability and governance options**

10 Under Article 2.2 of the Kyoto Protocol, Annex I countries were called to “...pursue limitation or
11 reduction of emissions of GHGs not controlled by the Montreal Protocol from aviation and marine
12 bunker fuels, working through the International Civil Aviation Organization and the International
13 Maritime Organization, respectively.” The Paris Agreement is different, in that ICAO (and the IMO)
14 are not named. As a result, the Paris Agreement, through the NDCs, seemingly covers CO₂ emissions
15 from domestic aviation (currently 35% of the global total) but does not cover international emissions.
16 A number of states and regions, including the UK, France, Sweden, and Norway, have declared their
17 intentions to include international aviation in their net zero commitments, while the EU, New Zealand,
18 California, and Denmark are considering doing the same (Committee on Climate Change 2019). The
19 Paris Agreement describes temperature-based goals, such that it is unclear how emissions of GHGs
20 from international aviation would be accounted for. Clearly, this is a less than ideal situation for clarity
21 of governance of international GHG emissions from both aviation and shipping. At its 40th General
22 Assembly (October 2019) the ICAO requested its Council to “...continue to explore the feasibility of a
23 long-term global aspirational goal for international aviation, through conducting detailed studies
24 assessing the attainability and impacts of any goals proposed, including the impact on growth as well
25 as costs in all countries, especially developing countries, for the progress of the work to be presented
26 to the 41st Session of the ICAO Assembly”. What form this goal will take is unclear until work is
27 presented to the 41st Assembly (Autumn, 2022). It is likely, however, that new accountability and
28 governance structures will be needed to support decarbonisation of the aviation sector.

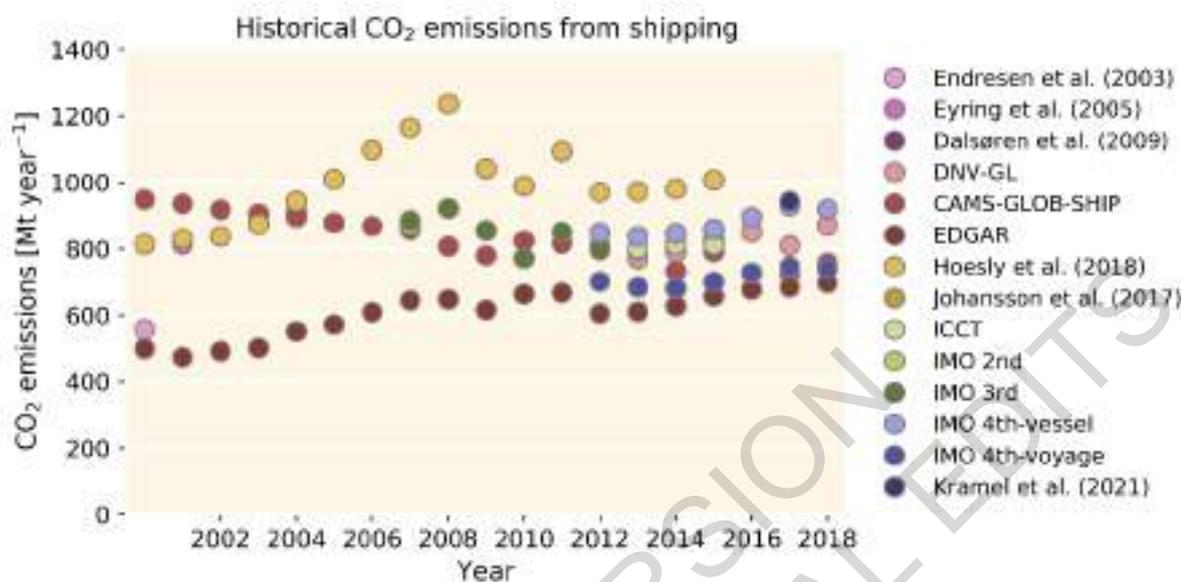

30 **10.6 Decarbonisation of Shipping**

31 Maritime transport is considered one of the key cornerstones enabling globalisation (Kumar and
32 Hoffmann 2002). But as for aviation, shipping has its challenges in decarbonisation, with a strong
33 dependency on fossil fuels without major changes since AR5. At the same time, the sector has a range
34 of opportunities that could help reduce emissions through not only changing fuels, but also by increasing
35 the energy efficiency, optimising operations and ship design, reducing demand, improving regulations,
36 as well as other options that will be reviewed in this section.

38 **10.6.1 Historical and current emissions from shipping**

39 Maritime transport volume has increased by 250% over the past 40 years, reaching an all-time high of
40 11 billion tons of transported goods in 2018 (UNCTAD 2019). This growth in transport volumes has
41 resulted in continued growth in GHG emissions from the shipping sector, despite an improvement in
42 the carbon intensity of ship operations, especially since 2014. The estimated total emissions from
43 maritime transport can vary depending on data set and calculation method, but range over 600 – 1,100
44 Mt CO₂ per year over the past decade (Figure 10. 14), corresponding to 2 - 3% of total anthropogenic
45 emissions. The legend in Figure 10.14 refers to the following data sources: (Endresen et al. 2003),
46 (Eyring et al. 2005), (Dalsøren et al. 2009), DNV-GL (DNV GL 2019), CAMS-GLOB-SHIP (Jalkanen

1 et al. 2014; Granier et al. 2019), EDGAR (Crippa et al. 2019), (Hoesly et al. 2018), (Johansson et al.
 2 2017), ICCT (Olmer et al. 2017), the IMO GHG Studies; IMO 2nd (Buhaug et al. 2009), IMO 3rd
 3 (Smith et al. 2014), IMO 4th-vessel and IMO 4th-voyage (Faber et al. 2020), and (Kramel et al. 2021).

 8 **shown in the label.**

10 10.6.2 Short lived climate forcers and shipping

11 Like aviation, shipping is also a source of emissions of the SLCFs described in Section 10.5, including
 12 nitrogen oxides (NO_x), sulphur oxides (SO₂ and SO₄), carbon monoxide (CO), black carbon (BC), and
 13 non-methane volatile organic carbons (NMVOCs) (Naik et al. 2021). Though SLCF have a shorter
 14 lifetime than the associated CO₂ emissions, these short-lived forcers can have both a cooling effect (e.g.,
 15 SO_x) or a warming effect (e.g., ozone from NO_x). The cooling from the SLCF from a pulse emission
 16 will decay rapidly and diminish after a couple of decades, whilst the warming from the long-lived
 17 substances lasts for centuries (Naik et al. 2021).

18 Emissions of SLCF from shipping not only affects the climate, but also the environment, air quality,
 19 and human health. Maritime transport has been shown to be a major contributor to coastal air quality
 20 degradation (Viana et al. 2014; Zhao et al. 2013; Jalkanen et al. 2014; Goldsworthy and Goldsworthy
 21 2015; Goldsworthy 2017). Sulphur emissions may contribute towards acidification of the ocean
 22 (Hassellöv et al. 2013). Furthermore, increases in sulphur deposition on the oceans has also been shown
 23 to increase the flux of CO₂ from the oceans to the atmosphere (Hassellöv et al. 2013). To address the
 24 risks of SO_x emissions from shipping, there is now a cap on the on the amount of sulphur content
 25 permissible in marine fuels (IMO 2013). There is also significant uncertainty about the impacts of
 26 pollutants emitted from ships on the marine environment (Blasco et al. 2014).

27 Pollution control is implemented to varying degrees in the modelling of the SSP scenarios (Rao et al.
 28 2017); for example, SSPs 1 and 5 assume that increasing concern for health and the environment result
 29 in more stringent air pollution policies than today (Naik et al. 2021). There is a downward trend in SO_x
 30 and NO_x emissions from shipping in all the SSPs, in compliance with regulations. The SLCF emission
 31 reduction efforts, within the maritime sector, are also contributing towards achieving the UN SDGs. In
 32 essence, while long lived GHGs are important for long term mitigation targets, accounting for short

1 lived climate forcers is important both for current and near-term forcing levels as well as broader air
2 pollution and SDG implications.

4 **10.6.3 Shipping in the Arctic**

5 Shipping in the Arctic is a topic of increasing interest. The reduction of Arctic summer sea ice increases
6 the access to the northern sea routes (Melia et al. 2016; Smith and Stephenson 2013; Aksenov et al.
7 2017; Fox-Kemper et al. 2021). Literature and public discourse on the increased access sometimes has
8 portrayed this trend as positive (Zhang et al. 2016b), as it allows for shorter shipping routes, e.g.
9 between Asia and Europe with estimated travel time savings of 25 – 40% (Aksenov et al. 2017).
10 However, the acceleration of Arctic cryosphere melt and reduced sea ice that enable Arctic shipping
11 reduce surface albedo and amplify climate warming (Eyring et al. 2021). Furthermore, local air
12 pollutants can play different roles in the Arctic. For example, Black Carbon (BC) emissions reduce
13 albedo and absorb heat in air, on snow and ice (Messner 2020; Browse et al. 2013; Kang et al. 2020;
14 Eyring et al. 2021). Finally, changing routing from Suez to the north-eastern sea route may reduce total
15 emissions for a voyage, but also shift emissions from low to high latitudes. Changing the location of
16 the emissions adds complexity to the assessment of the climatic impacts of Arctic shipping, as the local
17 conditions are different and the SLCF may have a different impact on clouds, precipitation, albedo and
18 local environment (Marelle et al. 2016; Fuglestvedt et al. 2014; Dalsøren et al. 2013). Observations
19 have shown that 5-25% of air pollution in the Arctic stem from shipping activity within the Arctic itself
20 (Aliabadi et al. 2015). Emissions outside of the Arctic can affect Arctic climate, and changes within the
21 Arctic may have global climate impacts. Both modelling and observations have shown that aerosol
22 emissions from shipping can have a significant effect on air pollution, and shortwave radiative forcing
23 (Peters et al. 2012; Roiger et al. 2014; Marelle et al. 2016; Dalsøren et al. 2013; Ødemark et al. 2012;
24 Righi et al. 2015).

25 Increased Arctic shipping activity may also impose increased risks to local marine ecosystems and
26 coastal communities from invasive species, underwater noise, and pollution (Halliday et al. 2017; IPCC
27 2019). Greater levels of Arctic maritime transport and tourism have political, as well as socio-economic
28 implications for trade, and nations and economies reliant on the traditional shipping corridors. There
29 has been an increase in activity from cargo, tankers, supply, and fishing vessels in particular (Zhao et
30 al. 2015; Winther et al. 2014). Projections indicate more navigable Arctic waters in the coming decades
31 (Smith and Stephenson 2013; Melia et al. 2016) and continued increases in transport volumes through
32 the northern sea routes (Winther et al. 2014; Corbett et al. 2010; Lasserre and Pelletier 2011). Emission
33 patterns and quantities, however, are also likely to change with future regulations from IMO, and
34 depend on technology developments, and activity levels which may depend upon geopolitics,
35 commodity pricing, trade, natural resource extractions, insurance costs, taxes, and tourism demand
36 (Johnston et al. 2017). The need to include indigenous peoples' voices when shaping policies and
37 governance of shipping activities in the high north is increasing (Dawson et al. 2020).

38 The Arctic climate and environment pose unique hazards and challenges with regards to safe and
39 efficient shipping operations: low temperature challenges, implications for vessel design, evacuation
40 and rescue systems, communications, oil spills, variable sea ice, and meteorological conditions
41 (Buixadé Farré et al. 2014). To understand the total implications of shipping in the Arctic, including its
42 climate impacts, a holistic view of synergies, trade-offs, and co-benefits is needed, with assessments of
43 impacts on not only the physical climate, but also the local environment and ecosystems. To furthermore
44 ensure safe operations in the Arctic waters, close monitoring of activities may be valuable.

10.6.4 Mitigation potential of fuels, operations and energy efficiency

A range of vessel mitigation options for the international fleet exist and are presented in this section. A variety of feedstocks and energy carriers can be considered for shipping. As feedstocks, fuels from biomass (advanced biofuels), fuels produced from renewable electricity and CO₂ capture from flue gas or the air (electro-, e-, or power-fuels), and fuels produced via thermochemical processes (solar fuels) can be considered. As energy carriers, synthetic fuels and the direct use of electricity (stored in batteries) are of relevance. The most prominent synthetic fuels discussed in literature are Hydrogen, Ammonia, Methane, Methanol, and synthetic hydrocarbon diesel. Figure 10.15 shows the emissions reductions potential for alternative energy carriers that have been identified as having the highest potential to mitigate operational emissions from the sector (Psaraftis 2015; DNV GL 2017; Hansson et al. 2019; Gilbert et al. 2018; Balcombe et al. 2019; Brynolf et al. 2014; Winebrake et al. 2019; Perčić et al. 2020; Bongartz et al. 2018; Biernacki et al. 2018; Faber et al. 2020; Sharafian et al. 2019; Seddiek 2015; ITF 2018b; Seithe et al. 2020; Xing et al. 2020; Czermański et al. 2020; Hua et al. 2018; Bicer and Dincer 2018a; Kim et al. 2020; Liu et al. 2020a; Hansson et al. 2020; Singh et al. 2018; Valente et al. 2021; Sadeghi et al. 2020; Nguyen et al. 2020; Stolz et al. 2021; Winkel et al. 2016; Chatzinikolaou and Ventikos 2013; Lindstad et al. 2015; Tillig et al. 2015; Traut et al. 2014; Teeter and Cleary 2014).

Low-carbon Hydrogen and Ammonia are seen to have a positive potential as a decarbonised shipping fuel. Hydrogen and Ammonia when produced from renewables or coupled to CCS, as opposed to mainly by fossil fuels with high life-cycle emissions (Bhandari et al. 2014), may contribute to significant CO₂-eq reductions of up to 70 - 80% compared to low-sulphur heavy fuel oil (Bicer and Dincer 2018b; Gilbert et al. 2018). These fuels have their own unique transport and storage challenges as Ammonia requires a pilot fuel due to difficulty in combustion, and Ammonia combustion could lead to elevated levels of NO_x, N₂O, or NH₃ emissions depending on engine technology used (DNV GL 2020). There is a need for the further development of technology and procedures for safe storage and handling of fuels such as Hydrogen and Ammonia both onboard and onshore for a faster rate of uptake of such shipping fuels (Hoegh-Guldberg et al. 2019), but they remain an encouraging decarbonisation option for shipping in the next decade.

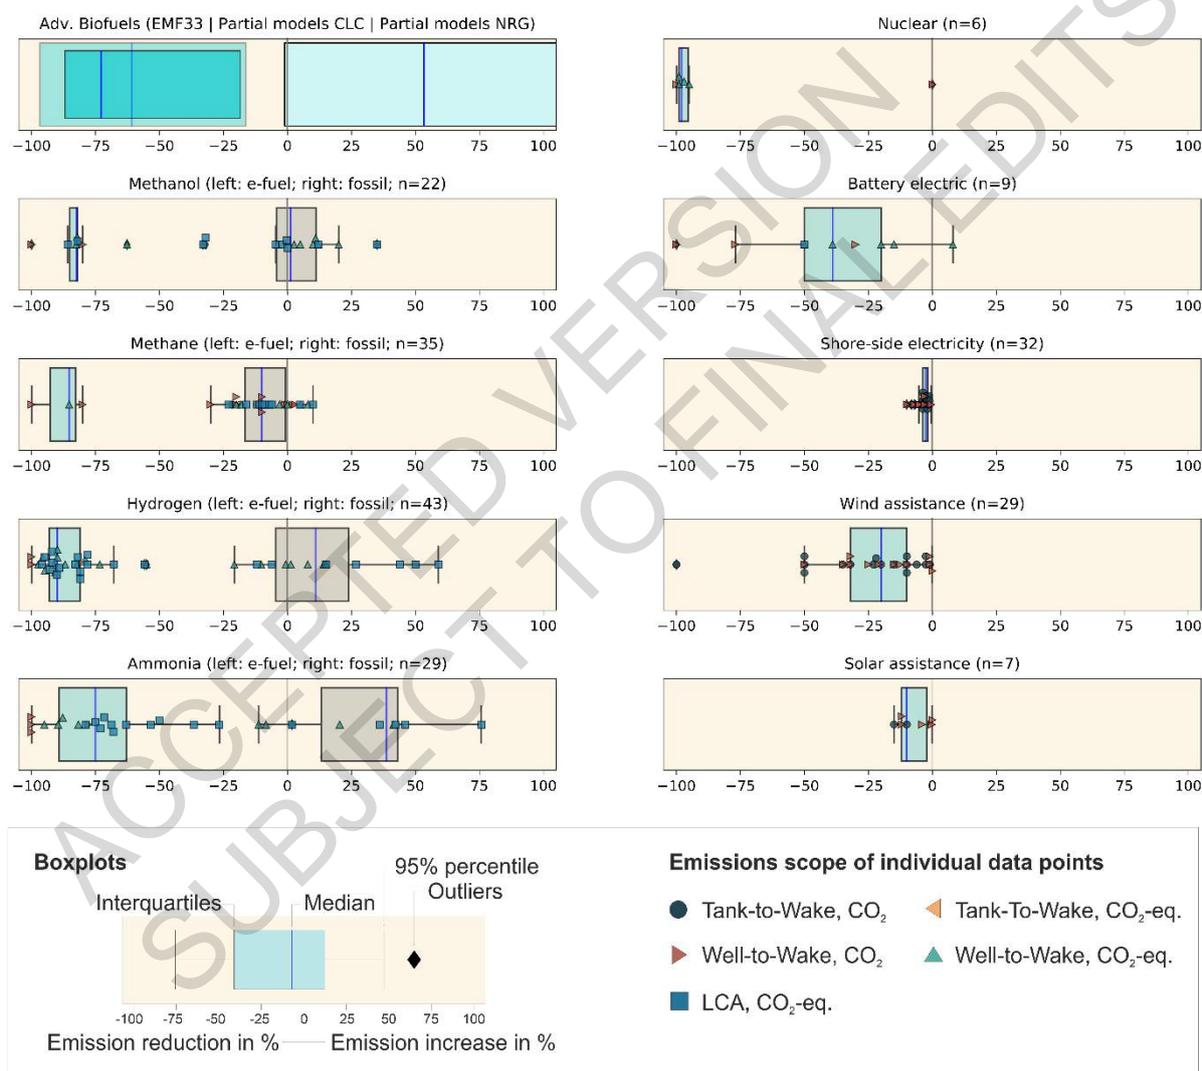

While Methanol produced from fossil sources induces an emission increase of +7.5% (+44%), e-Methanol (via Hydrogen from electrolysis based on renewable energy and carbon from direct air capture) reduces emission by 80% (82%). In general, several synthetic fuels, such as synthetic diesel, methane, Methanol, ethanol, and dimethyl ether (DME) could in principle be used for shipping (Horvath et al. 2018). The mitigation potential of these is though fully dependent on the sourcing of the Hydrogen and carbon required for their synthesis.

As noted in Section 10.3, LNG has been found to have a relatively limited mitigation potential and may not be viewed as a low-carbon alternative, but has a higher availability than other fuel options (Gilbert et al. 2018). Emission reductions across the full fuel life cycle are found in the order of 10%, with ranges reported from -30% (reduction) to +8% (increase), if switching from heavy fuel oil to LNG, as indicated in Figure 10.15 (Bengtsson et al. 2011). Regardless of the production pathway, the literature points to the risk of methane slip (emissions of unburnt methane especially at low engine loads and from transport to ports) from LNG fuelled vessels, with no current regulation on emission caps (Ushakov et al. 2019; Anderson et al. 2015; Peng et al. 2020). Leakage rates are a critical point for the total climate impact of LNG as a fuel, where high pressure engines remedy this more than low pressure ones. As discussed in 10.3, some consider LNG as a transition fuel, whilst some literature point to the risk of stranded assets due to the increasing decarbonisation regulation from IMO and the challenge of meeting IMO's 2030 emissions reductions targets using this fuel.

In addition to fossil and e-fuels, advanced biofuels might play a role to provide the energy demand for future shipping. Biomass is presently used to produce alcohol fuels (such as ethanol and Methanol), liquid biogas, or biodiesel that can be used for shipping and could reduce CO₂ emissions from this

1 segment. As explained in Box 10.2 and Chapter 7, the GHG footprint associated with biofuels is
 2 strongly dependent on the incurred land use and land use change emissions. Advanced biofuels from
 3 processing cellulose rather than sugar are likely to be more attractive in terms of the quantities required
 4 but are not commercially available Section 10.3. The estimates of emissions reductions from biofuels
 5 shown in Figure 10.15 rely on data from the Integrated Assessment Models –Energy Modelling Forum
 6 33 (IAM EMF33), partial models assuming constant land cover (CLC), and partial models using natural
 7 growth (NRG). Box 10.2 and Section 10.4 include a more detailed description of the assumptions
 8 underlying these models and their estimates. The results based on IAM EMF33 and CLC suggests
 9 median mitigation potential of around 73% for advanced biofuels in shipping, while the NRG based
 10 results suggest increased emissions from biofuels. The EMF33 and CLC results rely on modelling
 11 approaches compatible with the scenarios in the AR6 database (see Chapters 6 and Box 7.7 for a
 12 discussion about emissions from bioenergy systems).

13

14

15 **Figure 10.15** Boxplot of emission reductions potential compared to conventional fuels in the shipping
 16 sector. The x-axis is reported in %. Each individual marker represents a data point from the literature,
 17 where the blue square indicates a full LCA CO₂-eq value; light orange triangles tank – to – wake CO₂-eq.;
 18 light blue triangles well – to – wake CO₂-eq; dark orange triangles well – to – wake CO₂; and dark blue
 19 circle tank – to – wake CO₂ emission reduction potentials. The values in the figure rely on the 100-year
 20 GWP value embedded in the source data, which may differ slightly with the updated 100-year GWP
 21 values from WGI. ‘n’ indicates the number of data points per sub-panel. Grey shaded boxes represent

1 **data where the energy comes from fossil resources, and turquoise from low carbon renewable energy**
2 **sources. Advanced Biofuels EMF33 refers to emissions factors derived from simulation results from the**
3 **integrated assessment models EMF33 scenarios (darkest coloured box in top left panel). Biofuels partial**
4 **models CLC refers to partial models with constant land cover. Biofuels partial models NRG refers to**
5 **partial models with natural regrowth. For ammonia and Hydrogen, low-carbon electricity is produced**
6 **via electrolysis using low-carbon electricity, and ‘fossil’ refers to fuels produced via steam methane**
7 **reforming of natural gas.**

8
9 In addition to the fuels, there are other measures that may aid the low-carbon transition shipping. The
10 amounts and speed of uptake of alternative low- or zero-carbon fuels in ports depend upon investments
11 in infrastructure – including bunkering infrastructure, refinery readiness, reliable supply of the fuels, as
12 well as sustainable production. The ship lifetime and age also play a role, whereupon retrofitting ships
13 to accommodate engines and fuel systems for new fuel types may not be an option for older vessels. As
14 such, operational efficiency becomes more important (Bullock et al. 2020). There is some potential to
15 continue to improve the energy efficiency of vessels through operational changes (e.g., Traut et al.
16 2018), reducing the speed or ‘slow steaming’ (Bullock et al. 2020), and improved efficiency in port
17 operations (Viktorelius and Lundh 2019; Poulsen and Sampson 2020). There is also a growing interest
18 in onboard technologies for capturing carbon, with prototype ships underway showing 65-90% potential
19 reduction in CO₂ emissions (Japan Ship Technology Reserach Association et al. 2020; Luo and Wang
20 2017; Awoyomi et al. 2020). Challenges identified include CO₂ capture efficiency (Zhou and Wang
21 2014), increased operating costs, and limited onboard power supply (Fang et al. 2019). Furthermore,
22 designing CO₂ storage tanks for transport to shore may pose a challenge, as the volume and weight of
23 captured CO₂ could be up to four times more than standard oil (Decarre et al. 2010).

24 Changes in design and engineering provide potential for reducing emissions from shipping through a
25 range of measures, e.g., by optimizing hull design and vessel shape, power and propulsion systems that
26 include wind or solar assisted propulsion, and through improved operations of vessels and ports. Figure
27 10.15 shows that such measures may decrease emissions by 5 - 40%, though with a broad range in
28 potential (Bouman et al. 2017). Nuclear propulsion could decrease emissions from individual vessels
29 by 98%. Battery- or hybrid-electric ships have been identified as a means to reduce emissions in short-
30 sea shipping such as ferries and inland waterways (Gagatsi et al., 2016), which may also importantly
31 reduce near-shore SLCF pollution (Nguyen et al. 2020). Figure 10.15 shows that the median emission
32 from electric ships can be ~40% lower than equivalent fossil-based vessels but can vary widely. The
33 wide reduction potential of battery-electric propulsion is due to different assumptions about the CO₂
34 intensity of the electricity used and the levels of CO₂ footprints associated with battery production.

35 Although projections indicate continued increase in freight demand in the future, demand-side
36 reductions could contribute to mitigation. The development of autonomous systems may play a role
37 (Colling and Hekkenberg 2020; Liu et al. 2021) while 3-D printing can reduce all forms of freight as
38 parts and products can be printed instead of shipped (UNCTAD 2018). As more than 40% of transported
39 freight is fossil fuels, a lessened demand for such products in low emission scenarios should contribute
40 to reduce the overall maritime transport needs and hence emissions in the future (Sharmina et al. 2017).
41 An increase in alternative fuels on the other hand, may increase freight demand (Mander et al. 2012).
42 Potentials for demand-side reduction in shipping emissions may arise from improving processes around
43 logistics and packaging, and further taxes and charges could serve as leverage for reducing demand and
44 emissions.

45 The coming decade is projected to be costly for the shipping sector, as it is preparing to meet the 2030
46 and 2050 emission reduction targets set by the IMO (UNCTAD 2018). With enough investments,
47 incentives, and regulation, substantial reductions of CO₂ emissions from shipping could be achieved
48 through alternative energy carriers. The literature suggests that their cost could be manyfold higher than

1 for conventional fuels, which in itself could reduce demand for shipping, and hence its emissions, but
2 make the transition difficult. Hence R&D may help reduce these costs. The literature points to the need
3 for developing technology roadmaps for enabling the maritime transport sector to get on to pathways
4 for decarbonisation early enough to reach global goals (Kuramochi et al. 2018). Accounting for the full
5 life cycle of emissions of the vessels and the fuels is required to meet the overall long-term objectives
6 of cutting GHG and SLCF emissions. The urgency of implementing measures for reducing emissions
7 is considered to be high, considering the lifetime of vessels is typically 20 years, if not more.

9 **10.6.5 Accountability and governance options**

10 Regulatory frameworks for the shipping sector have been developed over time and will continue to do
11 so through bodies such as the IMO, which was established by the UN to manage international shipping.
12 The IMO strategy involves a 50% reduction in GHG emissions from international shipping by 2050
13 compared to 2008 (IMO 2018). The strategy includes a reduction in carbon intensity of international
14 shipping by at least 40% by 2030, and 70% by 2050, compared to 2008. IMO furthermore aims for the
15 sectoral phase out of GHG emissions as soon as possible this century.

16 In 2020, the IMO approved the short-term goal-based measure to reduce the carbon intensity of existing
17 international vessels. This measure addresses both technical and operational strategies. The operational
18 element is represented by a Carbon Intensity Indicator (CII), and the technical element is represented
19 by the Energy Efficiency Existing Ship Index (EEXI), which will apply to ships from 2023. The EEXI
20 builds upon the Energy Efficiency Design Index (EEDI), which is a legally binding mitigation
21 regulation for newbuild ships, established as a series of baselines for the amount of fuel ships may burn
22 for a particular cargo-carrying capacity. The EEDI differs per ship segment. E.g., ships built in 2022
23 and beyond should be 50% more energy efficient than in 2013. This legislation aims to reduce GHG
24 emissions in particular. Energy efficiency may be improved by several of the mitigation options
25 outlined above. The ship energy efficiency management plan (SEEMP) is seen as the international
26 governance instrument to improve energy efficiency and hence emissions from ships. SEEMP is a
27 measure to enable changes to operational measures and retrofits (see Johnson et al., 2013). The
28 combination of EEXI, EEDI, and SEEMP may reduce emissions by 23% by 2030 compared to a ‘no
29 policy’ scenario (Sims et al. 2014). With regards to accountability, it is mandatory for ships of $\geq 5,000$
30 gross tonnage to collect fuel consumption data, as well as specified data for e.g. transport work.
31 Similarly, the EU MRV (Monitoring, Reporting, Verification) requires mandatory reporting of a
32 vessel’s fuel consumption when operating in European waters.

33 Policy choices may enable or hinder changes, and gaps in governance structures may, to some degree,
34 hinder the objectives of mechanisms like SEEMP to improve energy efficiency and emissions. Policies
35 may be developed to incentivize investments in necessary changes to the global fleet and related
36 infrastructures. The literature argues that regulations and incentives that motivates mitigation through
37 speed optimisation, ship efficiency improvements, and retrofits with lower-carbon technologies at a
38 sub-global scale may contribute to immediate reductions in CO₂ emissions from the sector (Bows-
39 Larkin 2015). The role of the financial sector through initiatives such as the Poseidon Principle,
40 whereupon financial institutions limit lending to companies that fail to uphold environmental standards,
41 could also become increasingly important (Sumaila et al. 2021).

42 It has been proposed to make shipping corporations accountable for their emissions by making it
43 mandatory to disclose their vessel’s emissions reductions (Rahim et al. 2016). Market based
44 mechanisms may increasingly encourage ship operators to comply with IMO GHG regulations.
45 Development of policies such as carbon pricing / taxing to enable a business case for adopting low
46 carbon fuels could be a near term priority for acceleration of transformation of the sector (Hoegh-
47 Guldborg et al. 2019). The EU is considering including shipping in its carbon trading system, with the

1 details still to be agreed upon but expected to come into force in 2023, along with the CII. The
2 proposition is that shipowners who conduct voyages within Europe, or start or end at an EU port, will
3 have to pay for carbon permits to cover the CO₂ emitted by their vessel.

4 Regulations exist also to limit emissions of air pollution from shipping with the aim to improve
5 environment and health impacts from shipping in ports and coastal communities. In sulphur emission
6 control areas (SECAS), the maximum permissible sulphur content in marine fuels is 0.10% m/m
7 (mass/mass). These are further tightened by the IMO legislation on reducing marine fuel sulphur content
8 to a maximum of 0.5% in 2020 outside of SECAS, compared to 3.5% permissible since 2012 (MARPOL
9 Convention). The MARPOL Annex VI also limits the emissions of ozone depleting substances and
10 ozone precursors; NO_x, and VOCs from tankers (Mertens et al. 2018). The implementation of the
11 emission control areas have been shown to reduce the impacts on health and the environment (Viana et
12 al. 2015).

13 While there are many governance and regulatory initiatives that help reduce emissions from the
14 shipping sector, few are transformative on their own, unless zero carbon fuels can become available at
15 a reasonable cost as suggested in 10.3 and in scenarios outlined next.

17 **10.6.6 Transformation trajectories for the maritime sector**

18 Figure 10.16 shows CO₂ emissions from shipping in scenarios from the AR6 database and the 4th GHG
19 study by the IMO (Faber et al., 2020). Panel (a) shows that CO₂ emissions from shipping go down by
20 33-70% (5-95% percentile) by 2050 in the scenarios limiting warming to 1.5°C (C1-C2). By 2080,
21 median values for the same set of scenarios reach net zero CO₂ emissions. IAMs often do not report
22 emission pathways for shipping transport and the sector is underrepresented in most IAMs (Esmeijer et
23 al. 2020). Hence pathways established outside of IAMs can be different for the sector. Indeed, the IMO
24 projections for growth in transport demand (Faber et al. 2020) indicate increases by 40 - 100 % by 2050
25 for the global fleet. Faber and et al. (2020), at the same time predict, reductions in trade for fossil fuels
26 dependent on decarbonisation trajectories. The energy efficiency improvements of the vessels in these
27 scenarios are typically of 20 - 30%. This offsets some of the increases from higher demand in the future
28 scenarios. Fuels assessed by the 4th IMO GHG study were limited to HFO, MGO, LNG, and Methanol,
29 with a fuels mix ranging from 91 - 98% conventional fuel use and a small remainder of alternative fuels
30 (primarily LNG, and some Methanol). Panel (b) in Figure 10.16 shows average fleetwide emissions of
31 CO₂ emissions based on these aggregate growth and emission trajectories from the IMO scenarios. In
32 these scenarios, CO₂ emissions from shipping remain stable or grow compared to 2020 modelled levels.
33 These results contrast with the low emission trajectories in the C1-C2 bin in panel (a) of Figure 10.16.
34 It seems evident that the scenarios in the AR6 database explore a broader solutions space for the sector,
35 than the 4th GHG study by IMO. However, the 1.5°C - 2°C warming goal has led to an IMO 2050 target
36 of 40% reductions in carbon intensity by 2030, which would require emission reduction efforts to begin
37 immediately. Results from global models, suggest the solutions space for deep emission reductions in
38 shipping is available.

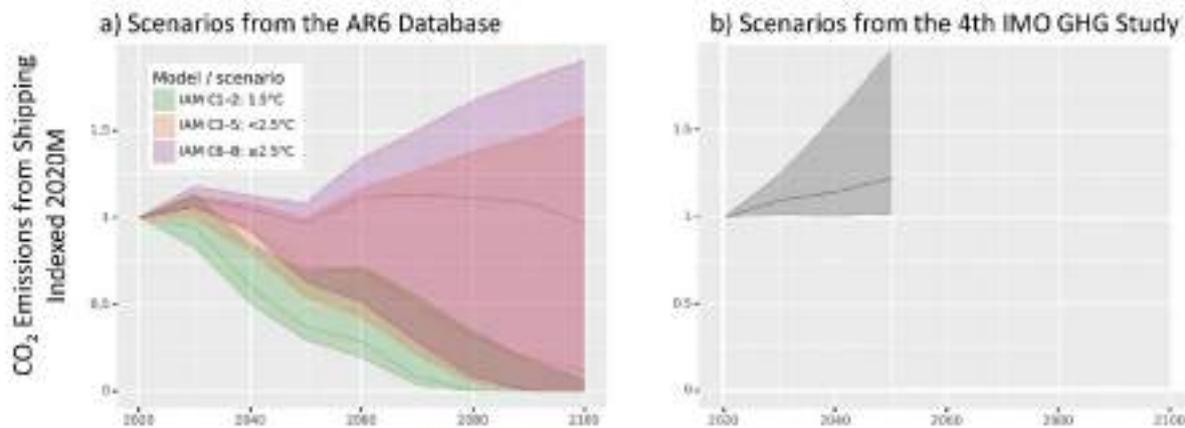

Figure 10.16 CO₂ emission from shipping scenarios indexed to 2020 Modelled year. Panel a) Scenarios from the AR6 database. Panel b) Scenarios from the 4th IMO GHG Study (Faber et al., 2020). Figures show median, 5th and 95th percentile (shaded area) for each scenario group.

Combinations of measures are likely needed for transformative transitioning of the shipping sector to a low-carbon future, particularly if an expected increase in demand for shipping services is realised (Smith et al. 2014; Faber et al. 2020). Both GHG and SLCF emissions decrease significantly in SSP1-1.9, where mitigation is achieved in the most sustainable way (Rao et al. 2017). Conversely, there are no emissions reductions in the scenarios presented by the IMO 4th GHG study, even though these scenarios incorporate some efficiency improvements and a slight increase in the use of LNG.

Options outlined in this chapter suggest a combination of policies to reduce demand, increase investments by private actors and governments, and develop the TRL of alternative fuels and related infrastructure (especially synthetic fuels). Some literature suggests that battery electric-powered short distance sea shipping could yield emission reductions given access to low carbon electricity. For deep sea shipping, advanced biofuels, Hydrogen, Ammonia, and synthetic fuels hold potential for significant emission reductions, depending on GHG characteristics of the fuel chain and resource base. Other options, such optimisation of speed and hull design and wind-assisted ships could also combine to make significant contributions in 2050 to further bring emissions down. In total a suite of mitigation options exists or is on the horizon for the maritime sector.

10.7 Scenarios from integrated, sectoral, and regional models

10.7.1 Transport scenario modelling

This section reviews the results of three types of models that systemically combine options to assess different approaches to generate decarbonisation pathways for the transport system: (1) integrated assessment models (IAMs); (2) global transport energy sectoral models (GTEM); and (3) national transport/energy models (NTEMs) (Yeh et al. 2017; Edelenbosch et al. 2017). Common assumptions across the three model types include trajectories of socioeconomic development, technological development, resource availability, policy, and behavioural change. The key differences underlying these models are their depth of technological and behavioural detail versus scope in terms of sectoral and regional coverage. In very general terms, the narrower the scope in terms of sectors and regions, the more depth on spatial, technological, and behavioural detail. A large set of scenarios from these models were collected in a joint effort led by Chapter 3 and supported by Chapter 10 and others. The

1 outcomes from over 100 models have been analysed for this chapter with the methodologies set out in
2 Annex III for the whole report.

3 GHG emissions from transport are a function of travel demand, travel mode, transport technology, GHG
4 intensity of fuels, and energy efficiency. These drivers can be organized around a group of levers that
5 can advance the decarbonisation of the transport system. The levers thus include reducing travel
6 activity, increasing use of lower-carbon modes, and reducing modal energy intensity and fuel carbon
7 content. This section explores each lever's contributions to the decarbonisation of the transport sector
8 by reviewing the results from the three model types IAM and G-/NTEMs.

9 IAMs integrate factors from other sectors that interact with the transport system endogenously, such as
10 fuel availability and costs. IAMs minimize mitigation costs to achieve a temperature goal *across all*
11 *sectors of the economy* over a long-time horizon (typically to 2100). IAMs typically capture mitigation
12 options for energy and carbon intensity changes with greater technology/fuel details and endogeneity
13 linked to the other sectors. In the scenarios with very large-scale electrification of the transport sector,
14 the coupling with the other sectors in fuel production, storage, and utilization becomes more important.
15 G-/NTEMs and related regional transport sectoral models have more details in transport demand,
16 technology, behaviours, and policies than IAMs, but treat the interactions with the other sectors
17 exogenously, potentially missing some critical interactions, such as the fuel prices and carbon intensity
18 of electricity. National models have detailed representation of national policies related to transport and
19 energy, sometimes with greater spatial resolution. Compared with IAMs, G-/NTEMs typically have
20 greater detailed representation to explore mitigation options along the activity and mode dimensions
21 where spatial, cultural, and behavioural details can be more explicitly represented. The appendix in
22 Annex III provides more details about these types of models. Scenarios for shipping and aviation are
23 handled in more detail in sections 10.5 and 10.6, respectively.

24 This section applies the following categorization of scenarios (see table 3.1 in Chapter 3 for more
25 details): C1 (1.5°C with no or limited Overshoot (OS)), C2 (1.5°C with high OS), C3 (>67% below
26 2°C), C4 (>50% below 2°C), C5 (below 2.5°C), C6 (below 3°C), C7 (above 3°C). A large share of the
27 scenarios was developed prior to 2020. Results from such the scenario are indexed to a modelled (non-
28 covid) year 2020, referred to as 2020Mod.

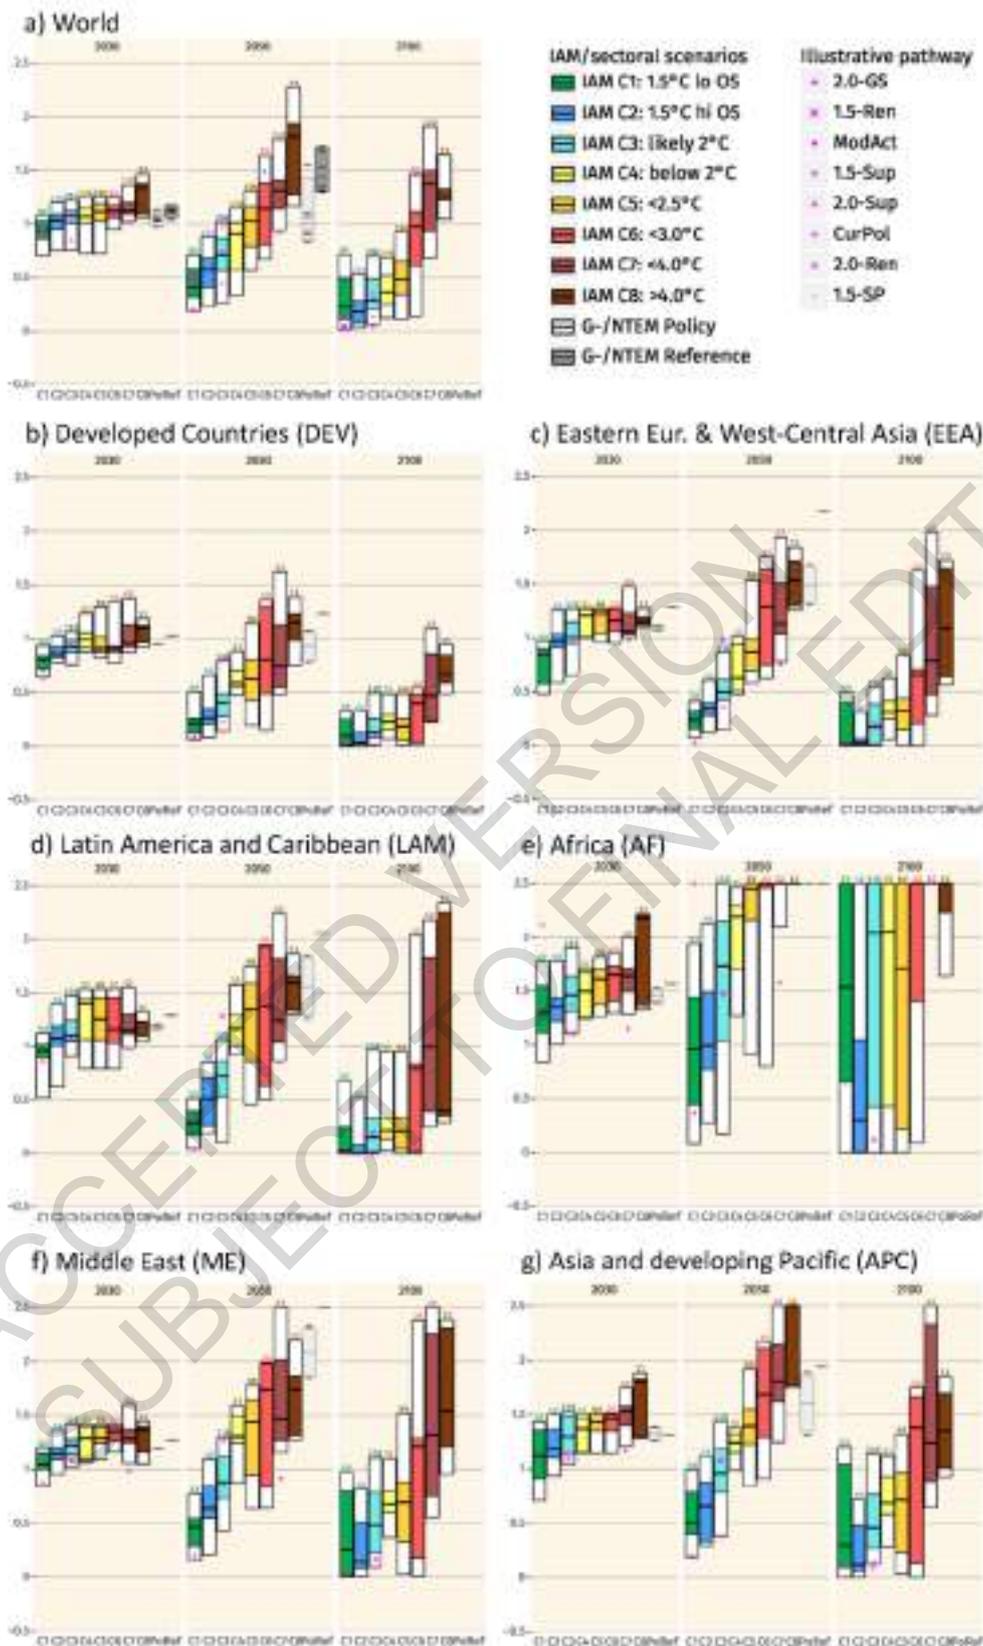

29

30 **10.7.2 Global emission trajectories**

31 In 2018, transport emitted 8.5 Gt CO₂eq, reaching a near doubling from 1990 levels after two decades
32 of 2% per year emissions growth (see Section 10.1). Assessing future trajectories, Figure 10.17 provides
33 an overview of direct CO₂ emissions estimates from the transport sector across IAMs (colour bars) and
34 selected global transport models (grey bars). The results from the IAMs are grouped in bins by different
35 temperature goal. Global energy transport models (GTEMs) are grouped into reference and policy bins,
36 since the transport sector cannot by itself achieve fixed global temperature goals. The policy scenarios
37 in G-/NTEMs cover a wide range of "non-reference" scenarios, which include, for example,
38 assumptions based on the "fair share action" principles. In these scenarios, transport emissions reach
39 emissions reductions consistent with the overall emission trajectories aligning with warming levels of
40 2°C. These scenarios may also consider strengthening existing transport policies such as increasing fuel
41 economy standards or large-scale deployments of electric vehicles. In most cases, these Policy scenarios
42 are not necessarily in line with the temperature goals explored by the IAMs.

Figure 10.17 Direct CO₂ emissions in 2030, 2050, and 2100 indexed to 2020 modelled year across R6 Regions and World. IAM results are grouped by temperature targets. Sectoral studies are grouped by reference and policy categories. Plots show 5th/95th percentile, 25th/75th percentile, and median. Numbers above the bars indicate the number of scenarios. Data from the AR6 scenario database.

1

2 According to the collection of simulations from the IAM and GTEM models shown in Figure 10.17,
3 global transport emissions could grow up to 2–47% (5–95th percentile) by 2030 and -6–130% by 2050
4 under the scenarios without firm commitments to meet a long-term temperature goal (i.e., C7-8
5 scenarios with temperature change above 3.0°C by 2100). Population and GDP growth and the
6 secondary effects, including higher travel service demand per capita and increased freight activities per
7 GDP, drive the growth in emissions in these scenarios (see Section 10.7.3). Though transport
8 efficiencies (energy use per pkm travelled and per ton-km of delivery) are expected to continue to
9 improve in line with the historical trends (see Section 10.7.4), total transport emissions would grow due
10 to roughly constant carbon intensity (Section 10.7.5) under the C7-8 (>3.0°C) scenarios. Significant
11 increases in emissions (> 150% for the medium values by 2050) would come from Asia and developing
12 Pacific (APC), the Middle East and (ME), and Africa (AF), whereas Developed Countries (DEV) would
13 have lower transport emissions (medium value -25% for C7 and 15% for C8) than the estimated 2020
14 level in 2050.

15 To meet temperature goals, global transport emissions would need to decrease by 17% (67–+23% for
16 the 5–95th percentile) below 2020Mod levels in the C3-5 scenario group (1.5 - 2.5°C, orange bars), and
17 47% (14–80% for the 5–95th percentile) in the C1-2 scenario group (below 1.5°C, green bars) by 2050.
18 However, transport-related emission reductions may not happen uniformly across regions. For example,
19 transport emissions from the Developed Countries (DEV), and Eastern Europe and West-Central Asia
20 (EEA) would decrease from 2020 levels by 2050 across all C1-2 scenarios, but could increase in Africa
21 (AF), Asia and developing Pacific (APC), Latin America and Caribbean (LAM) and the Middle East
22 (ME), in some of these scenarios. In particular, the median transport emissions in India and Africa could
23 increase by 2050 in C1-2 scenarios, while the 95th percentile emissions in Asia and developing Pacific
24 (APC), Latin America and Caribbean (LAM), and the Middle East (ME), could be higher in 2050 than
25 in 2020.

26 The Reference scenario emission pathways from GTEMs described in Figure 10.17 have similar ranges
27 as C7-8 scenario groups in 2050. The Policy scenarios are roughly in line with C6-7 scenarios for the
28 world region. The results suggest that the majority of the Policy scenarios examined by the GTEMS
29 reviewed here are in the range of the 2-3°C temperature goal scenarios examined by the IAMs (Gota et
30 al. 2016; Yeh et al. 2017; IEA 2017b; Fisch-Romito and Guivarch 2019). The NDCs in the transport
31 sector include a mix of measures targeting efficiency improvements of vehicles and trucks; improving
32 public transit services; decarbonising fuels with alternative fuels and technologies including biofuels,
33 fossil- or bio-based natural gas, and electrification; intelligent transport systems; and vehicle restrictions
34 (Gota et al. 2016). Because of the long lag-time for technology turnover, these measures are not
35 expected to change 2030 emissions significantly. However, they could have greater impacts on 2050
36 emissions.

37 Several GTEMs not included in AR6 scenario database have examined ambitious CO₂ mitigation
38 scenarios. For example, a meta-analysis of scenarios suggests that global transport emissions consistent
39 with warming levels of 2°C, would peak in 2020 at around 7-8 GtCO₂ and decrease to 2.5-9.2 Gt for
40 2°C with an average of 5.4 Gt by 2050 (Gota et al. 2019). For comparison, the IEA's Sustainable
41 Development Scenario (SDS) suggests global transport emissions decrease to 3.3 Gt (or 55% reduction
42 from 2020 level) by 2050 (IEA 2021f). In the latest IEA Net Zero by 2050 report proposes transport
43 emissions to be close to zero by 2050 (IEA 2021e). The latter is lower than the interquartile ranges of
44 the C1 group of scenarios from the AR6 database analysed here.

45 Low carbon scenarios are also available from national models (Latin America, Brazil, Canada, China,
46 France, Germany, Indonesia, India, Italy, Japan, Mexico, South Africa, UK, US) with a good
47 representation of the transport sector. The low carbon scenarios are either defined with respect to a
48 global climate stabilization level of e.g., 2°C /1.5°C Scenario (Dhar et al. 2018), or a CO₂ target that is

1 more stringent than what has been considered in the NDCs, such as the net zero emissions pathways
2 (Bataille et al. 2020; IEA 2021e). These studies have generally used bottom-up models (see Annex III)
3 for the analysis, but in some cases, they are run by national teams using global models (e.g., GCAM for
4 China and India). National studies show that transport CO₂ emissions could decline significantly in low-
5 carbon scenarios in all the developed countries reviewed (Bataille et al. 2015; Kainuma et al. 2015AD;
6 Viridis et al. 2015; Pye et al. 2015; Criqui et al. 2015; Kemfert et al.; Williams et al. 2015; Zhang et al.
7 2016a) in 2050 from the emissions in 2010 and reductions vary from 65% to 95%. However, in
8 developing countries reviewed (Altieri et al. 2015; Buira and Tovilla 2015; Teng et al. 2015; Rovere et
9 al. 2015; Siagian et al. 2015; Shukla et al. 2015; Di Sbroiavacca et al. 2014; Dhar et al. 2018), emissions
10 could increase in 2050 in the range of 35% - 83% relative to 2010 levels. Transport CO₂ emissions per
11 capita in the developing countries were much lower in 2010 (vary from 0.15 to 1.39 tCO₂ per capita)
12 relative to developed countries (vary from 1.76 to 5.95 tCO₂ per capita). However, results from national
13 modelling efforts suggest that, by 2050, the CO₂ emissions per capita in developed countries (vary from
14 0.19 to 1.04 tCO₂ per capita) could be much lower than in developing countries (vary from 0.21 to 1.7
15 tCO₂ per capita).

16 The transport scenario literature's mean outcomes suggest that the transport sector may take a less steep
17 emission reduction trajectory than the cross-sectoral average and still be consistent with the 2°C goal.
18 For example, most of the 1.5°C pathway scenarios (C1-2) reach zero-emission by 2060, whereas
19 transport sector emissions are estimated in the range of 20% of the 2020Mod level (4-65% for the 10th
20 – 90th percentiles) by 2100. This finding is in line with perspectives in the literature suggesting that
21 transport is one of the most difficult sectors to decarbonise (Davis et al. 2018). There is, however,
22 quite a spread in the results for 2050. Since temperature warming levels relate to global emissions from
23 all sectors, modelling results from IAMs tend to suggest that in the short and medium-term, there might
24 be lower cost mitigation options outside the transport sector. On the other hand, compared with G-
25 /NTEMs, some IAMs may have limited mitigation options available including technology, behavioural
26 changes, and policy tools especially for aviation and shipping. The models therefore rely on other
27 sectors and/or negative emissions elsewhere to achieve the overall desired warming levels. This
28 potential shortcoming should be kept in mind when interpreting the sectoral results from IAMs.

29

30 **10.7.3 Transport activity trajectories**

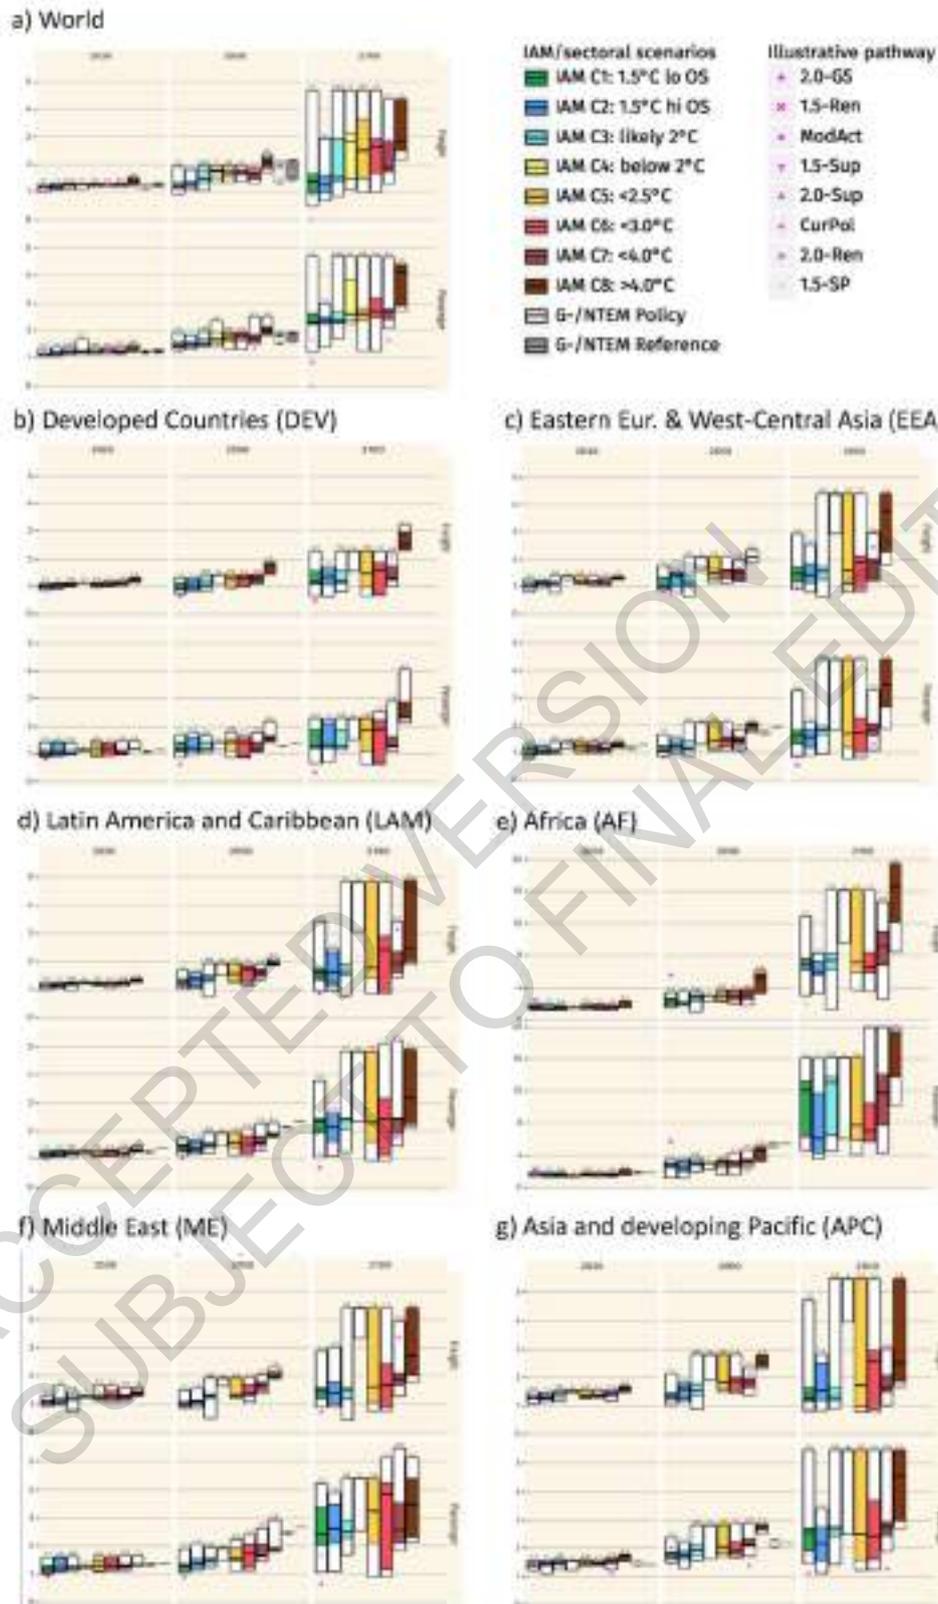

31 Growth in passenger and freight travel demand is strongly dependent on population growth and GDP.
32 In 2015, transport activities were estimated at around 35-50 trillion pkm or 5,000-7,000 pkm per person
33 per year, with significant variations among studies (IEA 2017b; ITF 2019). The number of passenger
34 cars in use has grown 45% globally between 2005-2015, with the most significant growth occurring in
35 the developing countries of Asia and the Middle East (119%), Africa (79%) and, South and Central
36 America (80%), while the growth in Europe and North America is the slowest (21% and 4%
37 respectively) (IOMVM 2021). On the other hand, car ownership levels in terms of vehicles per 1,000
38 people in 2015 were low in developing countries of Asia and the Middle East (141), Africa (42), South
39 and Central America (176), while in Europe and North America they are relatively high (581 and 670
40 respectively) (IOMVM 2021). The growth rate in commercial vehicles (freight and passenger) was 41%
41 between 2005 and 2015, with a somewhat more even growth across developed and developing countries
42 (IOMVM 2021).

43 Figure 10.18 shows activity trajectories for both freight and passenger transport based on the AR6
44 database for IAMs. According to demand projections from the IAMs, global passenger and freight
45 transport demand could increase relative to a modelled year 2020 across temperature goals. The median
46 transport demand from IAMs for all the scenarios in line with warming levels below 2.5°C (C1-C5)
47 suggests the global passenger transport demand could grow by 1.14-1.3 times in 2030 and by 1.5-1.8
48 times in 2050 (1.27-2.33 for the 5th – 95th percentile across C1-C5 scenarios) relative to modelled 2020

1 level. Developed regions including North America and Europe exhibit lower growth in passenger
2 demand in 2050 compared to developing countries across all the scenarios. In 2030, most of the global
3 passenger demand growth happens in Africa (AF) (44% growth relative to 2020), and Asia and
4 developing Pacific (APC) (57% growth in China and 59% growth in India relative to 2020) in the
5 below 2.5 scenario (C5). These regions start from a low level of per capita demand. For example, in
6 India, demand may grow by 84%. However, the per capita demand in 2010 was under 7,000 km per
7 person per year (Dhar and Shukla 2015). Similarly, in China, demand may grow by 52%, starting from
8 per capita demand of 8,000 km per person per year in 2010 (Pan et al. 2018). The per capita passenger
9 demand in these regions was lower than in developed countries in 2010, but it converges towards the
10 per capita passenger transport demand of advanced economies in less stringent climate scenarios (C6-
11 7). Demand for passenger travel would grow at a slower rate in the stricter temperature stabilization
12 scenarios (< 2.5 and 1.5 scenarios, C1-C5) compared to the scenarios with higher warming levels (C7-
13 C8). The median global passenger demand in the scenarios with warming levels below 1.5°C scenarios
14 (C1-C2) are 27% lower in 2050 relative to C8.

15 Due to limited data availability, globally consistent freight data is difficult to obtain. In 2015, global
16 freight demand was estimated to be 108 trillion tkm, most of which was transported by sea (ITF
17 2019). The growth rates of freight service demand vary dramatically among different regions: over the
18 1975–2015 period, road freight activity in India increased more than 9-fold, 30-fold in China, and 2.5-
19 fold in the US (Mulholland et al. 2018). Global freight demand continues to grow but at a slower rate
20 compared to passenger demand across all the scenarios in 2050 compared to modelled 2020 values.
21 Global median freight demand could increase by 1.17 -1.28 times in 2030 and 1.18-1.7 times in 2050
22 in all the scenarios with warming level below 2.5°C (C1-C5). Like passenger transport, the models
23 suggest that a large share of growth occurs in Africa (AF) and Asian regions (59% growth in India and
24 50% growth in China in 2030 relative to a modelled year 2020) in C5 scenario. Global median freight
25 demand grows slower in the stringent temperature stabilization scenarios, and is 40% and 22% lower
26 in 2050 in the below 1.5°C scenarios (C1-C2) and below 2.5°C scenarios (C3-C4), respectively,
27 compared to scenarios with warming levels of above 4°C (C8).

Plots show 5-95% percentile, 25th/75th percentile, and median. Numbers above the bars indicate the number of scenarios. Data from the AR6 scenario database.

1

2 GTEMs show broad ranges for future travel demand, particularly for the freight sector. These results
3 show more dependency on models than on baseline or policy scenarios. According to ITF Transport
4 Outlook (ITF 2019), global passenger transport and freight demand could more than double by 2050
5 in a business-as-usual (BAU) scenario. Mulholland et al. (2018) suggest the freight sector could grow
6 by 2.4-fold over 2015–2050 in the reference scenario, with the majority of growth attributable to
7 developing countries. The IEA suggests a more modest increase in passenger transport, from 51 trillion
8 pkm in 2014 to 110 trillion pkm in 2060, in a reference scenario without climate policies and a climate
9 scenario that would limit emissions below 2°C. The demand for land-based freight transport in 2060 is,
10 however, slightly lower in the climate scenario (116 trillion tkm) compared to the reference scenario
11 (130 trillion tkm) (IEA 2017b). The ITF, however, suggests that ambitious decarbonisation policies could
12 reduce global demand for passenger transport by 13–20% in 2050, compared to the business-as-usual
13 scenario (ITF 2019, 2021). The reduction in vehicle travel through shared mobility could reduce
14 emissions from urban passenger transport by 30% compared to the BAU scenario. Others suggest
15 reductions larger than 25%, on average, for both passenger and freight in 2030 and 2050 may be needed
16 to achieve very low carbon emission pathways (Fisch-Romito and Guivarch 2019). In absence of large-
17 scale carbon dioxide removal, few global studies highlight the need for significant demand reduction in
18 critical sectors (aviation, shipping and road freight) in well below 2°C scenarios (van Vuuren et al.
19 2018; Grant et al. 2021; Sharmina et al. 2021).

20 Many models find small differences in passenger transport demand across temperature goals because
21 IAM models rely on historical relationships between population, GDP, and demand for services to
22 estimate future demand. This assumption poses a limitation to the modelling efforts, as mitigation
23 efforts would likely increase travel costs that could result in lower transport demand (Zhang et al. 2018).
24 In most models, demand is typically an exogenous input. These models often assume mode shifts of
25 activities from the most carbon-intensive modes (driving and flying for passenger travel and trucking
26 for freight) to less carbon-intensive modes (public transit and passenger rails, and freight rail) to reduce
27 emissions.

28 Traditionally there is a disconnection between IAM models and bottom-up sectoral or city-based
29 models due to the different scale (both spatial and temporal) and focus (climate mitigation vs. urban
30 pollutions, safety (Creutzig 2016)). The proliferation of shared and on-demand mobility solutions are
31 leading to rebound effects for travel demand (Chen and Kockelman 2016; Coulombel et al. 2019) and
32 this is a new challenge for modelling. Some IAM studies have recently begun to explore demand-side
33 solutions for reducing transport demand to achieve very low-carbon scenarios through a combination
34 of culture and low-carbon lifestyle (Creutzig et al. 2018; van Vuuren et al. 2018); urban development
35 (Creutzig et al. 2015a); increased vehicle occupancy (Grubler et al. 2018); improved logistics and
36 streamline supply chains for the freight sector (Mulholland et al. 2018); and disruptive low-carbon
37 innovation, described as technological and business model innovations offering "novel value
38 propositions to consumers and which can reduce GHG emissions if adopted at scale" (Wilson et al.
39 2019). In the literature from national models, demand has been differentiated between conventional and
40 sustainable development scenarios through narratives built around policies, projects, and programs
41 envisaged at the national level (Shukla et al. 2015; Dhar and Shukla 2015) and price elasticities of travel
42 demand (Dhar et al. 2018). However, a greater understanding of the mechanisms underlying energy-
43 relevant decisions and behaviours (Brosch et al. 2016), and the motivations for sustainable behaviour
44 (Steg et al. 2015) are critically needed to realize these solutions in reality.

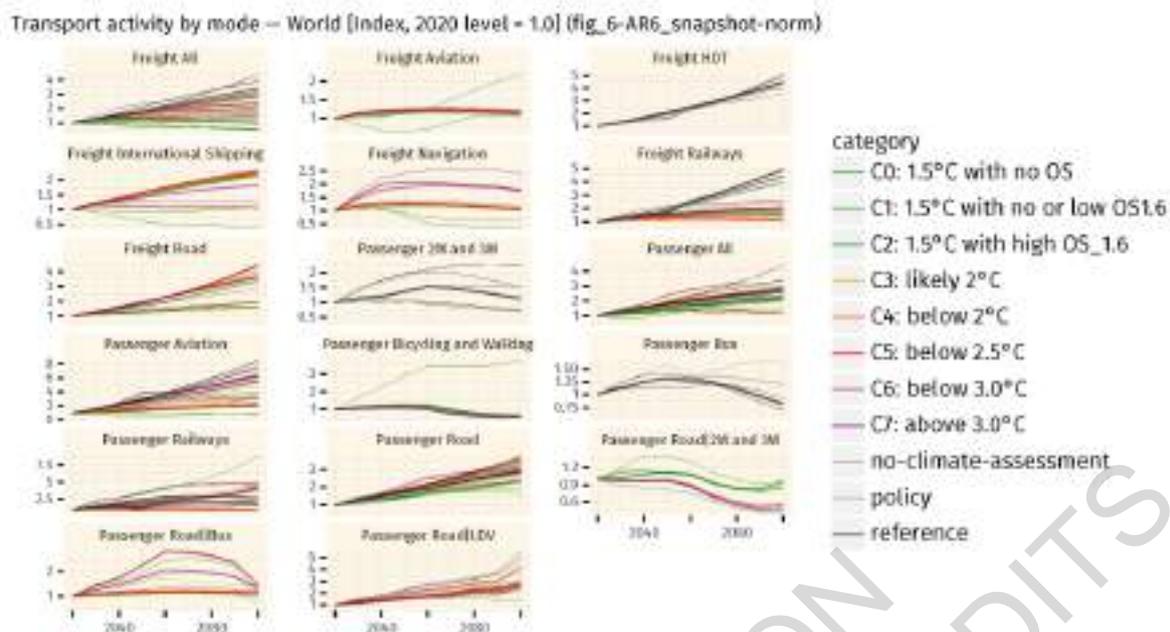

45 Overall, passenger and freight activity are likely to continue to grow rapidly under the C7 (>3.0°C)
46 scenarios, but most growth would occur in developing countries. Most models treat travel demand
47 exogenously following the growth of population and GDP, but they have limited representation of
48 responses to price changes, policy incentives, behavioural shifts, nor innovative mobility solutions that

1 can be expected to occur in more stringent mitigation scenarios Chapter 5 provides a more detailed
2 discussion of the opportunities for demand changes that may results from social and behavioural
3 interventions.

5 **10.7.4 Transport modes trajectories**

6 Globally over the last century, shares of faster transport modes have generally increased with increasing
7 passenger travel demand (Schafer and Victor 2000; Schäfer 2017). For short- to medium-distance
8 travel, private cars have displaced public transit, particularly in OECD countries, due to a variety of
9 factors, including faster travel times in many circumstances (Liao et al. 2020); increasing consumers'
10 value of time and convenience with GDP growth; and broader transport policies, e.g. provision of road
11 versus public transit infrastructure (Mattioli et al. 2020). For long-distance travel, travel via aviation for
12 leisure and business has increased (Lee et al. 2021). These trends do not hold in all countries and cities,
13 as many now have rail transit that is faster than driving (Newman et al. 2015a). For instance, public
14 transport demand rose from 1990 through 2016 in France, Denmark, and Finland (eurostat 2019). In
15 general, smaller and denser countries and cities with higher or increasing urbanization rates tend to have
16 greater success in increasing public transport share. However, other factors, like privatisation of public
17 transit (Bayliss and Mattioli 2018) and urban form (ITF 2021), also play a role. Different transport
18 modes can provide passenger and freight services, affecting the emissions trajectories for the sector.

19 Figure 10.19 shows activity trajectories for freight and passenger transport through 2100 relative to a
20 modelled year 2020 across different modes based on the AR6 database for IAMs and global transport
21 models. Globally, climate scenarios from IAMs, and policy and reference scenarios from global
22 transport models indicate increasing demand for freight and passenger transport via most modes through
23 2100 (Yeh et al. 2017; Zhang et al. 2018; Mulholland et al. 2018; Khalili et al. 2019). Road passenger
24 transport exhibits a similar increase (roughly tripling) through 2100 across scenarios. For road
25 passenger transport, scenarios that limit warming to 1.5 °C (C1-C2) have a smaller increase from
26 modelled 2020 levels (median increase of 2.4 times modelled 2020 levels) than do scenarios with higher
27 warming levels (C3-C8) (median increase of 2.7-2.8 times modelled 2020 levels). There are similar
28 patterns for passenger road transport via light-duty vehicle, for which median increases from modelled
29 2020 levels are smaller for C1-2 (3 times larger) than for C3-5 (3.1 times larger) or C6-7 (3.2 times
30 larger). Passenger transport via aviation exhibits a 2.2 times median increase relative to modelled 2020
31 levels under C1-2 and C3-5 scenarios but exhibits a 6.2 times increase under C6-C8. The only passenger
32 travel mode that exhibits a decline in its median value through 2100 according to IAMs is
33 walking/bicycling, in C3-5 and C6-8 scenarios. However, in C1-2 scenarios, walking/bicycling
34 increases by 1.4 times relative to modelled 2020 levels. At the 5th percentile of IAM solutions (lower
35 edge of bands in Figure 10.19), buses and walking/bicycling for passenger travel both exhibit significant
36 declines.

1
2 **Figure 10.19 Transport activity trajectories for passenger and freight across different modes. Global**

5 **are global transport models Ref and Policy scenarios. Data from the AR6 scenario database. Trajectories**
6 **span the 5th/95th percentiles across models with a solid line indicating the median value across models.**

7
8 For freight, Figure 10.19 shows that the largest growth occurs in transport via road (Mulholland et al.
9 2018). By 2100, global transport models suggest a roughly 4 times increase in median- heavy-duty
10 trucking levels relative to modelled 2020 levels, while IAMs suggest a 2-4 times increase in freight
11 transport by road by 2100. Notably, the 95th percentile of IAM solutions see up to a 4.7 times increase
12 in road transport through 2100 relative to modelled 2020 levels, regardless of warming level. Other
13 freight transport modes – aviation, international shipping, navigation, and railways – exhibit less growth
14 than road transport. In scenarios that limit warming to 1.5 °C (C1-C2), navigation and railway remain
15 largely unchanged and international shipping roughly doubles by 2100. Scenarios with higher warming
16 (i.e., moving from C1-2 to C6-8) generally lead to more freight by rail and less freight by international
17 shipping.

18 Relative to global trajectories, upper-income regions – including North America, Europe, and the
19 Pacific OECD – generally see less growth in passenger road via light-duty vehicle and passenger
20 aviation, given more saturated demand for both. Other regions like China exhibit similar modal trends
21 as the global average, whereas regions such as the African continent and Indian subcontinent exhibit
22 significantly larger shifts, proportionally, in modal transport than the globe. In particular, the African
23 continent represents the starkest departure from global results. Freight and passenger transport modes
24 exhibit significantly greater growth across Africa than globally in all available scenarios. Across Africa,
25 median freight and passenger transport via road from IAMs increases by 5-16 times and 4-28 times,
26 respectively, across warming levels by 2100 relative to modelled 2020 levels. Even C1 has considerable
27 growth in Africa via both modes (3-16 times increase for freight and 4-29 times increase for passenger
28 travel at 5th and 95th percentiles of IAM solutions by 2100).

29 As noted in Section 10.2, commonly explored mitigation options related to mode change include a shift
30 to public transit, shared mobility, and demand reductions through various means, including improved
31 urban form, teleconferences that replace passenger travel (Creutzig et al. 2018; Grubler et al. 2018;

1 Wilson et al. 2019), improved logistics efficiency, green logistics, and streamlined supply chains for
2 the freight sector (Mulholland et al. 2018). NDCs often prioritize options like bus improvements and
3 enhanced mobility that yield pollution, congestion, and urban development co-benefits, especially in
4 medium and lower-income countries (Fulton et al. 2017). Conversely, high-income countries, most of
5 which have saturated and entrenched private vehicle ownership, typically focus more on technology
6 options, e.g., electrification and fuel efficiency standards (Gota et al. 2016). Available IAM and regional
7 models are limited in their ability to represent modal shift strategies. As a result, mode shifts alone do
8 not differentiate climate scenarios. While this lack of representation is a limitation of the models, it is
9 unlikely that such interventions would completely negate the increases in demand the models suggest.
10 Therefore, transport via light-duty vehicle and aviation, freight transport via road, and other modes will
11 likely continue to increase through end-of-century. Consequently, fuel and carbon efficiency and fuel
12 energy and technology will probably play crucial roles in differentiating climate scenarios, as discussed
13 in the following sub-sections.

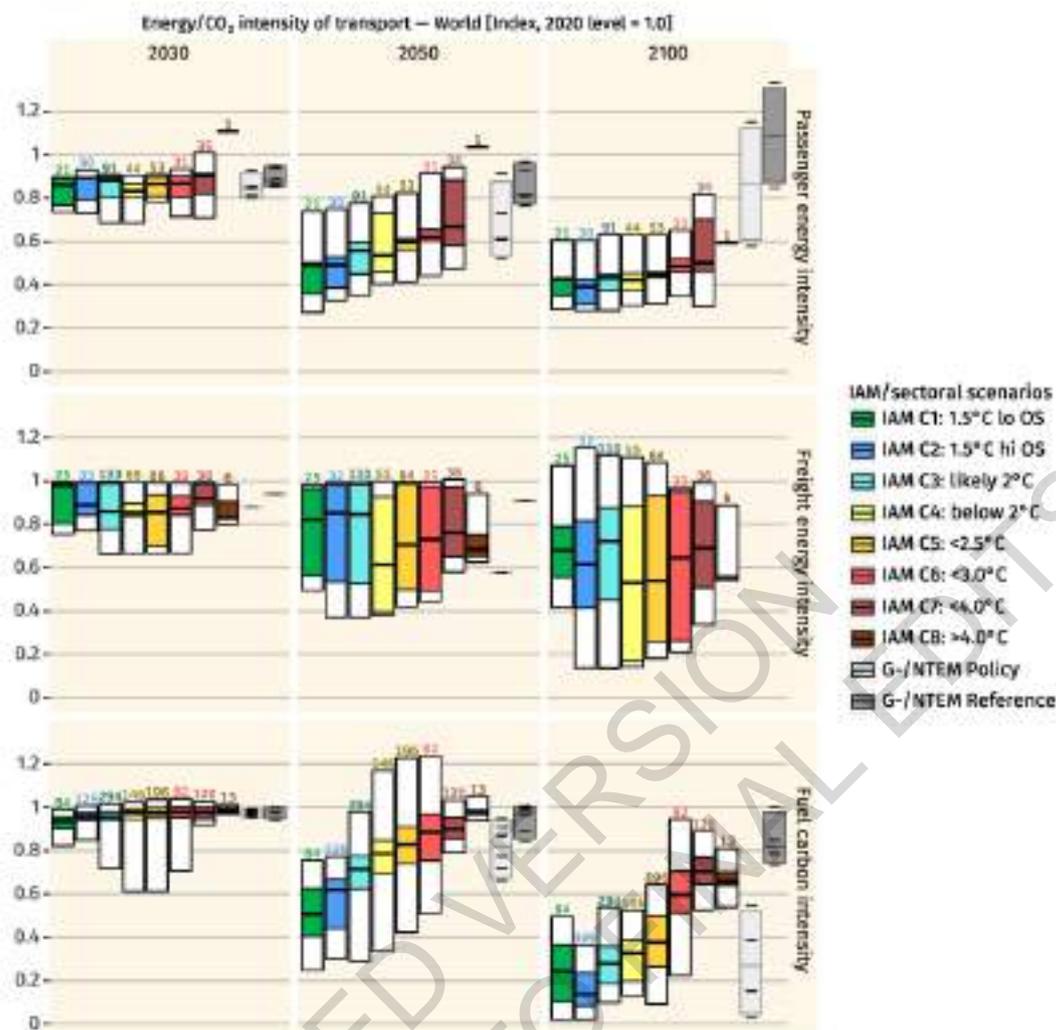

14

15 **10.7.5 Energy and Carbon efficiency trajectories**

16 This section explores what vehicle energy efficiencies and fuel carbon intensity trajectories, from the
17 data available in AR6 database from IAMs and GTEMs, could be compatible with different temperature
18 goals. Figure 10.20 shows passenger and freight energy intensity, and fuel carbon intensity indexed
19 relative to 2020Mod values. The top panel shows passenger energy intensity across all modes. LDVs
20 constitute a major share of this segment. (Yeh et al. 2017) report 2.5-2.75 MJ vkm⁻¹ in 2020 across
21 models for the LDV segment, which is also very close to the IEA estimate of 2.5 MJ vkm⁻¹ for the
22 global average fuel consumption for LDVs in 2017 (IEA 2020d). For reference, these numbers
23 correspond to 1.6-1.7 MJ pkm⁻¹ for an occupancy rate of 1.5. The following results of the AR6 database
24 are conditional on the corresponding reductions in fuel carbon intensity. Figure 10.20 shows that the
25 scenarios suggest that passenger transport's energy intensity drops to between 10%-23% (interquartile
26 ranges across C1-C4) in 2030 for the scenarios in line with warming levels below 2°C. In 2050, the
27 medians across the group of 1.5°C scenarios (C1-C2) and 2°C scenarios (C2-C3) suggest energy
28 intensity reductions of 51% and 45-46% respectively. These values correspond to annual average
29 energy efficiency improvement rates of 2.3-2.4% and 2.0-2.1%, respectively, from 2020 to 2050. For
30 reference, the IEA reports an annual energy efficiency improvement rate of 1.85% per year in 2005-16
31 (IEA 2020d). In contrast, the results from GTEMs suggest lower energy efficiency improvement, with
32 median values for policy scenarios of 39% reduction in 2050, corresponding to annual energy efficiency
33 improvement rates close to 1.6%. The IAM scenarios suggest median energy intensity reductions of
34 passenger transport of 57-61% by the end of the century would align with warming levels of both 1.5°C
35 and 2°C (C1-C4) given the corresponding decarbonisation of the fuels.

36

37

3 **year across scenarios. Plots show 5th/95th percentile, 25th/75th percentile, and median. Numbers above the**
4 **bars indicate the number of scenarios. Data from the AR6 scenario database.**

5
6 The scenarios in line with warming levels of 1.5°C or 2°C goals show different trends for freight's
7 energy intensity. The amount of overshoot and differences in demand for freight services and, to some
8 extent, fuel carbon intensities contribute to these differences. For the two scenarios aligning with the
9 warming levels of 1.5°C, the trajectories in 2030 and 2050 are quite different. The median scenario in
10 the high overshoot bin (C2) takes a trajectory with lower energy intensity improvements in the first half
11 of the century. In contrast, the limited overshoot scenario (C1) takes on a more steadily declining
12 trajectory across the means. The IAMs provide a less clear picture of required energy intensity
13 improvements for freight than for passenger associated with different temperature targets. As for the
14 carbon intensity of direct energy used across both passenger and freight, the modelling scenarios
15 suggest very moderate reductions by 2030. The interquartile ranges for the C1 scenarios suggest global
16 average reductions in carbon intensity of 5%-10%. Across the other scenarios compatible with warming
17 levels of 1.5°C or 2°C (C2-4), the interquartile ranges span from 1%-6% reductions in carbon intensity
18 of direct energy used for transport. For 2050 the scenarios suggest that dependence on fuel
19 decarbonisation increases with more stringent temperature targets. For the 1.5°C scenarios (C1), global
20 carbon intensity of energy used for transport decreases by 37%-60% (interquartile range) by 2050 with
21 a mean of 50% reduction. The IAM scenarios in the AR6 database do not suggest full decarbonisation

1 of transport fuels by 2100. The interquartile ranges across the C1-C4 set of scenarios, compatible with
2 warming levels of 2°C and less, span from 61%-91% reduction from 2020Mod levels.

3 Increasing occupancy rate of passenger transport (Grubler et al. 2018) and reducing empty miles or
4 increasing payload in freight deliveries (Gucwa and Schäfer 2013; McKinnon 2018) via improved
5 logistics efficiency or streamlined supply chains (Mulholland et al. 2018), can present significant
6 opportunities to effectively improve energy efficiency and decrease GHG emissions in transport.
7 However, the recent trends of consumer behaviours have shown a declining occupancy rate of light-
8 duty vehicles in industrialized countries (Schäfer and Yeh 2020), and the accelerating growing
9 preference for SUVs challenges emissions reductions in the passenger car market (IEA 2019d). These
10 trends motivate a strong focus on demand-side options.

11 Based on the scenario literature, a 51% reduction in median energy intensity of passenger transport and
12 a corresponding reduction of 38%-50% reduction in median carbon intensity by 2050 would be aligned
13 with transition trajectories yielding warming levels below 1.5°C by the end of the century. For
14 comparison, the LCA literature suggests a switch from current ICEs to current BEVs would yield a
15 reduction in energy intensity well beyond 45% and up to 70%, for a mid-sized vehicle (see Sections
16 10.4). Correspondingly, a switch from diesel or gasoline to low-carbon electricity or low-carbon
17 Hydrogen would yield carbon intensity reduction beyond the median scenario value. Thus, the LCA
18 literature suggests technologies exist today that would already match and exceed the median energy and
19 carbon intensities values that might be needed by 2050 for low warming levels.

20

21 **10.7.6 Fuel energy and technology trajectories**

22 Two mechanisms for reducing carbon emissions from the transport sector are fuel switching for current
23 vehicle technologies and transitioning to low carbon vehicle technologies. Figure 10.21 combines data
24 from IAMs and GTEMs on shares of transport final energy by fuel. These shares account for fuels uses
25 across modes - road, aviation, rail, and shipping- and both passenger and freight transport. Since the
26 technologies have different conversion efficiencies, these shares of final energy by fuel are necessarily
27 different from the shares of service (passenger- or ton-km) by fuel and shares of vehicle stock by fuel.
28 For example, a current battery-electric LDV powertrain is roughly 3 times more energy-efficient than
29 a comparable ICE powertrain (see Section 10.3, and Table 10.9 in Appendix 10.1); thus, fuel shares of
30 0.25 for electricity and 0.75 for oil could correspond to vehicle stock shares of 0.5 and 0.5, respectively.
31 In general, while models may project that EVs constitute a greater share of road vehicle stock, and
32 provide a greater share of road passenger-kilometres, their share of transport final energy (shown in
33 Figure 10.21) can still remain lower than the final energy share of fuels used in less-efficient (e.g. ICE)
34 vehicles. Thus, the shares of transport final energy by fuel presented in Figure 10.21 should be
35 interpreted with care.

36

37

38

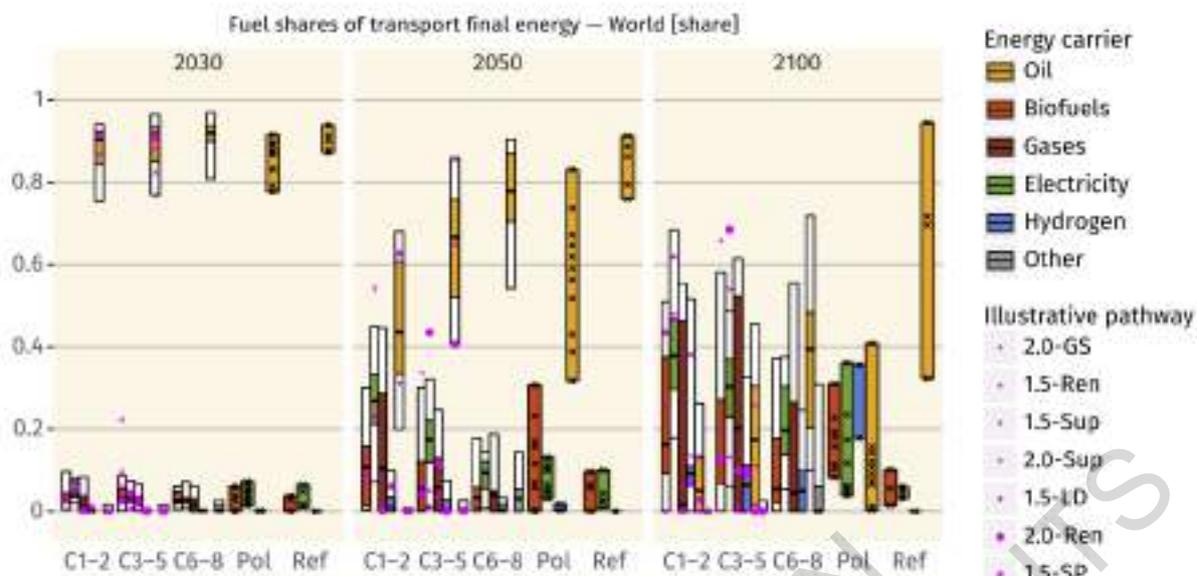

Figure 10.21 Global shares of final fuel energy in the transport sector in 2030, 2050, and 2100 for freight and passenger vehicles. Plots show 10th/90th percentile, 25th/75th percentile, and median. Data from the AR6 scenario database.

IAM and GTEM scenarios indicate that fuel and technology shifts are crucial to reduce carbon emissions to achieve lower levels of warming (Edelenbosch et al. 2017; IEA 2017b). Across the transport sector, a technology shift towards advanced fuel vehicles is the dominant driver of decarbonisation in model projections. This trend is consistent across climate scenarios, with larger decreases in the final energy share of oil in scenarios that achieve progressively lower levels of warming. Due to efficiency improvements; the higher efficiency of advanced fuel vehicles; and slower progress in the freight sector, the final energy share of oil decreases more rapidly after 2030. By 2050, the final energy shares of electricity, biofuels, and alternative gaseous fuels increase, with shares from electricity generally about twice as high (median values from 10%–30% across warming levels) as the shares from biofuels and gases (median values from 5%–10%). While IAMs suggest that the final energy share of hydrogen will remain low in 2050, by 2100 the median projections include 5%–10% hydrogen in transport final energy.

While only few IAMs report final energy shares by transport mode or passenger/freight, several relevant studies provide insights into fuel share trends in passenger LDVs and freight. The IEA suggests that full LDV electrification would be the most promising low-carbon pathway to meet a 1.75°C goal (IEA 2017b). The MIT Economic Projection and Policy Analysis (EPPA) model focuses on the future deployment of gasoline versus EV technologies in the global LDV stock (Ghandi and Paltsev 2019). These authors estimate that the global stock of vehicles could increase from 1.1 billion vehicles in 2015 up to 1.8 billion by 2050, with a growth in EVs from about 1 million vehicles in 2015 up to 500 million in 2050. These changes are driven primarily by cost projections (mostly in battery cost reductions). Similarly, the International Council on Clean Transport (ICCT) indicates that EV technology adoption in the light-duty sector can lead to considerable climate benefits. Their scenarios reach nearly 100% electrification of LDVs globally, leading to global GHG emissions ranging from 0% to -50% of 2010 LDV levels in 2050 (Lutsey 2015). Khalili *et al* (2019) estimate transport stocks through 2050 under aggressive climate mitigation scenarios that nearly eliminate road transport emissions. They find the demand for passenger transport could triple through 2050, but emissions

1 targets could be met through widespread adoption of BEVs (80% of LDVs) and, to a lesser extent, fuel
2 cell and plug-in hybrid electric vehicles. Contrary to these estimates, the US Energy Information
3 Administration (EIA) finds small adoption of electrification for LDVs and instead identifies diffusion
4 of natural gas-fuelled LDVs in OECD and, to a greater extent, non-OECD countries through 2040. This
5 trend occurs in a reference and a "low liquids" case, which lowers LDV ownership growth rates and
6 increases preferences for alternative fuel vehicles. A comprehensive overview of regional technology
7 adoption models across many methodological approaches can be found in (Jochem et al. 2018).

8 In freight transport, studies indicate a shift toward alternative fuels would need to be supplemented by
9 efficiency improvements. The IEA suggests efficiency improvements would be essential for
10 decarbonisation of trucks, aviation, and shipping in the short-to-medium term. At the same time, the
11 IEA suggests that fuel switching to advanced biofuels would be needed to decarbonise freight in the
12 long-term (IEA 2019d). Mulholland et al. (2018) investigated the impacts of decarbonising road freight
13 in two scenarios: countries complying with COP21 pledges and a second more ambitious reduction
14 scenario in line with limiting global temperature rise to 1.75°C. Despite the deployment of logistics
15 improvements, high-efficiency technologies, and low carbon fuels, activity growth leads to a 47%
16 increase in energy demand for road freight while overall GHG emissions from freight increase by 55%
17 (4.8 GtCO₂eq) in 2050 (relative to 2015) in the COP21 scenario. In the 1.75°C scenario, decarbonisation
18 happens primarily through a switch to alternative fuels (hybrid electric and full battery-electric trucks),
19 which leads to a 60% reduction in GHG emissions from freight in 2050 relative to 2015. Khalili et al.
20 (2019) also find substantial shifts to alternative fuels in HDVs under aggressive climate mitigation
21 scenarios. Battery electricity, Hydrogen fuel cell, and plug-in hybrid electric vehicles constitute 50%,
22 30%, and 15% of heavy-duty vehicles, respectively, in 2050. They also find 90% of buses would be
23 electrified by 2050.

24 25 **START BOX HERE**

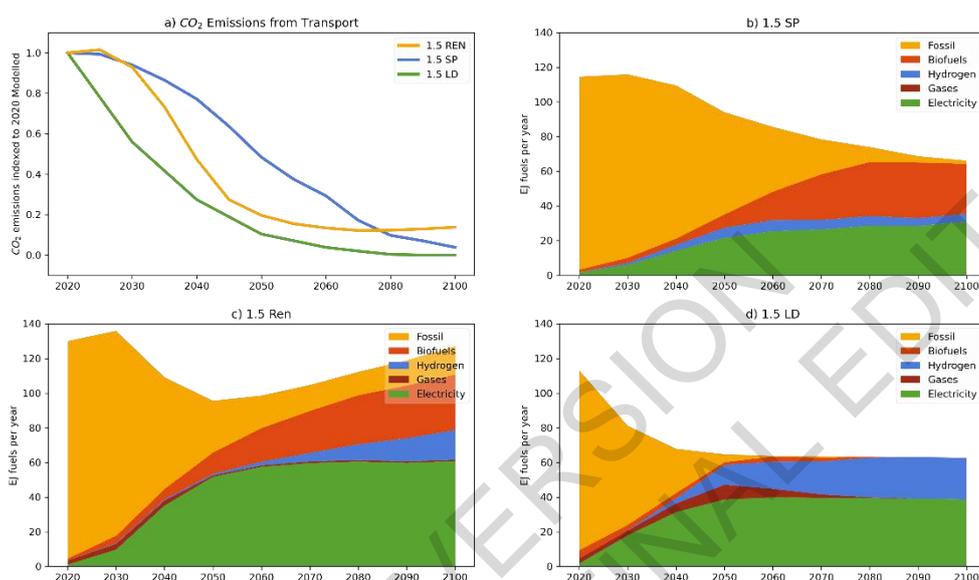

26 **Box 10.4 Three Illustrative Mitigation Pathways.**

27
28 Section 10.7 presents the full set of scenarios in the AR6 database and highlight the broader trends of
29 how the transport sector may transform in order to be compliant with different warming levels. This
30 box elaborates on three illustrative mitigation pathways (IMPs) to exemplify a few different ways the
31 sector may transform. A total of 7 illustrative pathways are introduced in section 3.2.5 of chapter 3. In
32 this box we focus on three of the IMPs: (1) focus on deep renewable energy penetration and
33 electrification (IMP-Ren), (2) low demand (IMP-LD) and (3) pathways that align with both sustainable
34 development goals as well as climate policies (IMP-SP). In particular, the variants of these three
35 scenarios limit warming to 1.5°C with no or limited overshoot (C1). All of the three selected pathways
36 reach global net zero CO₂ emissions across all sectors between 2060 and 2070, but not all reach net
37 zero GHG emissions (see Figure 3.4 Chapter 3). Panel (a) in Box 10.4, Figure 1 below shows the CO₂
38 trajectories for the transport sector for the selected IMPs. Please note that the year 2020 is modelled in
39 these scenarios. Therefore, the scenarios do not reflect the effects of the COVID-19 pandemic. For the
40 low demand scenarios IMP-LD and renewables pathway IMP-Ren, CO₂ emissions from the transport
41 sectors decrease to 10% and 20% of modelled 2020 levels by 2050, respectively. In contrast, the IMP-
42 SP has a steady decline of transport sector CO₂ emissions over the century. By 2050, this scenario has
43 a 50% reduction in emissions compared to modelled 2020 levels. Panels (b), (c) and (d) show energy
44 by different fuels for the three selected IMPs. The IMPs-SP yields a drop in energy for transport of
45 about 40% by the end of the century. CO₂ emission reductions are obtained through a phase-out of fossil
46 fuels with electricity and biofuels, complemented by a minor share of Hydrogen by the end of the
47 century. In IMP Ren, the fuel energy demand at the end of the century is in par with the 2020 levels,
48 but the fuel mix has shifted towards a larger share of electricity complimented by biofuels and a minor

1 share of Hydrogen. For the IMP-LD scenario, the overall fuel demand decreases by 45% compared to
 2 2020 levels by the end of the century. Oil is largely phased out by mid-century, with electricity and
 3 Hydrogen becoming the major fuels in the second half of the century. Across the three IMPs, electricity
 4 plays a major role, in combination with biofuels, Hydrogen, or both.

13 **END BOX HERE**

14

15 **10.7.7 Insights from the modelling literature**

16 This section provides an updated, detailed assessment of future transport scenarios from IAM and G-
 17 /NTEMs given a wide range of assumptions and under a set of policy targets and conditions. The
 18 scenario modelling tools are necessary to aggregate individual options and understand how they fit into
 19 mitigation pathways from a systems perspective. The scenarios suggest that 43% (30-63% for the inter
 20 quartile ranges) reductions in CO₂ emissions from the transport emissions CO₂ (below modelled 2020
 21 levels) by 2050 would be compatible with warming levels of 1.5°C (C1-C2 group). While the global
 22 scenarios suggest emissions reductions in energy supply sectors at large precede those in the demand
 23 sectors (see section 3.4.1), a subset of the scenarios also demonstrate that more stringent emission
 24 reductions in the transport sector are feasible. For example, the illustrative mitigation pathways IMP-
 25 REN and IMP-LD suggest emission reductions of respectively 80% and 90% are feasible by 2050 en-
 26 route to warming levels of 1.5°C (C1-C2) with low or no overshoot by the end of the century.

1 The scenarios from the different models project continued growth in demand for freight and passenger
2 services, particularly in developing countries. The potential of demand reductions is evident, but the
3 specifics of demand reduction measures remain less explored by the scenario literature. This limitation
4 not-withstanding, the IAM and GTEMs suggest interventions that reduce the energy and fuel carbon
5 intensity are likely crucial to successful mitigation strategies.

6 The scenario literature suggests that serious attempts at carbon mitigation in the transport sector must
7 examine the uptake of alternative fuels. The scenarios described in the IAMs and GTEMs literature
8 decarbonise through a combination of fuels. Across the scenarios, electrification plays a key role,
9 complemented by biofuels and Hydrogen. In general terms, electrification tends to play the key role in
10 passenger transport while biofuels and Hydrogen are more prominent in the freight segment. The three
11 illustrative mitigation pathways in Box 10.4 exemplify different ways these technologies may be
12 combined and still be compatible with warming levels of 1.5°C with low or no overshoot. Shifts towards
13 alternative fuels must occur alongside shifts towards clean technologies in other sectors, as all
14 alternative fuels have upstream impacts. Without considering other sectors, fuel shifts would not yield
15 their full mitigation potentials. These collective efforts are particularly important for the electrification
16 of transport, as the transformative mitigation potential is strongly dependent on the decarbonisation of
17 the power sector. In this regard, the scenario literature is well aligned with the LCA literature reviewed
18 in Section 10.4.

19 The models reviewed in this section would all generally be considered to have a good representation of
20 fuels, technologies, and costs, but they often better represent land transport modes than shipping and
21 aviation. While these models have their strengths in some areas, they have some limitations in other
22 areas, like behavioural aspects. Analogously, these models are also limited in their ability to account
23 for unexpected technological innovation such as a breakthrough in heavy vehicle fuels, AI, autonomy
24 and big data, even the extent of digital communications replacing travel (see Section 10.2). As a result
25 of these type of limitations, the models cannot yet provide a fully exhaustive set of options for
26 decarbonising the transport sectors. These limitations not-withstanding, the models can find solutions
27 encompassing the transport sector and its interactions with other sectors that are compatible with
28 stringent emissions mitigation efforts. The solution space of transportation technology trajectories is
29 therefore wider than explored by the models, so there is still a need to better understand how all options
30 in combination may support the transformative mitigation targets.

32 **10.8 Enabling conditions**

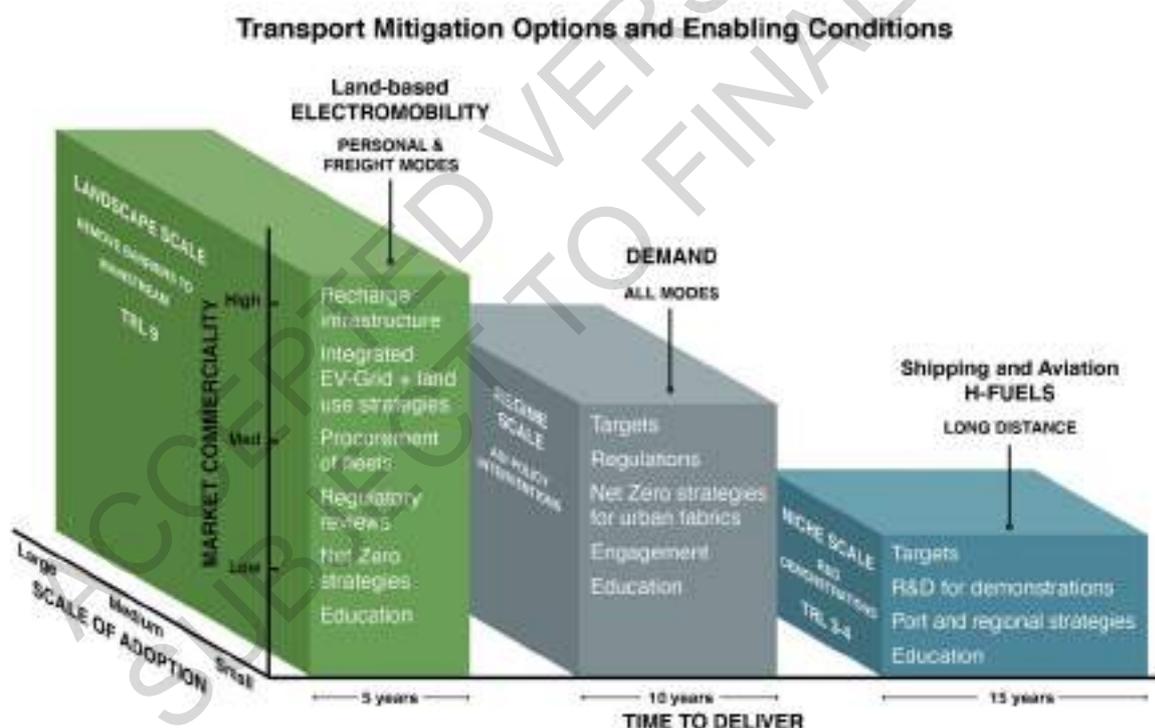

33 **10.8.1 Conclusions across the chapter**

34 This final section draws some conclusions from the chapter, provides an overview-based feasibility
35 assessment of the major transport mitigation options, as well as a description of emerging issues. The
36 section ends by outlining an integrated framework for enabling the transformative changes that are
37 emerging and required to meet the potential transformative scenarios from Section 10.7.

38 Transport is becoming a major focus for mitigation as its GHG emissions are large and growing faster
39 than for other sectors, especially in aviation and shipping. The scenarios literature suggests that without
40 mitigation actions, transport emissions could grow by up to 65% by 2050. Alternatively, successful
41 deployment of mitigation strategies could reduce sectoral emissions by 68%, which would be consistent
42 with the goal of limiting temperature change to 1.5°C above pre-industrial levels. This chapter has
43 reviewed the literature on all aspects of transport and has featured three special points of focus: (1) A
44 survey of life cycle analysis from the academic and industry community that uses these tools; (2) A
45 similar exercise of surveying the modelling community for top-down and bottom-up approaches to
46 identify decarbonisation pathways for the transport sector, and (3) For the first time in the IPCC,

1 separate sections on shipping and aviation. The analysis of the literature suggests three crucial
 2 components for the decarbonisation of the transport sector: demand and efficiency strategies,
 3 electromobility, and alternative fuels for shipping and aviation.

4 The challenge of decarbonisation requires a transition of the socio-technical system, which in turn
 5 depends on the combination of technological innovation and societal change (Geels et al. 2017). A
 6 socio-technical system includes technology, regulation, user practices and markets, cultural meaning,
 7 infrastructure, maintenance networks, and supply networks (Geels 2005) (see Cross Chapter Box 12 in
 8 Chapter 16). The multi-level perspective (MLP) is a framework that provides insights to assist
 9 policymakers when devising transformative transition policies (Rip and Kemp 1998; Geels 2002).
 10 Under the MLP framework, strategies are grouped into three different categories. The Micro level
 11 (niche) category includes strategies where innovation differs radically to that of the incumbent socio-
 12 technical system. The niche provides technological innovations a protected space during development
 13 and usually requires considerable R&D and demonstrations. In the Meso level (regime) state,
 14 demonstrations begin to emerge as options that can be adopted by leading groups who begin to
 15 overcome lock-in barriers from previous technological dependence. Finally, in the Macro level
 16 (Landscape) stage, main-streaming happens, and the socio-technical system enables innovations to
 17 breakthrough. Figure 10.22 maps the MLP stage for the major mitigation strategies identified in this
 18 chapter.

20 **Figure 10.22 Mitigation Options and Enabling Conditions for Transport. Niche scale includes strategies**
 21 **that still require innovation.**

22
 23
 24 *Demand and behaviour.* While technology options receive substantial attention in this chapter, there
 25 are many social and equity issues that cannot be neglected in any transformative change to mitigate
 26 climate change. Transport systems are socio-economic systems that include systemic factors that are
 27 developing into potentially transformative drivers of emissions from the sector. These systemic drivers
 28 include, for example, changes in urban form that minimises automobile dependence and reduces

1 stranded assets; behaviour change programs that emphasise shared values and economies; smart
2 technologies that enable better and more equitable options for transit and active transport as well as
3 integrated approaches to using autonomous vehicles; new ways of enabling electric charging systems
4 to fit into electricity grids creating synergistic benefits to grids, improving the value of electric transit,
5 and reducing range anxiety for EV users; and, new concepts for the future economy such as circular
6 economy, dematerialisation, shared economy that have the potential to affect the structure of the
7 transport sector. The efficacy of demand reductions and efficiency opportunities depends on the degree
8 of prioritisation and focus by government policy. Figure 10.22 suggests that innovative demand and
9 efficiency strategies are at the regime scales. While these strategies are moving beyond R&D, they are
10 not mainstreamed yet and have been shown to work much more effectively if combined with technology
11 changes as has been outlined in the transformative scenarios from Section 10.7 and in Chapter 5.

12 *Electromobility in Land-based Transport.* Since AR5, there has been a significant breakthrough in the
13 opportunities to reduce transport GHG emissions in an economically efficient way due to electrification
14 of land-based vehicle systems, which are now commercially available. EV technologies are particularly
15 well-established for light duty passenger vehicles, including micro mobility. Furthermore, there are
16 positive developments to enable EV technologies for buses, light and medium-duty trucks, and some
17 rail applications (though advanced biofuels and hydrogen may also contribute to the decarbonisation of
18 these vehicles in some contexts). In developing countries, where micro mobility and public transit
19 account for a large share of travel, EVs are ideal to support mitigation of emissions. Finally, demand
20 from critical materials needed for batteries has become a focus of attention, as described in Box 10.6.

21 Electromobility options are moving from regime to landscape levels. This transition is evident in the
22 trend of incumbent automobile manufacturers producing an increasing range of EVs in response to
23 demand, policy, and regulatory signals. EVs for light-duty passenger travel are largely commercial and
24 likely to become competitive with ICE vehicles in the early 2020's (Dia 2019; Bond et al. 2020;
25 Koasidis et al. 2020). As these adopted technologies increase throughout cities and regions,
26 governments and energy suppliers will have to deploy new supporting infrastructure to support them,
27 including reliable low-carbon grids and charging stations (Sierzchula et al. 2014). In addition,
28 regulatory reviews will be necessary to ensure equitable transition and achievement of SDG's,
29 addressing the multitude of possible barriers that may be present due to the incumbency of traditional
30 automotive manufacturers and associated supporting elements of the socio-technical system (Newman
31 2020b); and Chapter 6). Similarly, new partnership between government, industry, and communities
32 will be needed to support the transition to electromobility. These partnerships could be particularly
33 effective at supporting engagement and education programs ((Newman 2020b); and Chapter 8).

34 Deployment of electromobility is not limited to developed countries. The transportation sector in low-
35 and middle-income countries includes millions of gas-powered motorcycles within cities across Africa,
36 Southeast Asia, and South America (Ampersand 2020; Ehebrecht et al. 2018; Posada et al. 2011). Many
37 of these motorcycles function as taxis. In Kampala, Uganda, estimates place the number of motorcycle
38 taxis, known locally as boda-bodas, at around 40,000 (Ehebrecht et al. 2018). The popularity of the
39 motorcycle for personal and taxi use is due to many factors including lower upfront costs, lack of
40 regulation, and mobility in highly congested urban contexts (UNECE 2018; Posada et al. 2011). While
41 motorcycles are often seen as a more fuel-efficient alternative, emissions can be worse from 2-wheelers
42 than cars, particularly nitrogen oxides (NO_x), carbon monoxide (CO), and hydrocarbon (HC) emissions
43 (Vasic and Weilenmann 2006; Ehebrecht et al. 2018). These 2-wheeler emissions contribute to
44 dangerous levels of air pollution across many cities in low- and middle-income countries. In Kampala,
45 for example, air pollution levels frequently exceed levels deemed safe for humans by the World Health
46 Organization (WHO) (Airqo 2020; World Health Organization 2018; Kampala Capital City Authority
47 2018). To mitigate local and environmental impacts, electric boda boda providers are emerging in many
48 cities, including Zembo in Kampala and Ampersand in Kigali, Rwanda.

1 Bulawayo, the capital city of Zimbabwe, is also looking at opportunities for deploying electromobility
2 solutions. The city is now growing again after a difficult recent history, and there is a new emphasis on
3 achieving the Sustainable Development Goals (City of Bulawayo 2020a,b). With this goal in mind,
4 Bulawayo is seeking opportunities for investment that can enable leapfrogging private, fossil fuel
5 vehicle ownership. In particular, trackless trams, paired with solar energy, have emerged as a potential
6 pathway forward (Kazunga 2019). Trackless trams are a new battery-based mid-tier transit system that
7 could enable urban development around stations that use solar energy for powering both transit and the
8 surrounding buildings (Newman et al. 2019). The new trams are rail-like in their capacities and speed,
9 providing a vastly better mobility system that is decarbonised and enable low transport costs (Ndlovu
10 and Newman 2020). While this concept is only under consideration in Bulawayo, climate funding could
11 enable the wider deployment of such projects in developing countries.

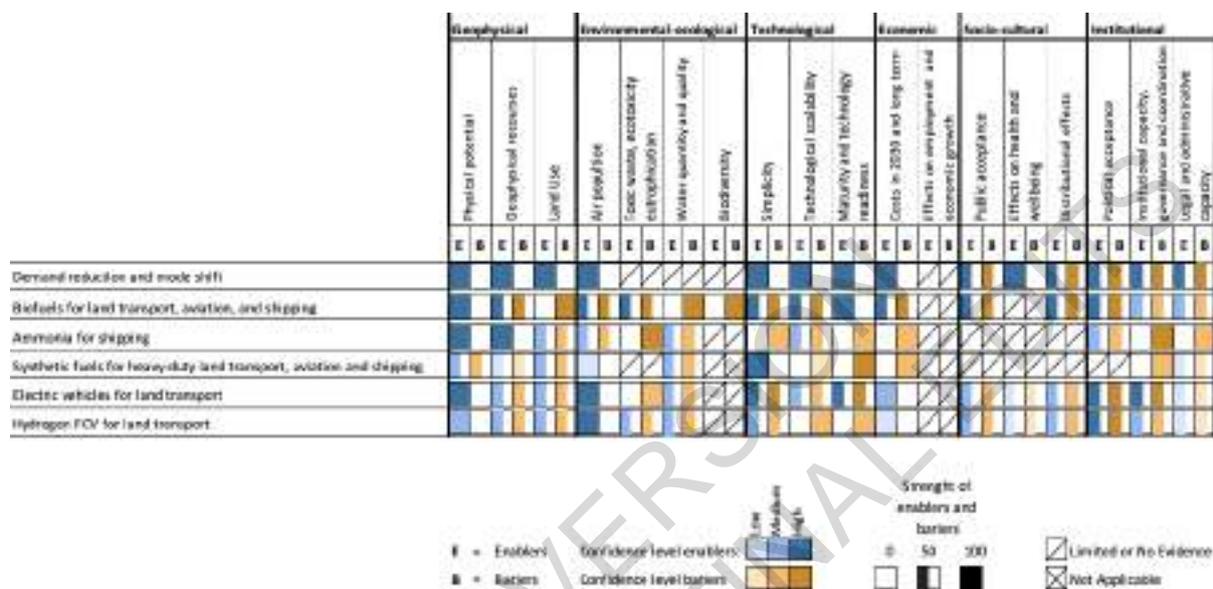

12 *Fuels for Aviation and Shipping.* Despite technology improvements for land-based transport, equivalent
13 technologies for long distance aviation and shipping remain elusive. Alternative fuels for use in long
14 range aviation and shipping are restricted to the niche level. The aviation sector is increasingly looking
15 towards synthetic fuels using low-carbon combined with CO₂ from direct air capture, while shipping is
16 moving towards Ammonia produced using low-carbon Hydrogen. Biofuels are also of interest for these
17 segments. To move out of the niche level, there is a need to set deployment targets to support
18 breakthroughs in these fuels. Similarly, there is a need for regulatory changes to remove barriers in new
19 procurement systems that accommodate uncertainty and risks inherent in the early adoption new
20 technologies and infrastructure (Borén 2019; Sclar et al. 2019; Marinaro et al. 2020). R&D programs
21 and demonstration trials are the best focus for achieving fuels for such systems. Finally, there is a need
22 for regulatory changes. Such regulatory changes need to be coordinated through ICAO and IMO as well
23 as with national implementation tools related to the Paris Agreement (see Box 10.5). Long-term visions,
24 including creative exercises for cities and regions will be required providing a protected space for the
25 purpose of trialling new technologies (Borén 2019; Geels 2019).

26

27 **10.8.2 Feasibility Assessment**

28 Figure 10.23 sets out the feasibility of the core mitigation options using the six criteria created for the
29 cross-sectoral analysis. This feasibility assessment outlines how the conclusions outlined in Section
30 10.8.1 fit into the broader criteria created for feasibility in the whole AR6 report and that emphasise the
31 SDGs. Figure 10.23 highlights that there is high confidence that demand reductions and mode shift can
32 be feasible as the basis of a GHG emissions mitigation strategy for the transport sector. However,
33 demand-side interventions work best when integrated with technology changes. The technologies that
34 can support such changes have a range of potential limitations as well as opportunities. EV have a
35 reliance on renewable resources (wind, solar, and hydro) for power generation, which could pose
36 constraints on geophysical resources, land use, water use. Furthermore, expanding the deployment of
37 EVs requires a rapid deployment of new power generation capacity and charging infrastructure. The
38 overall feasibility of electric vehicles for land transport is likely high and their adoption is accelerating.
39 HFCVs for land transport would also have constraints related to land geophysical resource needs, land
40 use, and water use. These constraints are likely higher than for EVs, since producing Hydrogen with
41 electricity reduces the overall efficiency of meeting travel demand. Furthermore, the infrastructure to
42 produce, transport, and deliver Hydrogen is under-developed and would require significant R&D and a
43 rapid scale-up. Thus, the feasibility of HFCV is likely lower than for EVs. Biofuels could be used in all
44 segments of the transport sector, but there may be some concerns about their feasibility. Specifically,
45 there are concerns about land use, water use, impacts on water quality and eutrophication, and
46 biodiversity impacts. Advanced biofuels could mitigate some concerns and the feasibility of using these
47 fuels likely varies by world region. The feasibility assessment for alternative fuels for shipping and
48 aviation suggests that Hydrogen-based fuels like Ammonia and synthetic fuels have the lowest

1 technology readiness of all mitigation options considered in this chapter. Reliance on electrolytic
 2 Hydrogen for the production of these fuels poses concerns about land and water use. Using Ammonia
 3 for shipping could pose risks for air quality and toxic discharges to the environment. The DAC/BECCS
 4 infrastructure that would be needed to produce synthetic fuel does not yet exist. Thus, the feasibility
 5 suggests that the technologies for producing and using these Hydrogen-based fuels for transport are in
 6 their infancy.
 7
 8

9
 10 **Figure 10.23 Summary of the extent to which different factors would enable or inhibit the deployment of**
 11 **mitigation options in Transport. Blue bars indicate the extent to which the indicator enables the**
 12 **implementation of the option (E) and orange bars indicate the extent to which an indicator is a barrier**
 13 **(B) to the deployment of the option, relative to the maximum possible barriers and enablers assessed. An**
 14 **‘X’ signifies the indicator is not applicable or does not affect the feasibility of the option, while a forward**
 15 **slash indicates that there is no or limited evidence whether the indicator affects the feasibility of the**
 16 **option. The shading indicates the level of confidence, with darker shading signifying higher levels of**
 17 **confidence. Appendix 10.3 provides an overview of the extent to which the feasibility of options may differ**
 18 **across context (e.g., region), time (e.g., 2030 versus 2050), and scale (e.g., small versus large), and includes**
 19 **a line of sight on which the assessment is based. The assessment method is explained in Annex II.11**

20
 21 **10.8.3 Emerging Transport Issues**

22 *Planning for integration with the power sector:* Decarbonising the transport sector will require
 23 significant growth in low-carbon electricity to power EVs, and more so for producing energy-intensive
 24 fuels, such as Hydrogen, Ammonia and synthetic fuels. Higher electricity demand will necessitate
 25 greater expansion of the power sector and increase land use. The strategic use of energy-intensive fuels,
 26 focussed on harder-to-decarbonise transport segments, can minimise the increase in electricity demand.
 27 Additionally, integrated planning of transport and power infrastructure could enable sectoral synergies
 28 and reduce the environmental, social, and economic impacts of decarbonising transport and energy. For
 29 example, smart charging of EVs could support more efficient grid operations. Hydrogen production,
 30 which is likely crucial for the decarbonisation of shipping and aviation, could also serve as storage for
 31 electricity produced during low-demand periods. Integrated planning of transport and power
 32 infrastructure would be particularly useful in developing countries where “greenfield” development
 33 doesn’t suffer from constraints imposed by legacy systems.

1 *Shipping and aviation governance*: Strategies to deliver fuels in sufficient quantity for aviation and
2 shipping to achieve transformative targets are growing in intensity and often feature the need to review
3 international and national governance. Some literature suggests that the governance of the international
4 transport systems could be included the Paris Agreement process (Gençsü and Hino 2015; Traut et al.
5 2018; Lee 2018). Box 10.6 sets out these issues.

6

7 **START BOX HERE**

8

9

Box 10.5 Governance Options for shipping and aviation

10 Whenever borders are crossed, the aviation and shipping sector creates international emissions that are
11 not assigned to states' Nationally Declared Contributions in the Paris Agreement. Emissions from these
12 segments are rapidly growing (apart from COVID affecting aviation) and are projected to grow between
13 60% to 220% by 2050 (IPCC 2018; UNEP 2020). Currently, the International Civil Aviation
14 Organization (ICAO) and the International Marine Organization (IMO), specialised UN Agencies, are
15 responsible for accounting and suggesting options for managing these emissions.

16 **Transformational goals?**

17 ICAO has two global aspirational goals for the international aviation sector: 2% annual fuel efficiency
18 improvement through 2050; and carbon neutral growth from 2020 onwards. To achieve these goals,
19 ICAO has established CORSIA – Carbon Offsetting and Reduction Scheme for International Aviation,
20 a market-based program.

21 In 2018, IMO adopted an 'Initial Strategy' on the reduction of GHG emissions from ships. This strategy
22 calls for a reduction of the carbon intensity of new ships through implementation of further phases of
23 the energy efficiency design index (EEDI). Similarly, the IMO calls for a 40% reduction of the carbon
24 intensity of international shipping by 2030, and is striving for a 70% reduction by 2050. Such reductions
25 in carbon intensity would result in an overall decline in emissions of 50% in 2050 (relative to 2008).

26 These goals are likely insufficiently transformative for the decarbonisation of aviation or shipping,
27 though they are moving towards a start of decarbonisation at a period in history where the options are
28 still not clear, as set out in Sections 10.5 and 10.6.

29 **Regulations?**

30 The ICAO is not a regulatory agency, but rather produces standards and recommended practices that
31 are adopted in national/international legislation. IMO does publish 'regulations' but does not have
32 power of enforcement. Non-compliance can be regulated by nation states if they so desire, as a ship's
33 'MARPOL' certificate, issued by the flag state of the ship, means there is some responsibility for states
34 with global shipping fleets.

35 **Paris?**

36 Some commentators have suggested that emissions from international aviation and shipping should be
37 part of the Paris Agreement (Gençsü and Hino 2015; Traut et al. 2018; Lee 2018; Rayner 2021) argue
38 that the shipping and aviation industries would prefer emissions to be treated under an international
39 regime rather than a national-oriented regime. If international aviation and shipping emissions were a
40 part of the Paris Agreement, it may remove something of the present ambiguity of responsibilities.
41 However, inclusion in the Paris agreement is unlikely to fundamentally change emissions trends unless
42 targets and enforcement mechanisms are developed either by ICAO and IMO or by nation states through
43 global processes.

44 **Individual nations?**

1 If international regulations do not occur, then the transformation of aviation and shipping will be left to
2 individual nations like Switzerland. In 2020, Switzerland approved a new CO₂ tax on flights (The Swiss
3 Parliament 2020) with part of its revenues earmarked for the development of synthetic aviation fuels,
4 to cover up to 80% of their additional costs compared to fossil jet fuel (Energieradar 2020). Hence,
5 appropriate financing frameworks will be a key to the large-scale market adoption of these fuels. Egli
6 et al. (2019) suggest that the successful design of renewable energy investment policies for solar and
7 wind power over the past 20 years could serve as a model for future synthetic aviation fuels production
8 projects “attracting a broad spectrum of investors in order to create competition that drives down
9 financing cost”, and with state investment banks building “investor confidence in new technologies.”
10 These national investment policies would provide the key enablers for successful deployments.

11 **END BOX HERE**

12 *Managing critical minerals:* Critical minerals are required to manufacture LIB’s and other renewable
13 power technologies. There has been growing awareness that critical minerals may face challenges
14 related to resource availability, labour rights, and costs. Box 10.6, below, sets out the issues showing
15 how emerging national strategies on critical minerals, along with requirements from major vehicle
16 manufacturers, are addressing the need for rapid development of new mines with a more balanced
17 geography, less use of cobalt through continuing LIB innovations, and a focus on recycling batteries.
18 The standardisation of battery modules and packaging within and across vehicle platforms, as well as
19 increased focus on design for recyclability are important. Given the high degree of potential
20 recyclability of LIBs, a near closed-loop system in the future would be a feasible opportunity to
21 minimise critical mineral issues.

22

23 **START BOX HERE**

24

25 **Box 10.6 Critical Minerals and The Future of Electro-Mobility and Renewables**

26 The global transition towards renewable energy technologies and battery systems necessarily involves
27 materials, markets, and supply chains on a hitherto unknown scale and scope. This has raised concerns
28 regarding mineral requirements central to the feasibility of the energy transition. Constituent materials
29 required for the development of these low carbon technologies are regarded as “critical” materials (US
30 Geological Survey 2018; Commonwealth of Australia 2019; Lee et al. 2020; Marinaro et al. 2020;
31 Sovacool et al. 2020). ‘Critical materials’ are critical because of their economic or national security
32 importance, or high risk of supply disruption (UK Government 2019). describes many of these materials
33 and rare earth elements (REEs) as “technologically critical” not only due to their strategic or economic
34 importance but the risk of short supply or price volatility (Marinaro et al. 2020). In addition to these
35 indicators, production growth and market dynamics are also incorporated into screening tools to assess
36 emerging trends in material commodities that are deemed as fundamental to the well-being of the nation
37 (NSTC 2018).

38 The critical materials identified by most nations are: REEs Neodymium and Dysprosium for permanent
39 magnets in wind turbines and electric motors; Lithium and Cobalt, primarily for batteries though many
40 other metals are involved (see figure below); and, Cadmium, Tellurium, Selenium, Gallium and Indium
41 for solar PV manufacture (Valero et al. 2018; Giurco et al. 2019). Predictions are that the transition to
42 a clean energy world will be significantly energy intensive (World Bank Group 2017; Sovacool et al.
43 2020) putting pressure on the supply chain for many of the metals and materials required.

44 Governance of the sustainability of mining and processing of many of these materials, in areas generally
45 known for their variable environmental stewardship, remains inadequate and often a source for conflict.
46 (Sovacool et al. 2020) propose four holistic recommendations for improvement to make these industries

1 more efficient and resilient: diversification of mining enterprises for local ownership and livelihood
2 benefit; improve the traceability of material sources and transparency of mining enterprise; exploration
3 of alternative resources; and the incorporation of minerals into climate and energy planning by
4 connecting to the NDCs under the Paris Accord.

5 **Resource Constraints?**

6 Valero et al. (2018) highlights that the demand for many of the REEs and other critical minerals will,
7 at the current rate of RE infrastructure growth, increase a multiple of 3,000 times or more by 2050.
8 Some believe this growth may reach constraints in supply (Giurco et al. 2019). Others suggest that the
9 minerals involved are not likely to physically run out (Sovacool et al. 2020) if well managed, especially
10 as markets are found in other parts of the world (for example the transition away from Lithium in brine
11 lakes to hard rock sources). Lithium hydroxide, more suitable for batteries, now competes well, in terms
12 of cost, when extracted from rock sources (Azevedo et al. 2018) due to the ability to more easily create
13 high quality Lithium Hydroxide from rock sources, even though brines provide a cheaper source of
14 Lithium *per se* (Kavanagh et al. 2018). Australia has proven resources for all the Li-ion battery minerals
15 and has a strategy for their ethical and transparent production (Commonwealth of Australia 2019).
16 Changes in the technology have also been used to create less need for certain critical minerals
17 (Månberger and Stenqvist 2018). Recycling of all the minerals is not yet well developed but is likely to
18 be increasingly important (Habib and Wenzel 2014; Golroudbary et al. 2019; World Bank Group 2017;
19 Giurco et al. 2019).

20 **International Collaboration**

21 There have been many instances since the 1950's when the supply of essential minerals has been
22 restricted by nations in times of conflict and world tensions, but international trade has continued under
23 the framework of the World Trade Organization. Keeping access open to critical minerals needed for a
24 low-carbon transition will be an essential role of the international community as the need for local
25 manufacture of such renewable and electro-mobility technologies will be necessary for local economies.
26 shows that the trend over the past 30 years has been for the US to move from being self-sufficient in
27 REEs to being 100% reliant on imports, predominantly from China, Japan, and France. In terms of
28 heavy REEs, essential for permanent magnets for wind turbines, China has a near-monopoly on REE
29 processing though other mines and manufacturing facilities are now responding to these constrained
30 markets (Stegen 2015; Gulley et al. 2018, 2019; Yan et al. 2020). China, on the other hand, is reliant
31 on other nations for the supply of other critical metals, particularly cobalt and lithium for batteries.

32 A number of Critical Materials Strategies have now been developed by nations developing the
33 manufacturing-base of new power and transport technologies. Some of these strategies pay particular
34 attention to the supply of lithium (Martin et al. 2017; Hache et al. 2019). For example, Horizon 2020, a
35 substantial EU Research and Innovation program, couples research and innovation in science, industry,
36 and society to foster a circular economy in Europe thus reducing these bottlenecks in the EU nations.
37 Similarly CREEN (Canada Rare Earth Elements Network) is supporting the US-EU-Japan resource
38 partnership with Australia (Klossek et al. 2016).

39 As renewables and electromobility-based development leapfrogs into the developing world it will be
40 important to ensure the critical minerals issues are managed for local security of supply as well as
41 participation in the mining and processing of such minerals to develop their own employment around
42 renewables and electro-mobility (Sovacool et al. 2020).

43 **END BOX HERE**

44
45 *Enabling creative foresight:* Human culture has always had a creative instinct that enables the future to
46 be better dealt with through imagination (Montgomery 2017). Science and engineering have often been

1 preceded by artistic expressions such as Jules Verne, who first dreamed of the Hydrogen future in 1874
2 in his novel *The Mysterious Island*. Autonomous vehicles have regularly occupied the minds of science
3 fiction authors and filmmakers (Braun 2019). Such narratives, scenario building, and foresighting are
4 increasingly seen as a part of the climate change mitigation process (Lennon et al. 2015; Muiderman et
5 al. 2020) and can ‘liberate oppressed imaginaries’ (Luque-Ayala 2018). (Barber 2021) have emphasised
6 the important role of positive images about the future instead of dystopian visions and the impossibility
7 of business-as-usual futures.

8 Transport visions can be a part of this cultural change as well as the more frequently presented visions
9 of renewable energy (Wentland 2016; Breyer et al. 2017). There are some emerging technologies like
10 Maglev, Hyperloop, and Drones that are likely to continue the electrification of transport even further
11 (Daim 2021) and which are only recently at the imagination stage. Decarbonised visions for heavy
12 vehicle systems appear to be a core need from the assessment of technologies in this chapter. Such
13 visioning or foresighting requires deliberative processes and the literature contains a growing list of
14 transport success stories based on such processes (Weymouth and Hartz-Karp 2015). Ultimately,
15 reducing GHG emissions from the transport sector would benefit from creative visions that integrate a
16 broad set of ideas about technologies, urban and infrastructure planning (including transport, electricity,
17 and telecommunication infrastructure), and human behaviour and at the same time can create
18 opportunities to achieve the SDGs.

19 *Enabling transport climate emergency plans, local pledges and net zero strategies:* National, regional
20 and local governments are now producing transport plans with a climate emergency focus (e.g. (Jaeger
21 et al. 2015; Pollard 2019)). Such plans are often grounded in the goals of the Paris Agreement, based
22 around Local Low Carbon Transport Roadmaps that contain targets for and involve commitments or
23 pledges from local stakeholders, such as workplaces, local community groups, and civil society
24 organisations. Pledges often include phasing out fossil-fuel based cars, buses, and trucks (Plötz et al.
25 2020), strategies to meet the targets through infrastructure, urban regeneration and incentives, and
26 detailed programs to help citizens adopt change. These institution-led mechanisms could include bike-
27 to-work campaigns, free transport passes, parking charges, or eliminating car benefits. Community-
28 based solutions like solar sharing, community charging, and mobility as a service can generate new
29 opportunities to facilitate low-carbon transport futures. Cities in India and China have established these
30 transport roadmaps, which are also supported by the UNCRD’s Environmentally Sustainable Transport
31 program (Baeumler et al. 2012; Pathak and Shukla 2016; UNCRD 2020). There have been concerns
32 raised that these pledges may be used to delay climate action in some cases (Lamb et al. 2020) but but
33 such pledges can be calculated at a personal level and applied through every level of activity from
34 individual, household, neighbourhood, business, city, nation or groups of nations (Meyer and Newman
35 2020) and are increasingly being demonstrated through shared communities and local activism
36 (Bloomberg and Pope 2017; Sharp 2018; Figueres and Rivett-Carnac 2020). Finally, the world’s major
37 financing institutions are also engaging in decarbonisation efforts by requiring their recipients to
38 commit to Net Zero Strategies before they can receive their funding (COVID Box, Chapter 1; Chapter
39 15; (Robins 2018; Newman 2020a)). As a result, transparent methods are emerging for calculating what
40 these financing requirements mean for transport by companies, cities, regions, and infrastructure
41 projects (see Chapters 8, 15). The continued engagement of financial institutions may, like in other
42 sectors, become a major factor in enabling transformative futures for transport as long as governance
43 and communities continue to express the need for such change.

44

45 **10.8.4 Tools and Strategies to Enable Decarbonisation of the Transport Sector**

46 Using the right tools and strategies is crucial for the successful deployment of mitigation options. Table
47 10.7 summarises the tools and strategies to enable electromobility, new fuels for aviation and shipping,
48 and the more social aspects of demand efficiency.

1

2

Table 10.7 Tools and Strategies for enabling mitigation options to achieve transformative scenarios

Tools and Strategies	Travel Demand Reductions and Fuel/Vehicle Efficiency	Light Vehicle Electromobility Systems	Alternative Fuel Systems for Shipping and Aviation
Education and R&D	TDR can be assisted with digitalisation, connected autonomous vehicle, EVs and Mobility as a Service (Marsden et al. 2018; Shaheen et al. 2018). Knowledge gaps on TDR exist for longer distance travel (intercity); non-mandatory trips (leisure; social trips), and travel by elder people. Travel demand foresighting tools can be open source (Marsden 2018).	Behaviour change programs help EV's become more mainstream. R&D will help on the socio-economic structures that impede adoption of EV's and the urban structures that enable reduced car dependence and how EV's can assist grids (Newman 2010; Taiebat and Xu 2019; Seto et al. 2021).	R&D is critical for new fuels and to test the full life cycle costs of various heavy vehicle options (Marinaro et al. 2020).
Access and Equity	TDR programs in cities can be inequitable. To avoid such inequities, there is a need for better links to spatial and economic development (Marsden et al, 2018), mindful of diverse local priorities, personal freedom and personal data (See Box on Smart Technologies in Section 10.2)	Significant equity issues with EV's in the transition period can be overcome with programs that enable affordable electric mobility, especially transit. (IRENA 2016)	Shipping is mostly freight and is less of a problem but aviation has big equity issues (Bows-Larkin 2015)
Financing Economic Incentives and Partnerships	Carbon budget implications of different demand futures should be published and used to help incentivize net zero projects (Marsden 2018). Business and community pledges for net zero can be set up in partnership agreements (see Section 10.8.3).	Multiple opportunities for financing, economic incentives, and partnerships with clear economic benefits can be assured especially using the role of value capture in enabling such benefits. The nexus between EV's and the electricity grid needs opportunities to demonstrate positive partnership projects (Zhang et al. 2014; Mahmud et al. 2018; Newman et al. 2018; Sovacool et al. 2018; Sharma and Newman 2020)	Taking R&D into demonstration projects is the main stage for heavy vehicle options and these are best done as partnerships. Government assistance will greatly assist in such projects as well as an R&D levy. Abolishing fossil fuel subsidies and imposing carbon taxes are likely to help in the early stages of heavy vehicle transitions (Sclar et al. 2019)
Co-benefits and Overcoming Fragmentation	A focus on people-centred solutions for future mobility with more pluralistic and feasible sets of outcomes for all people can be achieved	The SDG benefits in zero carbon light vehicle transport systems are being demonstrated and can now be quantified as nations	Heavy vehicle systems can also demonstrate SDG co-benefits if formulated with this in mind. Demonstrations of how innovations can also help

	when they focus on more than simple benefit cost ratios but include well-being and livelihoods, considering transport as a system, rather than loosely connected modes as well as behaviour change programs (Barter and Raad 2000; Newman 2010; Martens 2020).	mainstream this transition. Projects with transit and sustainable housing are more able to show such benefits. New Benefit Cost Ratio methods that focus on health benefits in productivity are now favouring transit and active transport (Buonocore et al. 2019; UK DoT 2019; Hamilton et al. 2021).	SDGs will attract more funding. Such projects need cross-government consideration (Pradhan et al. 2017).
Regulation and Assessment	Implementing a flexible regulatory framework is needed for most TDR (Li and Pye 2018). Regulatory assessment can help with potential additional (cyber) security risk due to digitalization, AVs, IoT, and big data (Shaheen and Cohen 2019). Assessment tools and methods need to take account of greater diversity of population, regions, blurring of modes, and distinct spatial characteristics (Newman and Kenworthy 2015).	With zero carbon light vehicle systems rapidly growing the need for a regulated target and assessment of regulatory barriers can assist each city and region to transition more effectively. Regulating EV's for government fleets and recharge infrastructure can establish incentives (Bocken et al. 2016).	Zero carbon heavy vehicle systems need to have regulatory barrier assessments as they are being evaluated in R&D demonstrations (Sclar et al. 2019).
Governance and Institutional Capacity	TDR works better if adaptive decision-making approaches focus on more inclusive and whole of system benefit-cost ratios (Yang et al. 2020; Marsden 2018)	Governance and institutional capacity can now provide international exchanges and education programs based on successful cities and nations enabling light vehicle decarbonisation to create more efficient and effective policy mechanisms towards self-sustaining markets (Greene et al. 2014; Skjølsvold and Ryghaug 2019)..	Governance and institutional capacity can help make significant progress if targets with levies for not complying. Carbon taxes would also affect these segments. A review of international transport governance is likely (Makan and Heyns 2018)
Enabling infrastructure	Ensuring space for active transport and urban activities is taken from road space where necessary (Gössling et al. 2021b). Increasing the proportion infrastructure that supports walking in urban areas will structurally enable reductions in car use (Section 10.2 and	Large-scale electrification of LDVs requires expansion of low-carbon power systems, while charging or battery swapping infrastructure is needed for some segments (Gnann et al. 2018; Ahmand et al. 2020)	In addition to increasing the capabilities to produce low or zero-carbon fuels for shipping and aviation, there is a need to invest in supporting infrastructure including low carbon power generation. New Hydrogen delivery and refuelling infrastructure may be needed (Maggio et al. 2019). For zero-carbon

	(Newman and Kenworthy 2015). Creating transit activated corridors of TOD-based rail or mid-tier transit using value capture for financing will create inherently less car dependence (McIntosh et al. 2017; Newman et al. 2019)		synthetic fuels, infrastructure is needed to support carbon capture and CO ₂ transport to fuel production facilities (Edwards and Celia 2018).

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1 **Frequently Asked Questions (FAQs)**

2 **FAQ 10.1 -How important is electro-mobility in decarbonising transport and are there major** 3 **constraints in battery minerals?**

4 Electromobility is the biggest change in transport since AR5. When powered with low-carbon
5 electricity, electric vehicles (EVs) provide a mechanism for major GHG emissions reductions from the
6 largest sources in the transport sectors, including cars, motor-bikes, tuk tuks, buses and trucks. The
7 mitigation potential of EVs depends on the decarbonization of the power system. EVs can be charged
8 by home or business renewable power before or in parallel to the transition to grid-based low-carbon
9 power.

10 Electromobility is happening rapidly in micro-mobility (e-autorickshaws, e-scooters, e-bikes) and in
11 transit systems, especially buses. EV adoption is also accelerating for personal cars. EVs can be used
12 in grid stabilization through smart charging applications.

13 The state-of-the-art Lithium-Ion Batteries (LIBs) available in 2020 are superior to alternative cell
14 technologies in terms of battery life, energy density, specific energy, and cost. The expected further
15 improvements in LIBs suggest these chemistries will remain superior to alternative battery technologies
16 in the medium-term, and therefore LIBs will continue to dominate the electric vehicle market.

17 Dependence on LIB metals will remain, which may be a concern from the perspective of resource
18 availability and costs. However, the demand for such metals is much lower than the reserves available,
19 with many new mines starting up in response to the new market particularly in a diversity of places.

20 Recycling batteries will significantly reduce long-term resource requirements. The standardisation of
21 battery modules and packaging within and across vehicle platforms, as well as increased focus on design
22 for recyclability are important. Many mobility manufacturers and governments are considering battery
23 recycling issues to ensure the process is mainstreamed.

24 The most significant enabling condition in electro-mobility is to provide electric recharging
25 opportunities and a strategy to show they can be helping the grid.

26 **FAQ 10.2 - How hard is it to decarbonise heavy vehicles in transport like long haul trucks, ships** 27 **and planes?**

28 Unlike for land transport vehicles, there are few obvious solutions to decarbonizing heavy vehicles like
29 international ships and planes. The main focus has been increased efficiency, which so far has not
30 prevented these large vehicles from becoming the fastest growing source of GHG globally. These
31 vehicles likely need alternative fuels that can be fitted to the present propulsion systems. Emerging
32 demonstrations suggest that ammonia, advanced biofuels, or synthetic fuels could become commercial.

33 Electric propulsion using hydrogen fuel cells or Li-ion batteries could work with short-haul aviation
34 and shipping, but the large long-lived vessels and aircraft likely
35 need alternative liquid fuels for most major long-distance functions.

36 Advanced biofuels, if sourced from resources with low GHG footprints, offer decarbonisation
37 opportunities. As shown in Chapters 2, 6, and 12, there are multiple issues constraining traditional
38 biofuels. Sustainable land management and feedstocks, as well as R&D efforts to improve
39 lignocellulosic conversion routes are key to maximise the mitigation potential from advanced biofuels.

40 Synthetic fuels made using CO₂ captured with DAC/BECCS and low-carbon hydrogen can
41 subsequently be refined to a net zero jet fuel or marine fuel. These fuels may also have less contrails-
42 based climate impacts and low emissions of local air pollution. However, these fuels still require
43 significant R&D and demonstration.

1 The deployment of low-carbon aviation and shipping fuels that support decarbonisation of the transport
2 sector will likely require changes to national and international governance structures

3 **FAQ 10.3 - How can governments, communities and individuals reduce demand and be more**
4 **efficient in consuming transport energy?**

5 Cities can reduce their transport-related fuel consumption by around 25% through combinations of more
6 compact land use and less car dependent transport infrastructure.

7 More traditional programs for reducing unnecessary high-energy travel through behaviour change
8 programs (i.e., taxes on fuel, parking, and vehicles or subsidies for alternative low-carbon modes),
9 continue to be evaluated with mixed results due to the dominance of time savings in an individual's
10 decision-making.

11 The circular economy, the shared economy, and digitalisation trends can support systemic changes that
12 lead to reductions in demand for transport services or expands the use of more efficient transport modes

13 COVID-19-based lockdowns have confirmed the transformative value of telecommuting replacing
14 significant numbers of work and personal journeys as well as promoting local active transport. These
15 changes may not last and impacts on productivity and health are still to be fully evaluated.

16 Solutions for individual households and businesses involving pledges and shared communities that set
17 new cultural means of reducing fossil fuel consumption, especially in transport, are setting out new
18 approaches for how climate change mitigation can be achieved.

41

1 **Appendix 10.1: Data and methods for life cycle assessment**

2 *IPCC LCA Data Collection Effort*

3 In mid-2020, the IPCC, in collaboration with the Norwegian University of Science and Technology,
4 released a request for data from the life cycle assessment community, to estimate the life cycle
5 greenhouse (GHG) emissions of various passenger and freight transport pathways. The data requested
6 included information about vehicle and fuel types, vintages, vehicle efficiency, payload, emissions from
7 vehicle and battery manufacturing, and fuel cycle emissions factors, among others.

8 Data submissions were received from approximately 20 research groups, referencing around 30 unique
9 publications. These submissions were supplemented by an additional 20 studies from the literature.
10 While much of this literature was focused on LDVs and trucks, relatively few studies referenced bus
11 and rail pathways.

12 *Harmonization method*

13 First, the datapoints were separated into categories based on the approximate classification (e.g., heavy-
14 duty vs medium-duty trucks), powertrain (i.e., ICEV, HEV, BEV, FCV), and fuel combination. For
15 each category of vehicle/powertrain/fuel, a simplified LCA that harmonizes values from across the
16 reviewed studies was constructed, using the following basic equation:

$$17 \quad \text{Life cycle GHG intensity} = \frac{FC}{P} * EF + \frac{VC}{P * LVKT}$$

18 Where:

- 19 • Life cycle GHG intensity represents the normalized life cycle GHG emissions associated with each
20 transportation mode, measured in g CO₂-eq/passenger-km or g CO₂-eq/tonne-km
- 21 • FC is the fuel consumption of the vehicle in MJ or kWh per km
- 22 • P represents the payload (measured in tonnes of cargo) or number of passengers, at a specified
23 utilization capacity (e.g., 50% payload or 80% occupancy)
- 24 • EF is an emissions factor representing the life cycle GHG intensity of the fuel used, measured in g
25 CO₂-eq/MJ or g CO₂-eq/kWh. A single representative EF value is selected for each fuel type. When
26 a given fuel type can be generated in different ways with substantially different upstream emissions
27 factors (e.g., H₂ from methane steam reforming vs H₂ from water electrolysis), these are treated as
28 two different fuel categories. The fuel emissions factors that were used are presented in Table 10.8
- 29 • VC are the vehicle cycle emissions of the vehicle, measured in g CO₂-eq /vehicle. This may
30 include vehicle manufacturing, maintenance and end-of-life, or just manufacturing.
- 31 • LVKT is the lifetime vehicle kilometres travelled

32 Note: for PHEVs, the value of FC/P*EF is a weighted sum of this aggregate term for each of battery
33 and diesel/gasoline operation.

34 Fuel emissions factors used are presented in Table 10.8. Note that the fuel emissions factors were
35 compiled from several studies that used different global warming potential (GWP) values in their
36 underlying assumptions, and therefore the numbers reported here may be slightly different if GWP₁₀₀
37 from the AR6 had been used. This difference would be small given the small contribution from non-
38 CO₂ gases to the total life cycle emissions. For example, methane emissions exist in the life cycle of
39 natural gas supply chains or natural gas dependent supply chains such as Hydrogen from SMR. Recent
40 data from the U.S. suggests emissions of approximately 0.2-0.3 g CH₄/MJ natural gas (Littlefield et al.
41 2017, 2019), which would range by no more than 1-2 g CO₂-eq/MJ natural gas (<3% of natural gas life

1 cycle emissions) when converting from a GWP₁₀₀ of 25 (AR4) or 36 (AR5) to the current (AR6) GWP₁₀₀
2 of 29.8.

3 For LDVs, the entire distribution of estimated life cycle emissions is presented for each
4 vehicle/powertrain/fuel category (as a boxplot). For trucks, rail and buses, only the low and high
5 estimates are presented (as solid bars) since the number of datapoints were not sufficient to present as
6 a distribution. Table 10.9 presents the low and high estimates of fuel efficiency for each category. The
7 references used are reported in the main text.

8 **Table 10.8 Fuel emissions factors used to estimate life cycle greenhouse gas (GHG) emissions of passenger**
9 **and freight transport pathways**

Fuel	Emissions factor	Units	Source
Gasoline	92	g CO ₂ -eq MJ ⁻¹	Submissions to IPCC data call (median)
Diesel	92	g CO ₂ -eq MJ ⁻¹	Submissions to IPCC data call (median)
Diesel, high	110	g CO ₂ -eq MJ ⁻¹	Diesel from oil sands: average of in-situ pathways (Guo et al. 2020)
Biofuels, IAM EMF33	25	g CO ₂ -eq MJ ⁻¹	From Chapter 7
Biofuels, partial models CLC	36	g CO ₂ -eq MJ ⁻¹	From Chapter 7
Biofuels, partial models NG	141	g CO ₂ -eq MJ ⁻¹	From Chapter 7
Compressed natural gas	71	g CO ₂ -eq MJ ⁻¹	Submissions to IPCC data call (median)
Liquefied natural gas	76	g CO ₂ -eq MJ ⁻¹	Submissions to IPCC data call (median)
Liquefied petroleum gas	78	g CO ₂ -eq MJ ⁻¹	Submissions to IPCC data call (median)
DAC FT-Diesel, wind electricity	12	g CO ₂ -eq MJ ⁻¹	From electrolytic Hydrogen produced using low-carbon electricity (Liu et al. 2020a)
DAC FT-Diesel, natural gas electricity	370	g CO ₂ -eq MJ ⁻¹	From electrolytic Hydrogen produced using natural gas electricity; extrapolated from (Liu et al. 2020a)
Ammonia, low carbon renewable	3.2	g CO ₂ -eq MJ ⁻¹	From electrolytic Hydrogen produced using low-carbon electricity via Haber-Bosch (Gray et al. 2021)
Ammonia, natural gas SMR	110	g CO ₂ -eq MJ ⁻¹	From H ₂ derived from natural gas steam methane reforming; via Haber-Bosch (Frattini et al. 2016)
Hydrogen, low carbon renewable	10	g CO ₂ -eq MJ ⁻¹	From electrolysis with low-carbon electricity (Valente et al. 2021)
Hydrogen, natural gas SMR	95	g CO ₂ -eq MJ ⁻¹	From steam-methane reforming (SMR) of fossil fuels (Valente et al. 2021)
Wind electricity	9.3	g CO ₂ -eq kWh ⁻¹	Submissions to IPCC data call (median)
Natural gas electricity	537	g CO ₂ -eq kWh ⁻¹	Submissions to IPCC data call (median)
Coal electricity	965	g CO ₂ -eq kWh ⁻¹	Submissions to IPCC data call (median)

10

11 For transit and freight, the life cycle harmonization exercise allows two aggregate parameters to vary
12 from the low to high among submitted values within each category: FC/P and VC/P. Aggregate
13 parameters are used to capture internal correlations (e.g., fuel consumption and payload both depend

1 heavily on vehicle size) and are presented in Table 10.10 to Table 10.14. The references used are
 2 reported in the main text.

3

^aAmmonia ICEV trucks are assumed to have the same fuel economy as diesel ICEVs due to lack of data.

^bAmmonia FCV trucks are assumed to have the same fuel economy as Hydrogen FCVs due to lack of data.

Table 10.14 Range of fuel efficiencies for freight rail by fuel and powertrain category, at an average payload

Fuel	Powertrain	Fuel efficiency (MJ/tonne-km)		Electric efficiency (kWh/tonne-km)	
		Low	High	Low	High
Diesel	ICEV	0.11	0.78		
Biodiesel	ICEV	0.11	0.78		
DAC FT-Diesel	ICEV	0.11	0.78		
Electricity	BEV			0.01	0.12
Hydrogen	FCV	0.10	0.10		

Appendix 10.2: Data and assumptions for life cycle cost analysis

Fuel cost ranges

For diesel, a range of 0.5-2.5 USD/L is used based on historic diesel costs across all OECD countries reported in the IEA Energy Prices and Taxes Statistics database (IEA 2021c) since 2010. The lower end of this range is consistent with the minimum projected value from the 2021 U.S. Annual Energy Outlook (low oil price scenario, 0.55 USD/L) (U.S. Energy Information Administration 2021). The upper end of the range encompasses both the maximum diesel price observed in the 2021 U.S. Annual Energy Outlook projections (high oil price scenario, 1.5 USD/L) (U.S. Energy Information Administration 2021), and the diesel price that would correspond to the 2020 IEA World Energy Outlook crude oil price projections (Stated Policies scenario) (IEA 2020b), assuming the historical price relationship between crude oil and diesel is maintained (1.5 USD/L). For reference, the IEA reports current world-average automotive diesel costs to be around 1 USD/L (IEA 2021d). The selected range also captures the current range of production costs for values for bio-based and synthetic diesels (51-144 Eur/MWh, corresponding to 0.6-1.70 USD/L), which are generally still higher than wholesale petroleum diesel costs (30-50 Eur/MWh corresponding to 0.35-0.6 USD/L), as reported by IEA (IEA 2020c). This range also encompasses costs for synthesized electro-fuels from electrolytic Hydrogen as reported in Chapter 6 (1.6 USD/L).

The range of electricity costs used here are consistent with the range of levelized cost of electricity estimates presented in Chapter 6 (20-200 USD/MWh).

For Hydrogen, a range of 1-13 USD/kg is used. The upper end of this range corresponds approximately to reported retail costs in the US (Burnham et al. 2021; Eudy and Post 2018b; Argonne National Laboratory 2020). Despite the high upper bound, lower costs (6-7 USD/kg) are already consistent with recent cost estimates of Hydrogen produced via electrolysis from Chapter 6 and current production cost estimates from IRENA (IRENA 2020). The lower end of the range (1 USD/kg) corresponds to projected

1 future price decreases for electrolytic Hydrogen (BNEF 2020; Hydrogen Council 2020; IRENA 2020),
2 and is consistent with projections from Chapter 6 for the low end of long-term future prices for fossil
3 Hydrogen with CCS.

4 *Vehicle efficiencies*

5 The vehicle efficiencies used in developing the life cycle cost estimates were derived from the
6 harmonized ranges used to develop life cycle GHG estimates and are presented in Table 10.9 to Table
7 10.14.

8 *Other inputs to bus cost model*

9 For buses, a 40-ft North American transit bus with a passenger capacity of 50, lifetime of 15 years, and
10 an annual mileage of 72,400 km based on data in the ANL AFLEET model (Argonne National
11 Laboratory 2020) is assumed. Maintenance costs were assumed to be 1 USD/mile for ICEV buses and
12 0.6 USD/mile for BEV and ICEV buses, also based on data from the AFLEET model (Argonne National
13 Laboratory 2020). For ICEV and BEV purchase costs, data from the National Renewable Energy
14 Laboratory (Johnson et al. 2020) is used for bounding ranges (430,000 to 500,000 USD for ICEV and
15 579,000 to 1,200,000 USD for BEV), which encompass the default values from AFLEET model
16 (Argonne National Laboratory 2020). Note that wider ranges are available in the literature (e.g., as low
17 as USD120,000 per bus in (Burnham et al. 2021) and (Harris et al. 2020)); but these are not included in
18 the sensitivity analysis to avoid conflating disparate vehicles. For FCV buses, the upper bound of the
19 purchase price range (1,200,000 USD) represents current costs in the U.S. (Argonne National
20 Laboratory 2020; Eudy and Post 2020), and the lower bound represents the target future value from the
21 U.S Department of Energy (Eudy and Post 2020).

22 *Other inputs to rail cost model*

23 For freight and passenger rail, powertrain and vehicle O&M costs in USD/km from the IEA Future of
24 Rail report (IEA 2019e) (IEA Figure 2.14 for passenger rail and IEA Figure 2.15 for freight rail) are
25 used as a proxy for non-fuel costs. The ranges span conservative and forward-looking cases. In addition,
26 the range for BEV rail ranges encompass short and long-distance trains – corresponding to 100-200 km
27 for passenger rail, and 400-750 km for freight rail. Note that all values exclude the base vehicle costs,
28 but they are expected not to be significant as they are amortized over the lifetime-km travelled. For
29 freight rail, a network that is representative of North America is assumed, with a payload of 2800 tonnes
30 per train (IEA Figure 1.17), assumed to be utilized at 100%, with a lifetime of 10 years, and an average
31 mileage of 120,000 km/year. For BEV freight rail, the range in powertrain costs are driven by battery
32 costs of 250-600 USD/kWh, while for FCV freight rail, the range in powertrain costs are driven by fuel
33 cell stack costs of 50-1000 USD/kW. For passenger rail, a network that is representative of Europe is
34 assumed, with an average occupancy of 180 passengers per train (IEA Figure 1.14), with a lifetime of
35 10 years, and an average mileage of 115,000 km/year.

36 *Other inputs to truck cost model*

37 Capital cost ranges vary widely in the literature depending on the exact truck model, size and other
38 assumptions. For ICEVs in this analysis, the lower bound (90,000 USD) corresponds to the 2020
39 estimate for China from (Moultak et al. 2017), and the upper bound (250,000 USD) corresponds to the
40 2030 projection for the US from the same study. These values encompass the full range reported by
41 Argonne (Burnham et al. 2021). The lower bound BEV cost (120,000 USD) is taken from 2030
42 projections for China (Moultak et al. 2017) and the upper bound (780,000 USD) is taken from 2020
43 cost estimates in the US (class 8 sleeper cab tractor) (Burnham et al. 2021). The lower bound for FCV
44 trucks (130,000 USD) corresponds to the 2050 estimate for class 8 sleeper cab tractors from Argonne
45 National Laboratory and the upper bound (290,000 USD) corresponds the 2020 estimate from the same

1 study (Burnham et al. 2021). These values span the full range reported by (Moultak et al. 2017) for the
2 US, Europe and China from 2020-2030.

3 The analysis uses a truck lifetime of 10 years and annual mileage of 140,000 km based on (Burnham et
4 al. 2021). An effective payload of 17 tonnes (80% of maximum payload of 21 tonnes) is assumed based
5 on reported average effective payload submitted by Argonne National Laboratory in response to the
6 IPCC LCA data collection call. A discount rate of 3% is used, based on (Burnham et al. 2021) and
7 consistent with the social discount rate from Chapter 3. Maintenance costs are assumed to be 0.15
8 USD/km for ICEV trucks and 0.09 USD/km for BEV and FCV trucks, as reported in (Burnham et al.
9 2021).

Biofuels for land transport, aviation, and shipping	+	±	-
<i>Role of contexts</i>	Climate conditions are an important factor for bioenergy viability. Land availability constrains might be expected for bioenergy deployment	Land and synthetic fertilizers are examples of limited resources to deploy large-scale biofuels, however the extent of this restrictions will depend on local and context specific conditions	Implementing biofuels may require additional land use. However, it will depend on context and local specific conditions.

Land-based measures to mitigate climate change: Potential and feasibility by country. <i>Global Change Biology</i>.</p>		
Ammonia for shipping	+	+	±
<i>Role of contexts</i>	A global ammonia supply chain is already established; the primary requirement for delivering greater carbon emission reductions will be through the production of ammonia using green hydrogen or CCS.	The use of ammonia would reduce reliance of fossil fuels for shipping and is expected to reduce reliance on natural resources when produced using green hydrogen. The primary resource requirements will be the supply of renewable electricity and clean water to produce green hydrogen, from which ammonia can be produced.	No major changes in land use for the vehicle. Increases may occur if the hydrogen is produced through electrolysis and renewable energy sources or hydrogen production with CCS.

Synthetic fuels for heavy-duty land transport, aviation, and shipping (e.g., DAC-FT)	±	±	±
<i>Role of contexts</i>	Fischer Tropsch chemistry is well established; pilot scale direct air capture (DAC) plants are already in operation; - does not qualify as a mitigation option except in regions with very low carbon electricity	+ Gasification can use a wide range of feedstocks; DAC can be applied in wide range of locations - Limited information available on potential limits related to large input energy requirements, or water use and required sorbents for DAC	No major changes in land use for the vehicle. Potential increases in land use for electricity generation (especially solar, wind or hydropower) for CO ₂ capture and fuel production; likely lower land use than crop-based biofuels

Electric vehicles for land transport	+	±	±
<i>Role of contexts</i>	Electromobility is being adopted across a range of land transport options including light-duty vehicles, trains and some heavy-duty vehicles, suggesting no physical constraints	Current dominant battery chemistry relies on minerals that may face supply constraints, including lithium, cobalt, and nickel. Regional supply/availability varies. Alternative chemistries exist; recycling may likewise alleviate critical material concerns. Similar supply constraints may exist for some renewable electricity sources (e.g., solar) required to support EVs. May reduce critical materials required for catalytic converters in ICEVs (e.g., platinum, palladium, rhodium)	No major changes in land use for the vehicle. Potential increases in land use for electricity generation (especially solar, wind or hydropower) and mineral extraction, but may be partially offset by a decrease in land use for fossil fuel production; likely lower land use than crop-based biofuels, or technologies with higher electricity use (e.g., those based electrolytic hydrogen)

Hydrogen FCV for land transport	+	±	±
<i>Role of contexts</i>	The use of fuel cells in the transport sector is growing, and will potentially be important in heavy-duty land transport applications	FCVs are reliant on critical minerals for manufacturing fuel cells, electric motors and supporting batteries. Platinum is the primary potential resource constraint for fuel cells; however, its use may decrease as the technology develops, and platinum is highly recyclable.

Biofuels for land transport, aviation, and shipping	±	±	-	-
<i>Role of contexts</i>	Biofuels may improve air quality due reduction in the emission of some pollutants, such as SOx and particulate matter, in relation to fossil fuels. Evidence is mixed for other pollutants such as NOx. The biofuels supply chain (e.g., due to increased fertilizer use) may negatively impact air quality.	Increased use of fertilizers and agrochemicals due the biofuel production may increase impacts in ecotoxicity and eutrophication; some biofuels may be less toxic than fossil fuel counterparts	Increasing production of biofuels may increase pressure in water resources due to the need of irrigation. However, some biofuel options may also improve these aspects in respect to conventional agriculture. These impacts will depend on specific local conditions.	Additional land use for biofuels may increase pressure on biodiversity. However, biofuel can also increase biodiversity depending on the previous land use. These impacts will depend on specific local conditions and previous land uses.

Nature Sustainability (2021): 1-8.			
Ammonia for shipping	±	-	±	LE

<i>Role of contexts</i>	If produced from green hydrogen or coupled with CCS, ammonia could reduce short lived climate forcers and particulate matter precursors including black carbon and SO ₂ . However, the combustion of ammonia could lead to elevated levels of nitrogen oxides and ammonia emissions	Ammonia is highly toxic, and therefore requires special handling procedures to avoid potential catastrophic leaks into the environment. That said, large volumes of ammonia are already safely transported internationally due to a high level of understanding of safe handling procedures. Additionally, the use of ammonia in shipping presents an additional risk to eutrophication and ecotoxicity from the release of ammonia in the water system - either via a fuel leak, or via unburnt ammonia emissions.	May increase or decrease water footprint depending on the upstream energy source	Lack of studies assessing the potential impacts of the technology on biodiversity.

Electric vehicles for land transport	+	-	±	LE

<i>Role of contexts</i>	Elimination of tailpipe emissions. If powered by nuclear or renewables, large overall improvements in air pollution. Even if powered partially by fossil fuel electricity, tailpipe emissions tend to occur closer to population and thus typically have larger impact on human health than powerplant emissions; negative air quality impacts may occur, but only in fossil fuel heavy grids	Some toxic waste associated with mining and processing of metals for battery and some renewable electricity supply chains (production and disposal)	May increase or decrease water footprint depending on the upstream electricity source	Potential biodiversity issues related to electricity generation; however fossil fuel supply chains also adversely impact biodiversity; net effect is unknown

Hydrogen FCV for land transport	+	±	±	LE
<i>Role of contexts</i>	Fuel cells' only tailpipe emission is water vapour. However, blue hydrogen production pathways may generate air pollutants nearby the production sites. Overall, FCV would reduce emissions of criteria air pollutants.	Mining of Platinum Group Metals may generate additional stress on the environment, compared to conventional technologies. Furthermore, the recycling of fuel cell stacks can generate additional impacts.	May increase or decrease water footprint depending on the upstream energy source	Lack of studies assessing the potential impacts of the technology on biodiversity.

Technological			
	Simplicity	Technological scalability	Maturity and technology readiness
Demand reduction and mode shift	+	+	+
<i>Role of contexts</i>	Application of Demand and Fuel efficiency measures can be scaled and developing countries can leapfrog to most advanced technology. India skipped Euro V, and implemented Euro VI from IV, but this shift will require investment in the short-term	Technology to deliver Demand and Fuel efficiency is readily available	Significant economic benefit in short and long term
<i>Line of sight</i>	Vashist, D., Kumar, N., & Bindra, M. (2017). Technical Challenges in Shifting from BS IV to BS-VI Automotive Emissions Norms by 2020 in India: A Review. <i>Archives of Current Research International</i> , 1-8; Clean Air Zone Framework. https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/863730/clean-air-zone-framework-feb2020.pdf		
Biofuels for land transport, aviation, and shipping	±	±	+
<i>Role of contexts</i>	Typically based on internal combustion engines, similar to fossil fuels, however, may require engine recalibration	Biofuels are scalable up to and may benefit from economies of scale; potential for scale up of sustainable crop production may be limited	There are many biofuels technologies that are already at commercial scale, while some technologies for advanced biofuels are still under development.

"A review on biofuels for light-duty vehicles in Europe." <i>Renewable and Sustainable Energy Reviews</i> (2020): 110398.		
Ammonia for shipping	-	±	±
<i>Role of contexts</i>	Requires either new engines or retrofits for existing engines. It is likely some ammonia will need to be mixed with a secondary fuel due its relatively low burning velocity and high ignition temperature. This would likely require existing powertrains to be modified to accept dual fuel mixes, including ammonia. Exhaust treatment systems are also required to deal with the release of unburnt ammonia emissions.	Ammonia supply chains are well established; transport and storage more feasible than hydrogen; scalability of electrolytic production routes remain a challenge for producing low GHG ammonia	The production, transport and storage of ammonia is mature based on existing international supply chains. The use of ammonia in ships is still the early stages of research and development. Further research and development will be required for ammonia to be widely used in shipping, including improving the efficiency of combustion, and treatment of exhaust emissions. Ammonia could also potentially be used in fuel cell powertrains in the future, but the development of this technology is even less mature at present.

Energy, https://doi.org/10.1016/j.apenergy.2020.115439 .
Hydrogen FCV for land transport	±	-	-

<i>Role of contexts</i>	Lower maintenance requirements compared to conventional technologies; potential issues with on-vehicle hydrogen storage, fuel cell degradation and lifetime; fewer weight and refuelling time barriers compared to electric vehicles	Currently the refuelling infrastructure is limited, but it is growing at the pace of the technology deployment. Challenges exist with transport and distribution of hydrogen. Electrolytic hydrogen not currently produced at scale.	The technology is already available to users for light duty vehicle applications and buses, but further improvements in fuel cell technology are needed. Use in heavy duty applications is currently constrained. Maturity and technology readiness level can vary for different parts of the supply chain, and is lower than for EVs

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1 Executive summary

2 **The Paris Agreement, the Sustainable Development Goals (SDGs) and the COVID-19 pandemic**
3 **provide a new context for the evolution of industry and mitigation of industry greenhouse gas**
4 **(GHG) emissions (*high confidence*)**. This chapter is focused on what is new since AR5. It emphasizes
5 the energy and emissions intensive basic materials industries and key strategies for reaching net zero
6 emissions. {11.1.1}

7 **Net zero CO₂ emissions from the industrial sector are possible but challenging (*high confidence*)**.
8 Energy efficiency will continue to be important. Reduced materials demand, material efficiency, and
9 circular economy solutions can reduce the need for primary production. Primary production options
10 include switching to new processes that use low to zero GHG energy carriers and feedstocks (e.g.,
11 electricity, hydrogen, biofuels, and carbon capture and utilization (CCU) for carbon feedstock) and
12 carbon capture and storage (CCS) for remaining CO₂. These options require substantial scaling up of
13 electricity, hydrogen, recycling, CO₂, and other infrastructure, as well as phase-out or conversion of
14 existing industrial plants. While improvements in the GHG intensities of major basic materials have
15 nearly stagnated over the last 30 years, analysis of historical technology shifts and newly available
16 technologies indicate these intensities can be reduced to net zero emissions by mid-century. {11.2, 11.3,
17 11.4}

18 **Whatever metric is used, industrial emissions have been growing faster since 2000 than emissions**
19 **in any other sector, driven by increased basic materials extraction and production (*high***
20 ***confidence*)**. GHG emissions attributed to the industrial sector originate from fuel combustion, process
21 emissions, product use and waste, which jointly accounted for 14.1 GtCO₂-eq or 24% of all direct
22 anthropogenic emissions in 2019, second behind the energy transformation sector. Industry is a leading
23 GHG emitter - 20 GtCO₂-eq or 34% of global emissions in 2019 - if indirect emissions from power and
24 heat generation are included. The share of emissions originating from direct fuel combustion is
25 decreasing and was 7 GtCO₂-eq, 50% of direct industrial emissions in 2019. {11.2.2}

26 **Global material intensity (in-use stock of manufactured capital, in tonnes per unit of GDP is**
27 **increasing (*high confidence*)**. In-use stock of manufactured capital per capita has been growing faster
28 than GDP per capita since 2000. Total global in-use stock of manufactured capital grew by 3.4% yr⁻¹ in
29 2000–2019. At the same time, per capita material stocks in several developed countries have stopped
30 growing, showing a decoupling from GDP per capita. {11.2.1, 11.3.1}

31 **Plastic is the material for which demand has been growing the strongest since 1970 (*high***
32 ***confidence*)**. The current >99% reliance on fossil feedstock, very low recycling, and high emissions
33 from petrochemical processes is a challenge for reaching net zero emissions. At the same time, plastics
34 are important for reducing emissions elsewhere, for example, light-weighting vehicles. There are as yet
35 no shared visions for fossil-free plastics, but several possibilities. {11.4.1.3}

36 **Scenario analyses show that significant cuts in global GHG emissions and even close to net zero**
37 **emissions from GHG intensive industry (e.g., steel, plastics, ammonia, and cement) can be**
38 **achieved by 2050 by deploying multiple available and emerging options (*medium confidence*)**.
39 Cutting industry emissions significantly requires a reorientation from the historic focus on important
40 but incremental improvements (e.g., energy efficiency) to transformational changes in energy and
41 feedstock sourcing, materials efficiency, and more circular material flows. {11.3, 11.4}

42 **Key climate mitigation options such as materials efficiency, circular material flows and emerging**
43 **primary processes, are not well represented in climate change scenario modelling and integrated**
44 **assessment models, albeit with some progress in recent years (*high confidence*)**. The character of
45 these interventions (e.g., appearing in many forms across complex value chains, making cost estimates
46 difficult) combined with the limited data on new fossil free primary processes help explain why they

1 are less represented in models than, for example, CCS. As a result, overall mitigation costs and the need
2 for CCS may be overestimated. {11.4.2.1}

3 **Electrification is emerging as a key mitigation option for industry** (*high confidence*). Electricity is
4 a versatile energy carrier, potentially produced from abundant renewable energy sources or other low
5 carbon options; regional resources and preferences will vary. Using electricity directly, or indirectly via
6 hydrogen from electrolysis for high temperature and chemical feedstock requirements, offers many
7 options to reduce emissions. It also can provide substantial grid balancing services, for example through
8 electrolysis and storage of hydrogen for chemical process use or demand response. {11.3.5}

9 **Carbon is a key building block in organic chemicals, fuels and materials and will remain**
10 **important** (*high confidence*). In order to reach net zero CO₂ emissions for the carbon needed in society
11 (e.g., plastics, wood, aviation fuels, solvents, etc.), it is important to close the use loops for carbon and
12 carbon dioxide through increased circularity with mechanical and chemical recycling, more efficient
13 use of biomass feedstock with addition of low GHG hydrogen to increase product yields (e.g., for
14 biomethane and methanol), and potentially direct air capture of CO₂ as a new carbon source. {11.3,
15 11.4.1}

16 **Production costs for very low to zero emissions basic materials may be high but the cost for final**
17 **consumers and the general economy will be low** (*medium confidence*). Costs and emissions reductions
18 potential in industry, and especially heavy industry, are highly contingent on innovation,
19 commercialization, and market uptake policy. Technologies exist to take all industry sectors to very low
20 or zero emissions, but require 5–15 years of intensive innovation, commercialization, and policy to
21 ensure uptake. Mitigation costs are in the rough range of 50–150 USD·tCO₂-eq⁻¹, with wide variation
22 within and outside this band. This affects competitiveness and requires supporting policy. Although
23 production cost increases can be significant, they translate to very small increases in the costs for final
24 products, typically less than a few percent depending on product, assumptions, and system boundaries.
25 {11.4.1.5}

26 **There are several technological options for very low to zero emissions steel, but their uptake will**
27 **require integrated material efficiency, recycling, and production decarbonisation policies** (*high*
28 *confidence*). Material efficiency can potentially reduce steel demand by up to 40% based on design for
29 less steel use, long life, reuse, constructability, and low contamination recycling. Secondary production
30 through high quality recycling must be maximized. Production decarbonisation will also be required,
31 starting with the retrofitting of existing facilities for partial fuel switching (e.g., to biomass or hydrogen),
32 CCU and CCS, followed by very low and zero emissions production based on high-capture CCS or
33 direct hydrogen, or electrolytic iron ore reduction followed by an electric arc furnace. {11.3.2, 11.4.1.1}

34 **There are several current and near horizon options to greatly reduce cement and concrete**
35 **emissions. Producer, user, and regulator education, as well as innovation and commercialization**
36 **policy are needed** (*medium confidence*). Cement and concrete are currently overused because they are
37 inexpensive, durable, and ubiquitous, and consumption decisions typically do not give weight to their
38 production emissions. Basic material efficiency efforts to use only well-made concrete thoughtfully and
39 only where needed (e.g., using right-sized, prefabricated components) could reduce emissions by 24–
40 50% through lower demand for clinker. Cementitious material substitution with various materials (e.g.,
41 ground limestone and calcined clays) can reduce process calcination emissions by up to 50% and
42 occasionally much more. Until a very low GHG emissions alternative binder to Portland cement is
43 commercialized, which does not look promising in the near to medium term, CCS will be essential for
44 eliminating the limestone calcination process emissions for making clinker, which currently represent
45 60% of GHG emissions in best available technology plants. {11.3.2, 11.3.6, 11.4.1.2}

46 **While several technological options exist for decarbonizing the main industrial feedstock**
47 **chemicals and their derivatives, the costs vary widely** (*high confidence*). Fossil fuel-based feedstocks

1 are inexpensive and still without carbon pricing, and their biomass- and electricity-based replacements
2 will likely be more expensive. The chemical industry consumes large amounts of hydrogen, ammonia,
3 methanol, carbon monoxide, ethylene, propylene, benzene, toluene, and mixed xylenes & aromatics
4 from fossil feedstock, and from these basic chemicals produces tens of thousands of derivative end-use
5 chemicals. Hydrogen, biogenic or air-capture carbon, and collected plastic waste for the primary
6 feedstocks can greatly reduce total emissions. Biogenic carbon feedstock is likely to be limited due to
7 competing land-uses. {11.4.1.3}

8 **Light industry and manufacturing can be largely decarbonized through switching to low GHG**
9 **fuels (e.g., biofuels and hydrogen) and electricity (e.g., for electrothermal heating and heat pumps)**
10 *(high confidence)*. Most of these technologies are already mature, for example for low temperature heat,
11 but a major challenge is the current low cost of fossil methane and coal relative to low and zero GHG
12 electricity, hydrogen, and biofuels. {11.4.1.4}

13 **The pulp and paper industry has significant biogenic carbon emissions but relatively small fossil**
14 **carbon emissions. Pulp mills have access to biomass residues and by-products and in paper mills**
15 **the use of process heat at low to medium temperatures allows for electrification** *(high confidence)*.
16 Competition for feedstock will increase if wood substitutes for building materials and petrochemicals
17 feedstock. The pulp and paper industry can also be a source of biogenic carbon dioxide and carbon for
18 organic chemicals feedstock and carbon dioxide removal (CDR) using CCS. {11.4.1.4}

19 **The geographical distribution of renewable resources has implications for industry** *(medium*
20 *confidence)*. The potential for zero emission electricity and low-cost hydrogen from electrolysis
21 powered by solar and wind, or hydrogen from other very low emission sources, may reshape where
22 currently energy and emissions intensive basic materials production is located, how value chains are
23 organized, trade patterns, and what gets transported in international shipping. Regions with bountiful
24 solar and wind resources, or low fugitive methane co-located with CCS geology, may become exporters
25 of hydrogen or hydrogen carriers such as methanol and ammonia, or home to the production of iron and
26 steel, organic platform chemicals, and other energy intensive basic materials. {11.2; 11.4; Box 11.1}

27 **The level of policy maturity and experience varies widely across the mitigation options** *(high*
28 *confidence)*. Energy efficiency is a well-established policy field with decades of experience from
29 voluntary and negotiated agreements, regulations, energy auditing and demand side-management
30 (DSM) programs (see AR5). In contrast, materials demand management and efficiency are not well
31 understood and addressed from a policy perspective. Barriers to recycling that policy could address are
32 often specific to the different material loops (e.g., copper contamination for steel and lack of
33 technologies or poor economics for plastics) or waste management systems. For electrification and fuel
34 switching the focus has so far been mainly on innovation and developing technical supply-side solutions
35 rather than creating market demand. {11.5.2, 11.6}

36 **Industry has so far largely been sheltered from the impacts of climate policy and carbon pricing**
37 **due to concerns for competitiveness and carbon leakage** *(high confidence)*. New industrial
38 development policy approaches needed for realising a transition to net zero GHG emissions are
39 emerging. The transition requires a clear direction towards net zero, technology development, market
40 demand for low-carbon materials and products, governance capacity and learning, socially inclusive
41 phase-out plans, as well as international coordination of climate and trade policies. It requires
42 comprehensive and sequential industrial policy strategies leading to immediate action as well as
43 preparedness for future decarbonisation, governance at different levels (from international to local) and
44 integration with other policy domains. {11.6}

1 **11.1 Introduction and new developments**

2 **11.1.1 About this chapter**

3 AR5 was published in 2014. The Paris Agreement and the 17 SDGs were adopted in 2015. An increasing
4 number of countries have since announced ambitions to be carbon neutral by 2045-2060. The COVID-
5 19 pandemic shocked the global economy in 2020 and motivated economic stimulus with demands for
6 green recovery and concerns for economic security. All this has created a new context and a growing
7 recognition that all industry, including the energy and emissions intensive industries, need to reach net
8 zero GHG emissions. There is an ongoing mind shift around the opportunities to do so, with
9 electrification and hydrogen emerging among key mitigation options as a result of renewable electricity
10 costs falling rapidly. On the demand side there has been renewed attention to end-use demand, material
11 efficiency and more and better-quality recycling measures. This chapter takes its starting point in this
12 new context and emphasizes the need for deploying innovative processes and practices in order to limit
13 the global warming to 1.5°C or 2°C (IPCC 2018a).

14 The industrial sector includes ores and minerals mining, manufacturing, construction and waste
15 management. It is the largest source of global GHG and CO₂ emissions, which include direct and
16 indirect fuel combustion related emissions, emissions from industrial processes and products use, as
17 well as from waste. This chapter is focused on heavy industry - the high temperature heat and process
18 emissions intensive basic materials industries that account for 65% of industrial GHG and over 70% of
19 industrial CO₂ emissions (waste excluded), where deployment of near-zero emissions technologies can
20 be more challenging due to capital intensity and equipment lifetimes compared with other
21 manufacturing industries. The transition of heavy industries to zero emissions requires supplementing
22 the traditional toolkit of energy and process efficiency, fuel switching, electrification, and
23 decarbonisation of power with material end-use demand management and efficiency, circular economy,
24 fossil-free feedstocks, CCU, and CCS. Energy efficiency was extensively treated in AR5 and remains a
25 key mitigation option. This chapter is focused mainly on new options and developments since AR5,
26 highlighting measures along the whole value chains that are required to approach zero emissions in
27 primary materials production.

28

29 **11.1.2 Approach to understanding industrial emissions**

30 The Kaya-identity offers a useful tool of decomposing emission sources and their drivers, as well as of
31 weighing the mitigation options. The one presented below (Equation 11.1) builds on the previous
32 assessments (IPCC 2014, 2018b; Hoegh-Guldberg et al. 2018), and reflect a material stock-driven
33 services-oriented vision to better highlight the growing importance of industrial processes (dominated
34 emissions increments in 2010-2019), product use and waste in driving emissions. Services delivery
35 (nutrition, shelter, mobility, education, etc., see chapter 5 for more detail) not only requires energy and
36 materials flows (fuels, food, feed, fertilizers, packaging, etc.), but also material stocks (buildings, roads,
37 vehicles, machinery, etc.), the mass of which has already exceeded 1000 Gtonnes (Krausmann et al.
38 2018). As material efficiency appears to be an important mitigation option, material intensity or
39 productivity (material extraction or consumption versus GDP (Hertwich et al. 2020; Oberle et al. 2019))
40 is reflected in the identity with two dimensions: as material stock intensity of GDP (tonnes per dollar)
41 and material intensity of building and operating accumulated in-use stock.¹ For sub-global analysis the
42 ratio of domestically used materials to total material production becomes important to reflect outsourced

FOOTNOTE¹ Accumulated material stock initially was introduced in the analysis of past trends (Krausmann et al. 2018; Wiedenhofer et al. 2019), but recently it was incorporated in different forms in the long-term projections for the whole economy (Krausmann et al. 2020) and for some sectors (buildings and cars in Hertwich et al. (2020)) with a steadily improving regional resolution (Krausmann et al. 2020).

1 materials production and distinguish between territorial and consumption-based emissions. The identity
2 for industry differs significantly from that for sectors with where combustion emissions dominates
3 (Lamb et al. 2021).

4 Recent progress in data availability that allows the integration of major emission sources along with
5 socio-economic metabolism, material flows and stock analysis enriches the identity for industry from a
6 perspective of possible policy interventions (Bashmakov 2021):

$$GHG = POP \cdot \frac{GDP}{POP} \cdot \frac{MStock}{GDP} \cdot \left[\frac{MPR + MSE}{MStock} \cdot Dm \cdot \left(\frac{E}{(MPR + MSE)} \cdot \frac{(GHGed + GHGeind)}{E} + \frac{GHGoth}{MPR + MSE} \right) \right]$$

7
8
9
10
11
Equation 11.1

Variables	Factors	Policies and drivers	
POP	population	demographic policies	Demand decarbonization
$\frac{GDP}{POP}$	services (expressed via GDP – final consumption and investments needed to maintain and expand stock) per capita	sufficiency and demand management (reduction)	
$\frac{MStock}{GDP}$	material stock ($MStock$ - accumulated in-use stocks of materials embodied in manufactured fixed capital) intensity of GDP	material stock efficiency improvement	
$\frac{MPR + MSE}{MStock}$	material inputs (both virgin (primary materials extraction, MPR) and recycled (secondary materials use, MSE)) per unit of in-use material stock	material efficiency, substitution and circular economy	
Dm	share of allocated emissions – consumption versus production emissions accounting (valid only for sub-global levels)*	trade policies including carbon leakage issues (localization versus globalization)	CBAM
$\frac{E}{(MPR + MSE)}$	sum of energy use for basic material production (Em), processing and other operational industrial energy use ($Eoind$) per unit of material inputs	energy efficiency of basic materials production and other industrial processes	Production decarbonization
$\frac{(GHGed + GHGeind)}{E}$	direct ($GHGed$) and indirect ($GHGeind$) combustion-related industrial emissions per unit of energy	electrification, fuel switching, and energy decarbonisation (hydrogen, CCUS-fuels)	
$\frac{GHGoth}{MPR + MSE}$	emissions from industrial processes and product use, waste, F-gases, indirect nitrogen emissions per unit of produced materials	feedstock decarbonisation (hydrogen), CCUS-industrial processes, waste and F-gases management	

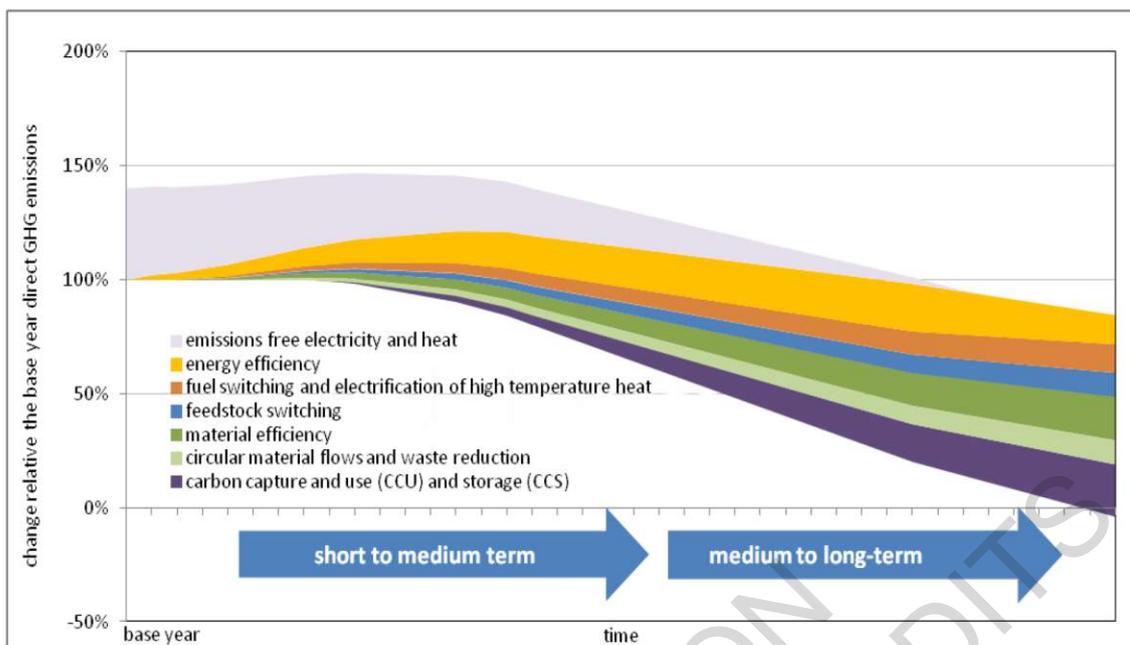

12
13 * $Dm=1$, when territorial emission is considered, and Dm equals the ratio of domestically used materials
14 to total material production for the consumption-based emission accounting). CBAM – carbon boarder
15 adjustment mechanism

16
17 Factors in (Equation 11.1) are interconnected by either positive or negative feedbacks: scrap-based
18 production or light weighing improves operational energy efficiency, while growing application of
19 carbon capture, use and storage (CCUS) brings it down and increase material demands (Hertwich et al.
20 2019; IEA 2020a, 2021a). There are different ways to disaggregate Equation 11.1: by industrial
21 subsectors (Bashmakov 2021); by reservoirs of material stock (buildings, infrastructure, vehicles,
22 machinery and appliances, packaging, etc.); by regions and countries (where carbon leakage becomes

1 relevant); by products and production chains (material extraction, production of basic materials, basic
2 materials processing, production of final industrial products); by traditional and low carbon technologies
3 used; and by stages of products' lives including recycling.

4 An industrial transition to net zero emissions is possible when the three last multipliers in Equation 11.1
5 (in square parentheses) are approaching zero. Contributions from different drivers (energy efficiency,
6 low carbon electricity and heat, material efficiency, switching to low carbon feedstock and CCUS) to
7 this evolution vary with time. Energy efficiency dominates in the short- and medium-term and
8 potentially long-term (in the range of 10-40% by 2050) (Crijns-Graus et al. 2020; IEA 2020a; IPCC
9 2018a), but for deep decarbonisation trajectories contributions from the other drivers steadily grow, as
10 the share of non-energy sources in industrial emissions rises and new technologies to address mitigation
11 from these sources mature (Material Economics 2019; CEMBUREAU 2020; BPS 2020; Hertwich et al.
12 2020, 2019; IEA 2021a, 2020a; Saygin and Gielen 2021) (Figure 11.1).

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

Mitigation options

	short to medium term	medium to long term
Decarbonizing production	Reduction of indirect emissions via lower carbon electricity and heat supply	Provision of emissions free electricity and high temperature heat
	Energy efficiency improvements to best available technologies	Energy efficiency approaching thermodynamic minimums
	Fuel switching, biomass and electricity use for high temperature process heat	Deep low carbon electrification, green hydrogen use
	Partial substitution of high carbon feedstock	Zero emissions feedstock (green hydrogen, biomass) for basic materials production
	Small scale and sectorally narrow concentrated CO ₂ flow CCUS	Broad scale, large-scale concentrated CO ₂ flow and possibly post-combustion CCUS
Decarbonizing demand	Material efficiency and substitution	Eco-design, material efficiency, demand reduction
	Increasing recycling rates	Circular material flows and effective industrial waste management

Base year and contributions from the drivers are only illustrative. Drivers' contribution varies across industries. Indirect emissions reduction is considered as outcome of mitigation activities in the energy sector, see chapter 6.

Figure 11.1 Stylized composition and contributions from different drivers to the transition of industry to net zero emissions

1 11.2 New trends in emissions and industrial development

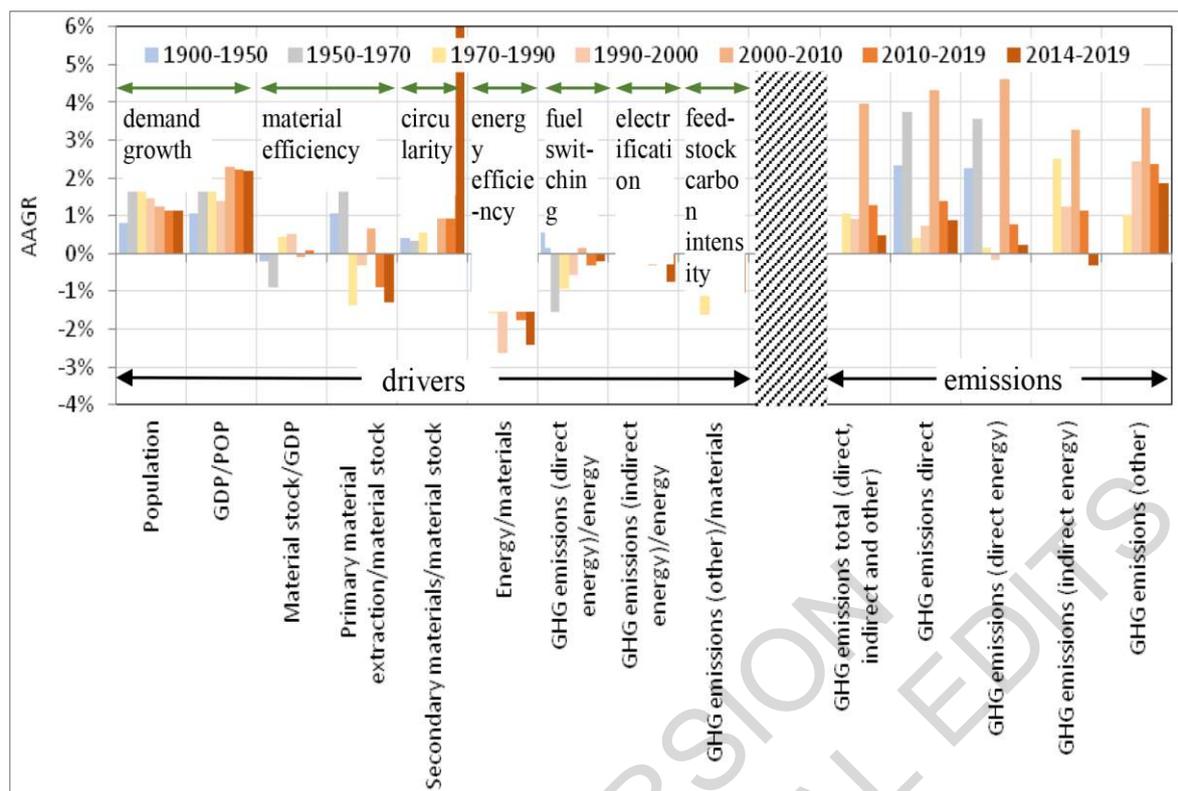

2 11.2.1 Major drivers

3 The use of materials is deeply coupled with economic development and growth. For centuries, humanity
4 has been producing and using hundreds of materials (Ashby 2012), the diversity of which skyrocketed
5 in the recent half-century to achieve the desired performance and functionality of multiple products
6 (density; hardness; compressive strength; melting point, resistance to mechanical and thermal shocks
7 and to corrosion; transparency; heat- or electricity conductivity; chemical neutrality or activity, to name
8 a few). New functions drive the growth of material complexity of products; for example, a modern
9 computer chip embodies over 60 different elements (Graedel et al. 2015).

10 Key factors driving up industrial GHG emissions since 1900 include population and per capita GDP,
11 ²while energy efficiency and non-combustion GHG emissions intensity (from industrial processes and
12 waste) has been pushing it down. Material efficiency factors – material stock intensity of GDP and ratio
13 of extraction, processing and recycling of materials per unit of built capital along with combustion-
14 related emissions intensity factors and electrification – were cyclically switching their contributions
15 with relatively limited overall impact. Growing recycling allowed for replacement of some energy
16 intensive virgin materials and thus contributed to mitigation. In 2014–2019, a combination of these
17 drivers allowed for a slowdown in the growth of industrial GHG emissions to below 1% (Figure 11.2
18 and Table 11.1), while to match a net zero emissions trajectory it should decline by 2% yr⁻¹ in 2020-
19 2030 and by 8.9% yr⁻¹ in 2030–2050 (IEA 2021a).

20 There are two major concepts of **material efficiency** (*ME*). The broader one highlights demand
21 reduction via policies promoting more intensive use, assuming sufficient (excl. luxury) living space or
22 car ownership providing appropriate service levels – housing days or miles driven and life-time
23 extension (Hertwich et al. 2019, 2020). This approach focuses on dematerialization of society
24 (Lechtenböhmer and Fishedick 2020), where a “dematerialization multiplier” (Pauliuk et al. 2021)
25 limits both material stock and GDP growth, as progressively fewer materials are required to build and
26 operate the physical in-use stock to deliver sufficient services. According to IRP (2020), reducing floor
27 space demand by 20% via shared and smaller housing compared to the reference scenario would
28 decrease Group of Seven (G7) countries’ GHG emissions from the material-cycle of residential
29 construction up to 70% in 2050. The narrower concept ignores demand and sufficiency aspects and
30 focuses on supply chains considering *ME* as less basic materials use to produce a certain final product,
31 for example, a car or meter squared of living space (OECD 2019a; IEA 2020a). No matter if the broader
32 or the narrower concept of *ME* is applied, in 1970-2019 it did not contribute much to the decoupling of
33 industrial emissions from GDP. This is expected to change in the future (Figure 11.2).

FOOTNOTE² In 2020 this factor played on the reduction side as the Covid-19 crisis led to a global decline in demand for basic materials, respective energy use and emissions by 3-5 % (IEA 2020a).

1

12
13 Material efficiency analysis mostly uses material intensity or productivity indicators, which compare
14 material extraction or consumption with GDP (Oberle et al. 2019; Hertwich et al. 2020). Those
15 indicators are functions of **material stock intensity of GDP** (tonnes per dollar) and material intensity
16 of building and operating accumulated in-use stock. Coupling services or GDP with the built stock
17 allows for a better evaluation of demand for primary basic materials (Cao et al. 2017; Liu et al. 2013;
18 Liu and Müller 2013; Müller et al. 2011; Pauliuk et al. 2013a; Krausmann et al. 2020; Hertwich et al.
19 2020; Wiedenhofer et al. 2019). Since 1970 material stock growth driven by industrialization and
20 urbanization slightly exceeded that of GDP and there was no decoupling,³ so in Kaya-like identities
21 material stock may effectively replace GDP. There are different methods to estimate the former (see
22 reviews in Pauliuk et al. (2015, 2019) and Wiedenhofer et al. (2019), the results of which are presented
23 for major basic materials with some geographical resolution (Pauliuk et al. 2013a; Liu and Müller 2013)
24 or globally (Graedel et al. 2011; Krausmann et al. 2018; Geyer et al. 2017; International Aluminium
25 Institute 2021a; Pauliuk et al. 2019; Wiedenhofer et al. 2019).

FOOTNOTE³ This conclusion is also valid separately for developed countries, rest of the world, and for China, when adjusted GDP for this country is used (Krausmann et al. 2020).

1 For a subset of materials, such as solid wood, paper, plastics, iron/steel, aluminium, copper, other
 2 metals/minerals, concrete, asphalt, bricks, aggregate, and glass, total in-use stock escalated from 36
 3 Gtonnes back in 1900 to 186 Gtonnes in 1970, 572 Gtonnes in 2000, and 960 Gtonnes in 2015, and by
 4 2020 it exceeded 1,100 Gtonnes, or 145 tonnes per capita (Krausmann et al. 2018, 2020; Wiedenhofer
 5 et al. 2019). In 1900–2019, the stock grew 31-fold, which is strongly coupled with GDP growth (36-
 6 fold). As the UK experience shows, material stock intensity of GDP may ultimately decline after
 7 services fully dominate GDP, and this allows for material productivity improvements to achieve
 8 absolute reduction in material use, as stock expansion slows down (Streeck et al. 2020). While the
 9 composition of basic materials within the stock of manufactured capital was evolving significantly,
 10 overall stock use associated with a unit of GDP has been evolving over the last half-century in a quite
 11 narrow range of 7.7–8.6 t per 1000 USD (2017 PPP) showing neither signs of decoupling from GDP,
 12 nor saturation as of yet. Mineral building materials (concrete, asphalt, bricks, aggregate, and glass)
 13 dominate the stock volume by mass (94.6% of the whole stock, with the share of concrete alone standing
 14 at 43.5%), followed by metals (3.5%) and solid wood (1.4%). The largest part of in-use stock of our
 15 ‘cementing societies’ Cao et al. (2017) is constituted by concrete: about 417 Gt in 2015 Krausmann et
 16 al. (2018) extrapolated to 478 Gt (65 tonnes per capita) in 2018, which contains about 88 Gt of cement⁴.
 17 The iron and steel stock is assessed at 25-35 Gtonnes (Gielen et al. 2020; Wang et al. 2021; Wiedenhofer
 18 et al. 2019), while the plastics stock reached 2.5-3.2 Gtonnes (Geyer et al. 2017; Wiedenhofer et al.
 19 2019; Saygin and Gielen 2021) and the aluminium stock approached 1.1 Gtonnes (International
 20 Aluminium Institute 2021a), or just 0.1% of the total. In sharp contrast to global energy intensity, which
 21 has more than halved since 1900 (Bashmakov 2019), in 2019 material stock intensity (in-use stock of
 22 manufactured capital per GDP) was only 14% below the 1900 level, but 15% above the 1970 level. In-
 23 use stock per capita has been growing faster than GDP per capita since 2000 (Figure 11.3). The growth
 24 rate of total in-use stock of manufactured capital was 3.8% in 1971-2000 and 3.5% in 2000-2019, or
 25 32-35 Gt·yr⁻¹, to which concrete and aggregates contributed 88%. Recent demand for stockbuilding
 26 materials was 51-54 Gt·yr⁻¹, to which recycled materials recently contributed only about 10% of material
 27 input. About 46-49 Gtonnes·yr⁻¹ was virgin inputs, which after accounting for processing waste and
 28 short-lived products (over 8 Gtonnes·yr⁻¹) scale up to 54-58 Gtonnes·yr⁻¹ of primary extraction
 29 (Krausmann et al. 2017, 2018; UNEP and IRP 2020). The above indicates that we have only begun to
 30 exploit the potential for recycling and circularity more broadly.

31

FOOTNOTE⁴ Cement stock for 2014 was estimated at 75 Gtonnes (Cao et al. 2020).

1 **Figure 11.3 Raw natural materials extraction since 1970. In windows: left - growth of population, GDP**
 2 **and basic materials production (1990=100) in 1990–2020; right - production of major basic materials and**
 3 **in-use stock per capita versus income level (1900–2018, brown dots are for 2000–2018).** The regressions
 4 provided show that for more recent years elasticity of material stock to GDP was greater than unity, comparing
 5 with the lower unity in preceding years.

6 Source: Developed based on IEA (2020b); Maddison Project (2018); UNEP and IRP (2020); Wiedenhofer et al.
 7 (2019); World Steel Association (2021); International Aluminium Institute (2021a); Statista (2021a,b); World
 8 Bank (2021); U.S. Geological Survey (2021).

9
 10 Total **extraction of all basic materials** (including biomass and fuels) in 2017 reached 92 Gtonnes·yr⁻¹,
 11 which is 13 times above the 1900 level (Figure 11.3).⁵ When recycled resources are added, total material
 12 inputs exceed 100 Gtonnes (Circle Economy 2020). In Equation 11.1 *MPR* represents only material
 13 inputs to the stock, excluding dissipative use –biomass (food and feed) and combusted fuels. Total
 14 extraction of stock building materials (metal ores and non-metallic minerals) in 2017 reached 55
 15 Gtonnes·yr⁻¹.⁶ In 1970–2018, it grew 4.3-fold and the ratio of *MPR* to accumulated in-use capital has
 16 nearly been constant since 1990 along with ratio to GDP (Figure 11.3).

17 End-of-life waste from accumulated stocks along with (re)-manufacturing and construction waste is
 18 assessed at 16 Gtonnes·yr⁻¹ in 2014 and can be extrapolated in 2018 to 19 Gtonnes·yr⁻¹ (Krausmann et
 19 al. 2018; Wiedenhofer et al. 2019), or 1.8% from stock of manufactured capital. Less than 6 Gtonnes·yr⁻¹
 20 was recycled and used to build the stock (about 10% of inputs⁷). While the circularity gap is still large,
 21 and limited circularity was engineered into accumulated stocks,⁸ **material recycling** mitigated some
 22 GHG emissions by replacing energy intensive virgin materials.⁹ When the stock saturates, in closed
 23 material loops the end-of-life materials waste has to be equal to material input, and primary production
 24 therefore has to be equal to end-of-life waste multiplied by unity minus recycling rate. When the latter
 25 grows, as the linear metabolism is replaced with the circular one, the share of primary materials
 26 production in total material input declines.

27 Recycling rates for metals are higher than for other materials: the end-of-life scrap input ratio for 13
 28 metals is over 50%, and stays in the range 25–50% for another ten, but even for metals recycling flows
 29 fail to match the required inputs (Graedel et al. 2011). Globally, despite overall recycling rates being at
 30 85%, the all scrap ratio for steel production in recent years stays close to 35–38% (IEA 2021b; Gielen
 31 et al. 2020) ranging from 22% in China (only 10% in 2015) to 69% in the US and to 83% in Turkey
 32 (BIR 2020). For end-of-life scrap this ratio declined from 30% in 1995–2010 to 21–25% after 2010
 33 (Gielen et al. 2020; Wang et al. 2021).

34 For aluminium, the share of scrap-based production grew from 17% in 1962 to 34% in 2010 and
 35 stabilized at this level till 2019, while the share of end-of-life scrap grew from 1.5% in 1962 to nearly
 36 20% in 2019 (International Aluminium Institute 2021a). The global recycling (mostly mechanical) rate

FOOTNOTE⁵ IRP (2020) estimate 2017 material extraction at 94 Gtonnes·yr⁻¹.

FOOTNOTE⁶ It approaches 60 Gtonnes·yr⁻¹ after construction and furniture wood and feedstock fuels are added
 (Krausmann et al. 2018; UNEP and IRP 2020; Wiedenhofer et al. 2019).

FOOTNOTE⁷ Mayer et al. (2019) found that in 2010–2014 secondary to primary materials ratio for the EU-28 was
 slightly below 9%.

FOOTNOTE⁸ According to Circle Economy (2020) 8.6 Gtonnes·yr⁻¹ or 8.6% of total inputs for all resources.

FOOTNOTE⁹ Environmental impacts of secondary materials are much (up to an order of magnitude) lower
 compared to primary materials (OECD 2019a; Wang et al. 2021; IEA 2021a), but to enable and mobilize
 circularity benefits it requires social system and industrial designing transformation (Oberle et al. 2019).

1 for plastics is only 9–10%¹⁰ (Geyer et al. 2017; Saygin and Gielen 2021) and that for paper progressed
2 from 34% in 1990 to 44% in 2000 and to over 50% in 2014–2018 (IEA 2020b).

3 The limited impacts of material efficiency factors on industrial GHG emissions trends reflect the lack
4 of integration of material efficiency in energy and climate policies which partly results from the
5 inadequacy of monitored indicators to inform policy debates and set targets;¹¹ lack of high-level political
6 focus and industrial lobbying; uncoordinated policy across institutions and sequential nature of decision-
7 making along supply chains; carbon pricing policy lock-in with upstream sectors failing to pass carbon
8 costs on to downstream sectors (due to compensation mechanisms to reduce carbon leakage) and so
9 have no incentives to exploit such options as light-weighting, reusing, re-manufacturing, recycling,
10 diverting scrap, extending product lives, using products more intensely, improving process yields, and
11 substituting materials (Skelton and Allwood 2017; Gonzalez Hernandez et al. 2018b; Hilton et al. 2018).
12 Poor progress with material efficiency is part of the reason why industrial GHG emissions are perceived
13 as ‘hard to abate’, and many industrial low-carbon trajectories to 2050 leave up to 40% of emissions in
14 place (Material Economics 2019; IEA 2021a). The importance of this factor activation rises as in-use
15 material stock is expected to scale up by a factor of 2.2–2.7 to reach 2215–2720 Gtonnes by 2050
16 (Krausmann et al. 2020). Material extraction in turn is expected to rise to 140–200 Gtonnes·yr⁻¹ by 2060
17 (Hertwich et al. 2020; OECD 2019a) providing unsustainable pressure on climate and environment and
18 calling for fundamental improvements in material productivity.

19 In 2014–2019, the average annual growth rate (AAGR) of global **industrial energy use** was 0.4%
20 compared to 3.2% in 2000–2014, following new policies and trends, particularly demonstrated by
21 China¹² (IEA 2020b,d). Whatever metric is applied, industry (coal transformation, mining, quarrying,
22 manufacturing and construction) driven mostly by material production, dominates global energy
23 consumption. About two fifths of energy produced globally goes to industry, directly or indirectly.
24 Direct energy use (including energy used in coal transformation) accounts for nearly 30% of total final
25 energy consumption. When supplemented by non-energy use, the share for the post AR5 period (2015–
26 2019) stands on average close to 40% of final energy consumption, and at 28.5% of primary energy
27 use.¹³ With an account of indirect energy use for the generation of power and centralized heat to be
28 consumed in industry, the latter scales up to 37%. Industrial energy use may be split by: material
29 production and extraction (including coal transformation) 51% on average for 2015–2019, non-energy
30 use (mostly chemical feedstock) 22%¹⁴, and other energy use (equipment, machinery, food and tobacco,
31 textile, leather etc.) 27%. Energy use for material production and feedstock¹⁵ makes about three quarters
32 (73%) of industrial energy consumption and is responsible for 77% of its increment in 2015–2019 (based
33 on IEA (2021a)).

34 For over a century **industrial energy efficiency** improvements have partially offset growth in GHG
35 emissions. Industrial energy use per ton of extracted materials (ores and building materials as a proxy

FOOTNOTE¹⁰ IEA (2021a) assesses the global plastics collection rate at 17% for 2020.

FOOTNOTE¹¹ Significant progress with data and indicators was reached in recent years with the development of several global coverage material flows datasets (Oberle et al. 2019).

FOOTNOTE¹² China contributed three fourth of global industrial energy use increment in 2000–2014. Since 2014 China’s share in global industrial energy use slowly declines reaching about a third in 2018 (IEA 2020d).

FOOTNOTE¹³ This fits well 28.8% average for 1900–2018 with a slow trend to decline by 0.01% yr⁻¹ in response to the growing share of services in global GDP, around which about 60-years-long cycles can be observed.

FOOTNOTE¹⁴ Industry also produce goods traditionally used as feedstock –hydrogen and ammonia – which in the coming future may be widely used as energy carriers.

FOOTNOTE¹⁵ Mapping global flows of fuel feedstock allows for better tailoring downstream mitigation options for chemical products (Levi and Cullen 2018).

1 for materials going through the whole production chain to final products) fell by 20% in 2000–2019 and
2 by 15% in 2010–2019, accelerated driven by high energy prices to $2.4\% \cdot \text{yr}^{-1}$ in 2014–2019 matching
3 the values observed back in 1990–2000 (Figure 11.2). Assessed per value added using market exchange
4 rates, industrial energy intensity globally dropped by 12% in 2010–2018, after its 4% decline in 2000–
5 2010, resulting in 2000–2018 decline by 15% (IEA 2020b,a). The 2020 COVID crisis slowed down
6 energy intensity improvements by shifting industrial output towards more energy intensive basic
7 materials (IEA 2020e). Specific energy consumption per tonne of iron and steel, chemicals and cement
8 production in 2019 were about 20% below the 2000 level (IEA 2020b,a). This progress is driven by
9 moving towards best available technologies (BATs) for each product through new and highly efficient
10 production facilities in China, India and elsewhere, and by the contribution from recycled scrap metals,
11 paper and cardboard.

12 Physical energy intensity for the production of materials typically declines and then stabilizes at the
13 BAT level once the market is saturated, unless a transformative new technology enters the market
14 (Gutowski et al. 2013; Crijns-Graus et al. 2020; IEA 2021a) Thus, the energy saving effect of switching
15 to secondary used material comes to the forefront, as energy consumption per tonne for many basic
16 primary materials approach the BATs. This highlights the need to push towards circular economy,
17 materials efficiency, reduced demand, and fundamental process changes (e.g. towards electricity and
18 hydrogen based steel making). Improved recycling rates allow for a substantial reduction in energy use
19 along the whole production chain – material extraction, production, and assembling – which is in great
20 excess of energy used for collection, separation, treatment, and scrap recycling minus energy used for
21 scrap landfilling. IEA (2019b) estimates, that by increasing the recycling content of fabricated metals
22 average specific energy consumption (SEC) for steel and aluminium may be halved by 2060. Focusing
23 on whole systems ‘integrative design’ expands efficiency resource much beyond the sum of potentials
24 for individual technologies. Material efficiency coupled with energy efficiency can deliver much greater
25 savings than energy efficiency alone. Gonzalez Hernandez et al. (2018b) stress that presently about half
26 of steel or aluminium are scrapped in production or oversized for targeted services. They show that
27 resource efficiency expressed in exergy as a single metric for both material and energy efficiency for
28 global iron and steel sector is only 33%, while secondary steelmaking is about twice more efficient
29 (66%), than ore-based production (29%). While shifting globally in ore-based production from average
30 to the best available level can save $6.4 \text{ EJ} \cdot \text{yr}^{-1}$, the saving potential of shifting to secondary steelmaking
31 is $8 \text{ EJ} \cdot \text{yr}^{-1}$, and limited mostly by scrap availability and steel quality requirements.

32

33 **11.2.2 New trends in emissions**

34 GHG emissions attributable to the industrial sector (see chapter 2) in 2019 originate from industrial fuel
35 combustion ($7.1 \text{ GtCO}_2\text{-eq}$ direct and about 5.9 Gtonnes indirect from electricity and heat generation¹⁶);
36 industrial processes ($4.5 \text{ GtCO}_2\text{-eq}$) and products use (0.2 Gtonnes), as well as from waste (2.3 Gtonnes)
37 (Figure 11.4a-b). Overall industrial direct GHG emission amounts to $14.1 \text{ GtCO}_2\text{-eq}$, Figure 11.4c and
38 Table 11.1) and scales up to $20 \text{ GtCO}_2\text{-eq}$ after indirect emissions are added,¹⁷ putting industry (24%,
39 direct emissions) second after the energy sector in total GHG emissions and lifting it to the leading

FOOTNOTE¹⁶ Indirect emissions are assessed based on EDGAR database (Crippa et al. 2021). IEA database reports 6 Gt of CO_2 for 2019 (IEA 2020f).

FOOTNOTE¹⁷ Based on Crippa et al. (2021) and Minx et al. (2021). In 2019, industrial CO_2 only emissions were 10.4 GtCO_2 , which due to wider industrial processes and product use (IPPU) coverage exceeds CO_2 emission assessed by IEA (2021a) at 8.9 Gt for 2019 and at $8.4\text{--}8.5 \text{ Gtonnes}$ for 2020.

1 position after indirect emissions are allocated (34% in 2019)¹⁸. The corresponding shares for 1990–2000
2 were 21% for direct emissions and 30% - for both direct and indirect (Crippa et al. 2021; Lamb et al.
3 2021; Minx et al. 2021). As the industrial sector is expected to decarbonize slower than other sectors it
4 will keep this leading position for coming decades (IEA 2021a). In 2000–2010, total industrial emissions
5 have been growing faster (3.8% yr⁻¹), than in any other sector (see chapter 2, mostly due to the dynamics
6 shown by basic materials extraction and production. Industry contributed nearly half (45%) of overall
7 incremental global GHG emissions in the 21st century.

8 Industrial sector GHG emissions accounting is complicated by carbon storage in products (Levi and
9 Cullen 2018). About 35% of chemicals' mass is CO₂, which is emitted at use stage - decomposition of
10 fertilizers, or plastic waste incineration (Saygin and Gielen 2021), and sinks. Re-carbonation
11 mineralization of alkaline industrial materials and wastes (aka the “sponge effect”) provide 0.6–1
12 GtCO₂-yr⁻¹ uptake by cement containing products¹⁹ (Cao et al. 2020; Guo et al. 2021); see section 11.3.6
13 for further discussion in decarbonisation context.

14 In 1970–1990, industrial direct combustion-related emissions were growing modestly, and in 1990–
15 2000 even switched to a slowly declining trend, steadily losing their share in overall industrial
16 emissions. Electrification was the major driver behind both indirect and total industrial emissions in
17 those years. This quiet evolution was interrupted in the beginning of the 21st century, when total
18 emissions increased by 60–68% depending on the metric applied (the fastest growth ever seen). In 2000–
19 2019 iron and steel and cement absolute GHGs increased more than any other period in history
20 (Bashmakov 2021). Emissions froze temporarily in 2014–2016, partly in the wake of the financial crisis,
21 but returned to their growth trajectory 2017–2019 (Figure 11.4a).

22 The largest incremental contributors to industrial emissions 2010–2019 are industrial processes at 40%,
23 then indirect emissions (25%), and only then direct combustion (21%), followed by waste (14%, Figure
24 11.4). Therefore, to stop emission growth and to switch to zero carbon pathway more mitigation efforts
25 should be focused on industrial processes, products use and waste decarbonisation along with the
26 transition to low carbon electrification (Hertwich et al. 2020).

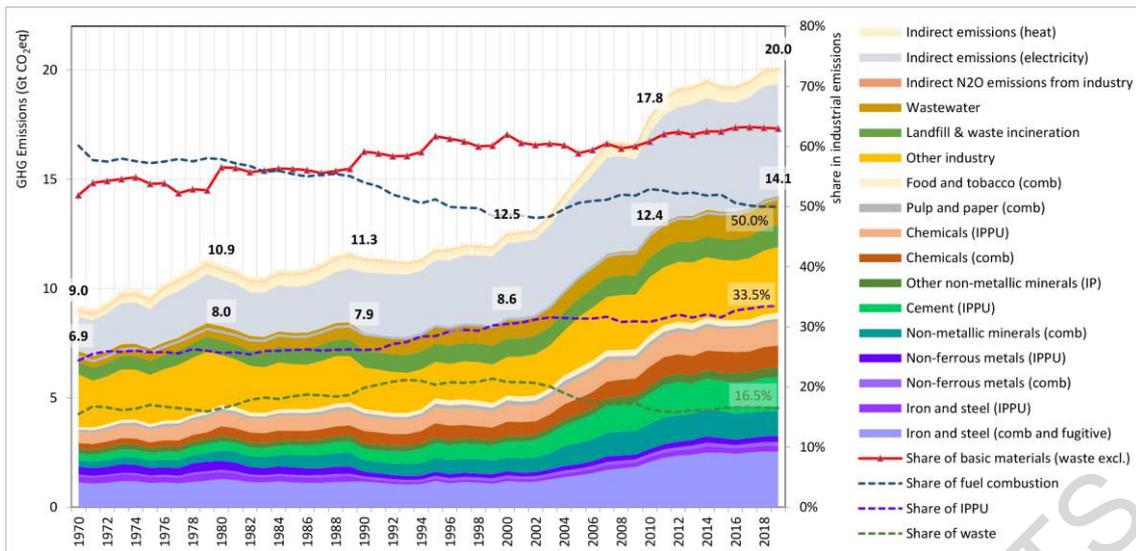

27 Basic materials production dominates both direct industrial GHG emissions (about 62%, waste
28 excluded)²⁰ as well as direct industrial CO₂ emissions (70%), led by iron and steel, cement, chemicals,
29 and non-ferrous metals (Figure 11.4e). Basic materials also contribute 60% to indirect emissions. In a
30 zero-carbon power world, with industry lagging behind in the decarbonisation of high-temperature
31 processes and feedstock, it may replace the energy sector as the largest generator of indirect emissions
32 embodied in capital stock²¹. According to Circle Economy (2020) and Hertwich et al. (2020), GHG
33 emissions embodied in buildings and infrastructure, machinery and transport equipment exceed 50% of
34 their present carbon footprint.

FOOTNOTE¹⁸ According to IEA (2020f) industry fuel combustion CO₂ only emissions contributed 24% to total
combustion emissions, but combined with indirect emission it accounted for 43% in 2018.

FOOTNOTE¹⁹ There are suggestions to incorporate carbon uptake by cement containing products in IPCC
methodology for national GHG inventories (Stripple et al. 2018).

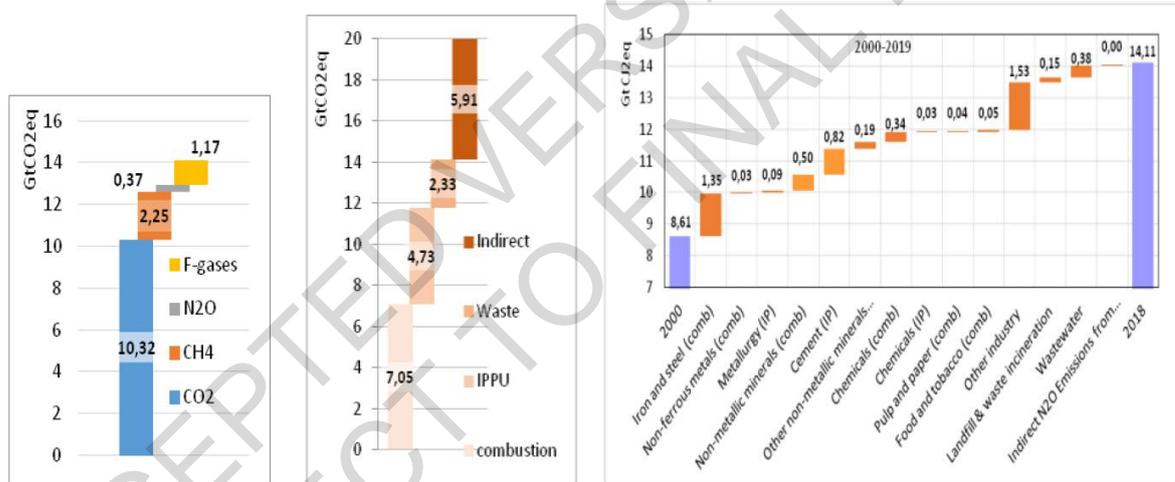

FOOTNOTE²⁰ Crippa et al. (2021) and IEA (2020a) assess materials related scope 1+2 (direct and indirect
emissions) correspondingly at 10.3 for 2019 and at 10.7 for 2018. Hertwich (2021) updated estimates for the global
cradle-to-gate material production related GHG emissions for 2018 at 11.8 Gtonnes (5.1 Gtonnes for metals, 3.7
Gtonnes for non-metallic minerals, 1.8 Gtonnes for plastics and rubber, 1 Gtonne for wood) –which is about 69%
of direct and indirect industrial emissions (waste excluded). These assessments are consistent as transportation of
basic materials contributes around 1 GtCO₂-eq. to GHG emissions.

FOOTNOTE²¹ According to Hertwich et al. (2020), of 11.5 GtCO₂-eq 2015 global materials GHG footprint about
5 Gt were embodied in buildings and infrastructure, and nearly 3 Gtonnes in machinery, vehicles, and electronics.

4
5

(a) Industrial emissions by source (left scale) and emissions structure (right scale). Comb – indicates direct emissions from fuels combustion. IPPU – indicates emissions from industrial processes and product use. Indirect emissions from electricity and heat generation are shown on the top. Shares on the right are shown for direct emissions

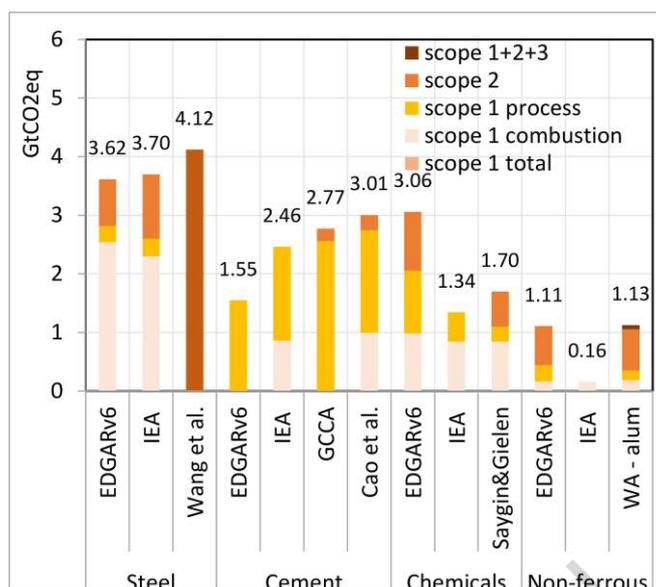

6
7

(b) 2019 direct combustion and process emissions split by GHGs

(c) 2019 emissions split by major sources

(d) increments of GHG emissions by sources (direct emissions only)

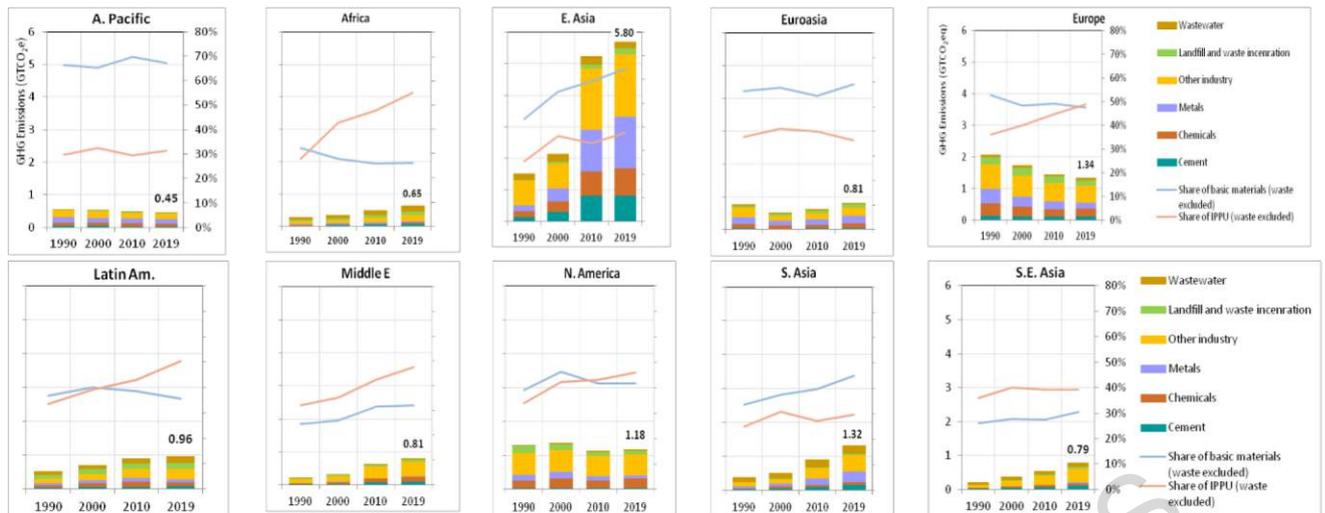

(e) 2019-2020 emissions by major basic materials production

Figure 11.4 Industrial sector direct global GHG emissions

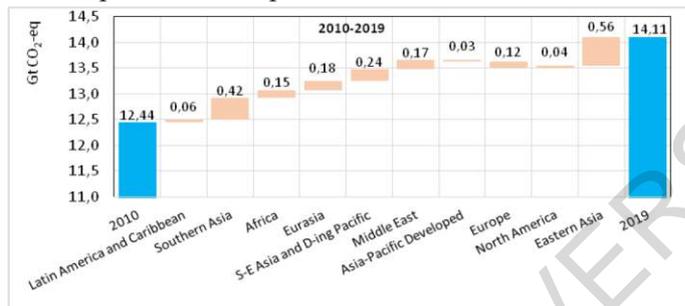

Source: Calculated based on emissions data from Crippa et al., (2021) and Minx et al., (2021). Indirect emissions were assessed using IEA (2021b). For the figure (e): IEA (2020b, 2021a); Cao et al. (2020); Wang et al. (2021); International Aluminium Institute (2021a) and GCCA (2021a).

In 1970–2000, direct GHG emissions per unit of energy showed steady decline interrupted by noticeable growth in 2001–2018 driven by fast expansion of steel and cement production in China (Figure 11.5), where in 2000–2015 on average every month 12 heavy industrial facilities were built (IEA 2021a). Non-energy related GHG emissions per unit of extracted materials decline continuously, as the share of not carbon intensive building materials (aggregates and sand) grows.

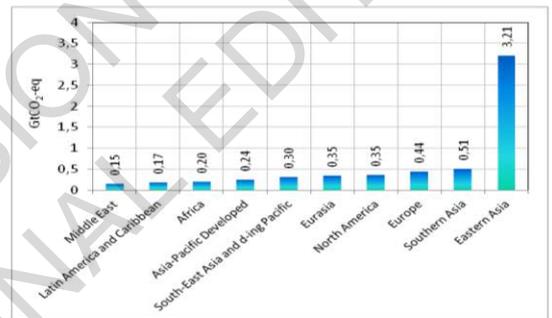

Wang et al. (2021)'s conclusion that iron and steel carbon intensity stagnated in 1995–2015 due to skyrocketing carbon intensive material production in China and India (Figure 11.5) may be extended to 2020 (Bashmakov 2021) and to other basic materials. For aluminium carbon intensity declined in 2010–2019 by only 2% (International Aluminium Institute 2021a). Carbon intensity of cement making since 2010 is down by only 4%. In 1990–2019 it fell by 19.5%, mostly due to energy efficiency improvements (by 18.5%) as the carbon intensity of the fuel mix declined only by 3% (GCCA 2021b). Historical analysis shows the carbon intensity of steel production has declined with “stop and go” patterns in 50–60 years cycles, reflective of the major jumps in best available technology. From 1900–1935 and from 1960–1990 specific scope 1+2+3 emissions fell by 1.5–2.5 tCO₂ per tonne, or as much as needed now to achieve net zero. While historical declines were mostly due to commissioning large capacities with new technologies, with total emissions growing, by 2050 and beyond the decline will likely materialize via new ultra low emission capacity replacements pushing absolute emissions to net zero (Bataille et al. 2021b).

11.2.3 Industrial development patterns and supply chains (regional)

2 The dramatic increase in industrial emissions after 2000 is clearly associated with China's²² and other
3 non-OECD Asian countries' economic growth, which dominated both absolute and incremental
4 emissions (Figure 11.5a-b).

5 More recent 2010–2019 trends show that regional contributions to additional emissions are distributed
6 more evenly, while a large part still comes from Asian countries, where both rates of economic growth
7 and the share of industrial emissions much exceed the global average. All other regions also contributed
8 to total industrial GHG emissions. Structural shifts towards emissions from industrial processes and
9 products use are common for many regions (Figure 11.5a).

10 **Economic development.** Regional differences in emission trends are determined by the differences
11 observed in economic development, trade and supply chain patterns. The major source of industrial
12 emissions is production of energy intensive materials, such as iron and steel, chemical and
13 petrochemicals, non-ferrous metals and non-metallic products. Steel and cement are key inputs to
14 urbanization and infrastructure development (buildings and infrastructure are responsible for about
15 three fourths of the steel stock). Application of a “services-stock-flow-emissions” perspective
16 (Wiedenhofer et al. 2019; Haberl et al. 2021; Bashmakov 2021) shows that relationship patterns
17 between stages of economic development, per capita stocks and flows of materials are not trivial with
18 some clear transition points. Cao et al. (2017) mapped countries by four progressive stages in cement
19 stock per capita S-shape evolution as a function of income and urbanization: initial stage for developing
20 countries with a low level and slow linear growth; take-off stage with accelerated growth; slowdown
21 stage; and finally a shrinking stage (represented by just a few countries with very high incomes
22 exceeding 40k USD 2010 per capita) and urbanization levels above 80%. Bleischwitz et al. (2018) use
23 a similar approach with 5 stages to study material saturation effects for apparent consumption and stocks
24 per capita for steel, cement, aluminium, and copper. This logic may be generalized to other materials
25 from which in-use stock is built. While globally cement in-use stock is about 12 tonnes per capita, in
26 developed countries it is 15-30 tonnes per capita, but order of magnitude lower in developing states
27 with high per capita escalation rates (Cao et al. 2017). When stocks for some materials saturate – per
28 capita stock peaks – the ‘scrap age’ is coming (Pauliuk et al. 2013a). Steel in-use stock has already
29 saturated in advanced economies at 14±2 tonnes per capita due to largely completed urbanization and
30 infrastructure developments and a switch towards services-dominated economy. This saturation level
31 is 3-4 times that of the present global average, which is below 4 tonnes per capita (Pauliuk et al. 2013a;
32 Wiedenhofer et al. 2019; Graedel et al. 2011). China is entering the maturing stage of steel and cement
33 consumption resulting in a moderate projection of additional demand followed by expected industrial
34 emissions peaking in the next 10-15 years (Bleischwitz et al. 2018; Zhou et al. 2013; Wu et al. 2019;
35 OECD 2019a; Zhou et al. 2020). But many developing countries are still urbanizing, and the growing
36 need for infrastructure services results in additional demand for steel and cement. Materials intensity of
37 the global economy is projected by OECD (2019a) to decline at 1.3% yr⁻¹ till 2060, driven by improving
38 resource efficiency and the switch to circular economy, but with a projected tripling of global GDP it
39 means a doubling of projected materials use (OECD 2019a). Under the business-as-usual scenario,
40 India's demand for steel may more than quadruple over the next 30 years (de la Rue du Can et al. 2019;
41 Dhar et al. 2020). In the IEA (2021a) Net Zero Energy scenario saturation effect along with material
42 efficiency counterbalances activity effects and keeps demand growth for basic materials modest while
43 escalate demand for critical materials (copper, lithium, nickel, graphite, cobalt and others).

44 **International trade and supply chain.** In Equation 11.1 the share of allocated emissions (Dm) equals
45 unity when territorial emission is considered, and to the ratio of domestically used materials to total

FOOTNOTE²² In 2020 China accounted for nearly 60% of global steel and cement production (IEA 2021a) and in 2015 over than half of the material production associated emissions occurred in China (Hertwich 2021).

1 material production for consumption-based emission accounting. Tracking consumption-based
2 emissions provides additional insights in the global effectiveness of national climate policies. Carbon
3 emissions embodied in international trade are estimated to account for 20-30% of global carbon
4 emissions (Meng et al. 2018; OECD.Stat 2019) and are the reason for different emissions patterns of
5 OECD versus non-OECD countries (chapter 2).

6 Based on OECD.Stat (2019) datasets, 2015 CO₂ emissions embodied in internationally traded industrial
7 products (manufacturing and mining excluding fuels) by all countries are assessed at 3 GtCO₂, or 30%
8 of direct CO₂ emission in the industrial sector as reported by Crippa et al. (2021). OECD countries
9 collectively have reduced territorial emissions (shares of basic materials in direct emissions in those
10 regions decline, (Figure 11.5b), but demonstrated no progress in reducing outsourced emissions
11 embedded in imported industrial products (Arto and Dietzenbacher 2014; OECD.Stat 2019).
12 Accounting for net carbon emissions embodied in international trade of only industrial products (1283
13 mln tCO₂ in 2015) escalates direct OECD industrial CO₂ emissions (1333 mln tCO₂ of energy-related
14 and 502 mln tCO₂ of industrial processes) 1.7 fold, 2.3-fold for the US, 1.5-fold for the EU, and more
15 than triples it for the UK, while cutting (*Dm*) by a third for China and Russia (IEA 2020f; OECD.Stat
16 2019). In most OECD economies, the amount of CO₂ embodied in net import from non-OECD countries
17 is equal to, or even greater than, the size of their Paris 2030 emissions reduction commitments. In the
18 UK, parliament Committee on Energy and Climate Change requested that a consumption-based
19 inventory be complementarily used to assess the effectiveness of domestic climate policy in delivering
20 absolute global emissions reductions (Barrett et al. 2013; UKCCC 2019a). It should be noted that the
21 other side of the coin is that exports from countries with lower production carbon intensities can lead
22 to overall less emissions than if production took place in countries with high carbon intensities, which
23 may become critical in the global evolution toward lower emissions. The evolution of *Dm* to the date
24 was driven mostly by factors other than carbon regulation often equipped with carbon leakage
25 prevention tools. Empirical tests have failed to date to detect meaningful “carbon leakage” and impacts
26 of carbon prices on net import, direct foreign investments, volumes of production, value added,
27 employment, profits, and innovation in industry (Acworth et al. 2020; Branger et al. 2016; Carratù et
28 al. 2020; Ellis et al. 2019; Saussay and Sato. 2018; Zachmann and McWilliams 2020; Naegelé and
29 Zaklan 2019; Pyrka et al. 2020; Sartor 2013). In the coming years availability of large low-cost
30 renewable electricity potential and cheap hydrogen may become a new driver for relocation of such
31 carbon intensive industries as steel production (Gielen et al. 2020; Bataille 2020a; Bataille et al. 2021a;
32 Saygin and Gielen 2021).

33

34 **11.3 Technological developments and options**

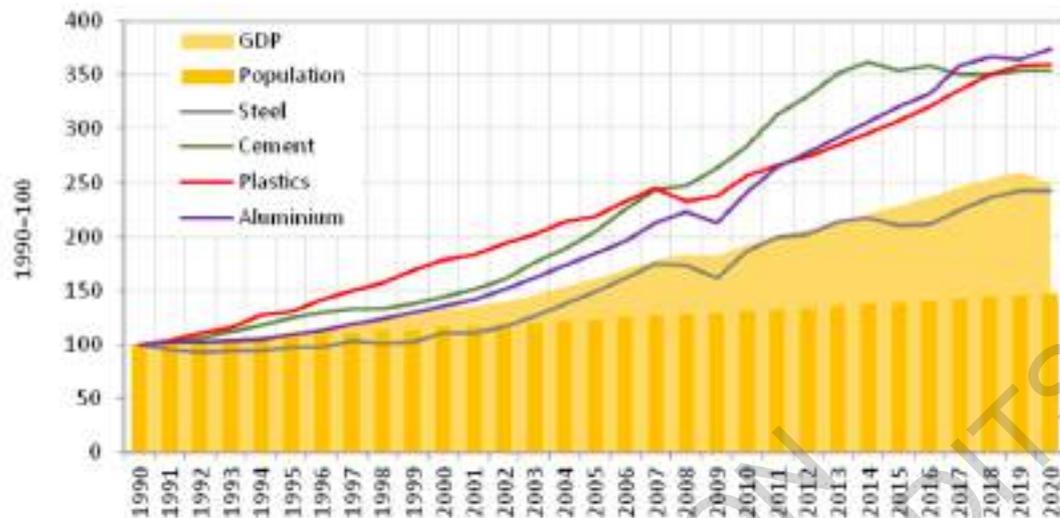

35 The following overview of technical developments and mitigation options which relate to the industrial
36 sector is organised in six equally important strategies: (i) demand for materials. (ii) materials efficiency,
37 (iii) circular economy and industrial waste, (iv) energy efficiency, (v) electrification and fuel switching,
38 and (vi) CCUS, feedstock and biogenic carbon. Each strategy is described in detail, followed by a
39 discussion of possible overlaps and interactions between strategies and how conflicts and synergies can
40 be addressed through integration of the approaches.

41

42 **11.3.1 Demand for materials**

43 Demand for materials is a key driver of energy consumption and CO₂ emissions in the industrial sector.
44 Rapid growth in material demand over the last quarter century has seen demand for key energy-intensive
45 materials increase 2.5– to 3.5–fold (see Figure 11.6), with growth linked to, and often exceeding,
46 population growth and economic development. The International Energy Agency explains, “as

1 economies develop, urbanise, consume more goods and build up their infrastructure, material demand
 2 per capita tends to increase considerably. Once industrialised, an economy's material demand may level
 3 off and perhaps even begin to decline" (IEA 2019b).

4
 5 **Figure 11.6 Growth in global demand for selected key materials and global population, 1990–2019**

6 Notes: Based on global values, shown indexed to 1990 levels (=100). Steel refers to crude steel production.
 7 Aluminium refers to primary aluminium production. Plastic refers to the production of subset of key thermoplastic
 8 resins. Cement and concrete follow similar demand patterns.

9 Sources: 1990–2018: IEA (2020b). 2019–2020: World Steel Association (2021); International Aluminium Institute
 10 (2021a); U.S. Geological Survey (2021); GCCA (2021a); World Bank (2021); Statista (2021b).
 11

12 The Kaya-like identity presented earlier in the chapter (Equation 11.1) suggests that material demand
 13 can be decoupled from population and economic development by two means: (i) reducing the
 14 accumulated material stock (MStock) used to deliver material services; and, (ii) reducing the material
 15 (MPR +MSE) required to maintain material stocks (MStock). Such material demand reduction
 16 strategies are linked upstream to material efficiency strategies (the delivery of goods and services with
 17 less material demand, and thus energy and emissions) and to demand reduction behaviours, through
 18 concepts such as sufficiency, sustainable consumption and social practice theory (Spangenberg and
 19 Lorek 2019). Materials demand can also be influenced through urban planning, building codes and
 20 related socio-cultural norms that shape the overall demand for square meters per capita of floor space,
 21 mobility and transport infrastructures (Chapter 5).

22 Modelling suggests that per capita material stocks saturate (level off) in developed countries and
 23 decouple from GDP. Pauliuk et al. (2013b) demonstrated this saturation effect in an analysis of in-use
 24 steel stocks in 200 countries, showing that per capita steel in stocks in countries with a long industrial
 25 history (e.g. US, UK, Germany) had saturation levels between 11 and 16 tonnes. More recently,
 26 Bleischwitz et al. (2018) confirmed the occurrence of a saturation effect for four materials (steel,
 27 cement, aluminium and copper) in four industrialised countries (Germany, Japan, UK, US) together
 28 with China. These findings have led to the revision of some material demand forecasts, which
 29 previously had been based solely on population and economic trends.

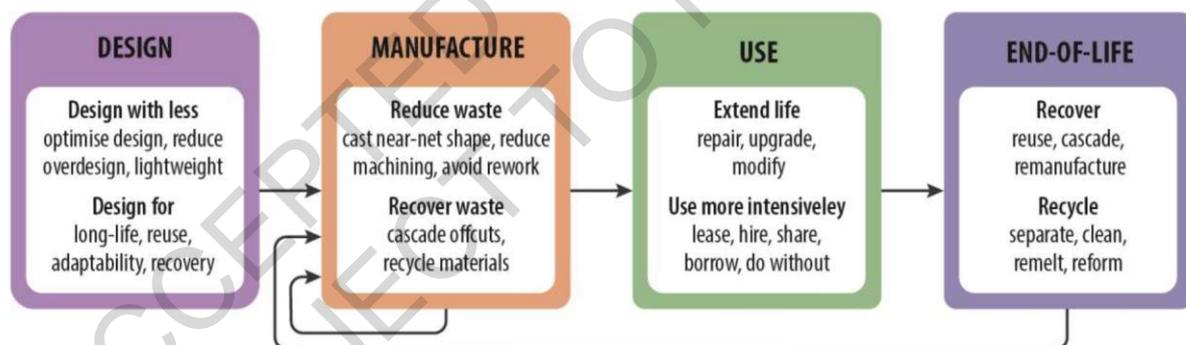

30 The saturation effect for material stocks is critical for managing material demand in **developed**
 31 **countries**. Materials are required to meet demand for the creation of new stocks and the maintenance
 32 of existing stocks (Gutowski et al. 2017). Once saturation is attained the need for new stocks is
 33 minimised, and materials are only required for replacing old stocks and maintenance. Saturation allows
 34 material efficiency strategies (such as lightweight design, longer lifetimes, and more intense use) to
 35 reduce the required per capita level of material stocks, and material circularity strategies (closing

1 material loops through remanufacture, reuse, recycling) to lessen the energy and carbon impacts
 2 required to maintain the material stock. However, it should be noted that some materials still show little
 3 evidence of saturation (i.e., plastics, see Box 11.2). Furthermore, meeting climate change targets in
 4 developed countries will require the construction of new low-carbon infrastructures (i.e., renewable
 5 energy generation, new energy distribution and storage systems, electric vehicles and building heating
 6 systems) which may increase demand for emissions intensive materials (i.e. steel, concrete, glass).

7 For **developing countries**, who are still far from saturation levels, strong growth for new products and
 8 the creation of new infrastructure capacity may still drive global material demand. However, there is an
 9 expectation that economic development can be achieved at lower per capita material stock levels, based
 10 on the careful deployment of material efficiency and circularity by design (Grubler et al. 2018).

11.3.2 Material efficiency

13 ME—the delivery of goods and services with less material—is increasingly seen as an important
 14 strategy for reducing GHG emissions in industry (IEA 2017, 2019b). Options to improve ME exist at
 15 every stage in the life-cycle of materials and products, as shown in Figure 11.7. This includes: designing
 16 products which are lighter, optimising to maintain the end-use service while minimizing material use,
 17 designing for circular principles (i.e. longer life, reusability, repairability, and ease of high quality
 18 recycling); pushing manufacturing and fabrication process to use materials and energy more efficiently
 19 and recover material wastes; increasing the capacity, intensity of use, and lifetimes of product in use;
 20 improving the recovery of materials at end-of-life, through improved remanufacturing, reuse and
 21 recycling processes. For more specific examples see Allwood et al. (2012); Rissman et al. (2020); Scott
 22 et al. (2019); Hertwich et al. (2019) and Lovins (2018).

24
 25 **Figure 11.7 Material efficiency strategies across the value chain**

26 Source: derived from strategies in Allwood et al. (2012).

27
 28 ME provides plentiful options to reduce emissions, yet because interventions are dispersed across
 29 supply chains and span many different stakeholders, this makes assessing mitigation potentials and
 30 costs more challenging. For this reason, ME interventions have traditionally been under-represented in
 31 climate change scenario modelling and integrated assessment models (IAMs) (Grubler et al. 2018;
 32 Allwood 2018). However, two advances in the modelling of materials flows have underpinned the
 33 recent emergence of ME options being included in climate scenario modelling.

34 Firstly, over many years, the academic community has built up detailed global material flow maps of
 35 the processing steps involved in making energy-intensive materials. Some prominent recent examples
 36 include: steel (Gonzalez Hernandez et al. 2018b), pulp and paper (Van Ewijk et al. 2018),
 37 petrochemicals (Levi and Cullen 2018). In addition, material flow maps at the regional and sectoral

1 levels have flourished, for example, steel (Serrenho et al. 2016) and cement (Shanks et al. 2019) in the
2 UK; automotive sheet-metal (Horton et al. 2019); and steel powder applications (Azevedo et al. 2018).
3 The detailed and transparent physical mapping of material supply chains in this manner enables ME
4 interventions to be traced back to where emissions are released, and allows these options to be compared
5 against decarbonisation and traditional energy efficiency measures (Levi and Cullen 2018). For
6 example, a recent analysis by Hertwich et al. (2019) makes the link between ME strategies and reducing
7 greenhouse gas emissions in buildings, vehicles and electronics, while Gonzalez Hernandez et al.
8 (2018a) examines leveraging ME as a climate strategy in EU policy. Research to explore the combined
9 analysis of materials and energy, using exergy analysis (for steel, (Gonzalez Hernandez et al. 2018b))
10 allows promising comparisons across industrial sectors.

11 Secondly, many ME interventions result in immediate GHG emissions savings (short-term), for
12 example, light-weighting products, re-using today's product components, and improving manufacturing
13 yields. Yet, for other ME actions emissions savings are delayed temporally (long-term). For example,
14 designing a product for future reuse, or with a longer-life, only reaps emissions savings at the end of
15 the product life, when emissions for a replacement product are avoided. Many durable products have
16 long life-times (cars >10 years, buildings >40 years) which requires dynamic modelling of material
17 stocks, over time, to enable these actions to be included in scenario modelling activities. Consequently,
18 much effort has been invested recently to model material stocks in use, to estimate their lifetimes, and
19 anticipate the future waste and replenishment materials to maintain existing stocks and grow the
20 material stock base. Dynamic material models have been applied to material and product sectors, at the
21 country and global level. These include, for example: vehicles stocks in the UK (Serrenho et al. 2017;
22 Craglia and Cullen 2020) and in China (Liu et al. 2020); buildings stocks in the UK (Cabrera Serrenho
23 et al. 2019), China (Hong et al. 2016; Cao et al. 2018, 2019) and the European Union (Sandberg et al.
24 2016); electronic equipment in Switzerland (Thiébaud et al. 2017); specific material stocks, such as
25 cement (Cao et al. 2020, 2017), construction materials (Sverdrup et al. 2017; Habert et al. 2020), plastics
26 (Geyer et al. 2017), copper (Daehn et al. 2017), and all metals (Elshkaki et al. 2018); all materials in
27 China (Jiang et al. 2019), Switzerland (Heeren and Hellweg 2019) and the world (Krausmann et al.
28 2017).

29 These two advances in the knowledge base have allowed the initial inclusion of some ME strategies in
30 energy and climate change scenario models. The International Energy Agency (IEA) first created a ME
31 scenario (MES) in 2015, with an estimated 17% reduction in industrial energy demand in 2040 (IEA
32 2015). World energy outlook report includes a dedicated sub-chapter with calculations explicitly on
33 industrial material efficiency (IEA 2019c). They also include ME options in their modelling frameworks
34 and reporting, for example for petrochemicals (IEA 2018a), and in the Material Efficiency in Clean
35 Energy Transitions report (IEA 2019b). In Grubler et al. (2018) 1.5 degree Low Energy Demand (LED)
36 scenario, global material output decreases by 20% from today, by 2050, with one-third due to
37 dematerialisation, and two-thirds due to ME, resulting in significant emissions savings. Material
38 Economics analysis of Industrial Transformation 2050 (Material Economics 2019), found that resource
39 efficiency and circular economy measures (i.e. ME) could almost halve the 530 MtCO₂ yr⁻¹ emitted by
40 the basic materials sectors in the EU by 2050. Finally, the Emissions gap report, UNEP (2019) includes
41 an assessment of potential material efficiency savings in residential buildings and cars.

42 Clearly, more work is required to fully integrate ME strategies into mainstream climate change models
43 and future scenarios. Efforts are focused on endogenising ME strategies within climate change
44 modelling, assessing the synergies and trade-offs which exist between energy efficiency and ME
45 interventions, and building up data for the assessment emissions saved and the cost of mitigation from
46 real ME actions. This requires analysts to work in cross-disciplinary teams and to engage with
47 stakeholders from across the full breadth of material supply chains. Efforts should be prioritised to
48 foster engagement between the IAM community and emerging ME models based in the Life Cycle

1 Assessment, Resource Efficiency, and Industrial Ecology communities (see also Sharmina et al.
2 (2021)).

3

4 **11.3.3 Circular economy and industrial waste**

5 Circular economy (CE) is another effective approach to mitigate industrial GHG emissions and has
6 been widely promoted worldwide since the fourth IPCC assessment report (AR4). From an industrial
7 point of view, CE focuses on closing the loop for materials and energy flows by incorporating policies
8 and strategies for more efficient energy, materials and water consumption, while emitting minimal
9 waste to the environment (Geng et al. 2013). Moving away from a linear mode of production
10 (sometimes referred to as an “extract-produce-use-discard” model), CE promotes the design of durable
11 goods that can be easily repaired, with components that can be reused, remanufactured, and recycled
12 (Wiebe et al. 2019). In particular, since CE promotes reduction, reuse and recycling, a large amount of
13 energy and GHG intense virgin material processing can be reduced, leading to significant carbon
14 emission reductions. For example, in the case of aluminium, the energy efficiency of primary
15 production is relatively close to best available technology (See **Figure 11.8**) while switching to
16 production using recycled materials requires only about 5% as much energy (11.4.1.4). However,
17 careful evaluation is needed from a life cycle perspective since some recycling activities may be energy
18 and emission intensive, for example, chemical recycling of plastics (11.4.1.3).

19 As one systemic approach, CE can be seen as conducted at different levels, namely, at the micro-level
20 (within a single company, such as process integration and cleaner production), meso-level (between
21 three or more companies, such as industrial symbiosis or eco-industrial parks) and macro-level (cross-
22 sectoral cooperation, such as urban symbiosis or regional eco-industrial network). Each level requires
23 different tools and policies, such as CE-oriented incentive and tax policies (macro-level), and eco-
24 design regulations (micro-level). This section is focused on industry and a broader discussion of the CE
25 concept is found in Box 12.2 and section 5.3.4.2.

26 **Micro-level:** More firms have begun to implement the concept of CE, particularly multi-national
27 companies, since they believe that multiple benefits can be obtained from CE efforts, and it has become
28 common across sectors (D’Amato et al. 2019). Typical CE tools and policies at this level include cleaner
29 production, eco-design, environmental labelling, process synthesis, and green procurement. For
30 instance, leading chemical companies are incorporating CE into their industrial practices, for example,
31 through the design of more recyclable and degradable plastics, a differentiated and market-driven
32 portfolio of resins, films and adhesives that deliver a total package that is more sustainable, cost-
33 efficient and capable of meeting new packaging and plastics preferences. Problematically, at the same
34 time the plastics industry is improving recyclability it has, for example, been expanding into markets
35 without recycling capacity (Mah 2021). Similarly, automakers are pursuing strategies to increase the
36 portion of new vehicles that is fully recyclable when they reach end of life, with increasing ambitions
37 for using recycled material, largely motivated by end-of-life vehicle regulations. This will require
38 networks are available to collect and sort all the materials in vehicles, and policy incentives to do it
39 (Wiebe et al. 2019; Soo et al. 2021).

40 **Meso-level:** Industrial parks first appeared in Manchester, UK, at the end of the 19th century and they
41 have been implemented in industrialized countries for maximizing energy and material efficiency,
42 which has also merit for CO₂ emissions reduction, as stated well in AR5. Industrial parks reduce the
43 cost of infrastructure and utilities by concentrating industrial activities in planned areas, and are typical
44 founded around large, long term anchor companies. Complementary industries and services provided
45 by industrial parks can entail diversified effects on the surrounding region and stimulate regional
46 development (Huang et al. 2019a). This is crucial for small and medium enterprises (SMEs) because
47 they often lack access to information and funds for sophisticated technologies.

1 Typical CE tools and policies at this level include sustainable supply chains and industrial symbiosis.
2 A common platform for sharing information and enhancing communication among industrial
3 stakeholders through the application of information and telecommunication technologies is helpful for
4 facilitating the creation of industrial symbiosis. The main benefit of industrial symbiosis is the overall
5 reduction of both virgin materials and final wastes, as well as reduced/avoided transportation costs from
6 byproduct exchanges among tenant companies, which can specifically help small and medium sized
7 enterprises to improve their growth and competitiveness. From climate perspective, this indicates
8 significant industrial emission mitigation since the extraction, processing of virgin materials and the
9 final disposal of industrial wastes are more energy-intensive. Also, careful site selection of such parks
10 can facilitate the use of renewable energy. Due to these advantages, eco-industrial parks have been
11 actively promoted, especially in East Asian countries, such as China, Japan and South Korea, where
12 national indicators and governance exist (Geng et al. 2019). For instance, the successful implementation
13 of industrial symbiosis at Dalian Economic and Technological Development Zone has achieved
14 significant co-benefits, including GHG emission reduction, economic and social benefits and improved
15 ecosystem functions (Liu et al. 2018). Another case at Ulsan industrial park, South Korea, estimated
16 that 60,522 tonnes CO₂ were avoided annually through industrial symbiosis between two companies
17 (Kim et al. 2018b). The case of China shows a great potential of implementing these measures,
18 estimating 111 million tonne CO₂ equivalent will be reduced in 213 national-level industrial parks in
19 2030 compared with 2015 (Guo et al. 2018). As such, South Korea's national eco-industrial park project
20 has reduced over 4.7 million tonne CO₂ equivalent through their industrial symbiosis efforts (Park et al.
21 2019). Meso-level CE solutions have been identified as essential for industrial decarbonisation (see
22 11.4.3). Moreover, waste prevention as the top of the so-called "waste hierarchy" can be promoted on
23 the meso-level for specific materials or product systems. For instance, the European Environment
24 Agency published a report on plastic waste prevention approaches in all EU 28 member states (Wilts
25 and Bakas 2019). However, challenges exist for industrial symbiosis activities, such as the inter-firm
26 contractual uncertainties, the lack of synergy infrastructure, and the regulations that hamper reuse and
27 recycling. Therefore, necessary legal reforms are needed to address these implementation barriers.

28 **Macro-level:** The macro- level uses both micro- and meso-level tools within a broader policy strategy,
29 addressing the specific challenge of CE as a cross-cutting policy (Wilts et al. 2016). More synergy
30 opportunities exist beyond the boundary of one industrial park. This indicates the necessity of scaling
31 up industrial symbiosis to urban symbiosis. Urban symbiosis is defined as the use of by-products (waste)
32 from cities as alternative raw materials for energy sources for industrial operations (Sun et al. 2017). It
33 is based on the synergistic opportunity arising from the geographic proximity through the transfer of
34 physical sources (waste materials) for environmental and economic benefits. Japan is the first country
35 to promote urban symbiosis. For instance, the Kawasaki urban symbiosis efforts can save over 114,000
36 tons of CO₂ emission annually (Ohnishi et al. 2017). Another simulation study indicates that Shanghai
37 (the largest Chinese city) has a potential of saving up to 16.8 MtCO₂ through recycling all the available
38 wastes (Dong et al. 2018). As such, the simulation of urban energy symbiosis networks in Ulsan, South
39 Korea indicates that 243,396 tCO₂⁻¹·yr⁻¹ emission and 48 million USD·yr⁻¹ fuel cost can be saved (Kim
40 et al. 2018a). Moreover, Wiebe et al. (2019) estimates that the adoption of the CE can lead to a
41 significantly lower global material extraction compared to a baseline. Their global results range from a
42 decrease of about 27% in metal extraction to 8% in fossil fuel extraction and use, 8% in forestry
43 products, and about 7% in non-metallic minerals, indicating significant climate change benefits. A
44 macro-perspective calculation on the circulation of iron in Japan's future society shows that CO₂
45 emissions from the steel sector can be reduced by 56% as per the following assumptions: the amount
46 recovered from social stock is the same as the amount of inflow, and all scrap was used domestically,
47 and the export of steel products is halved (LCS 2018). A key challenge is to go beyond ensuring proper
48 waste management to setting metrics, targets and incentives to preserve the incorporated value in
49 specific waste streams. Estimations for Germany have shown that despite recycling rates of 64% for all

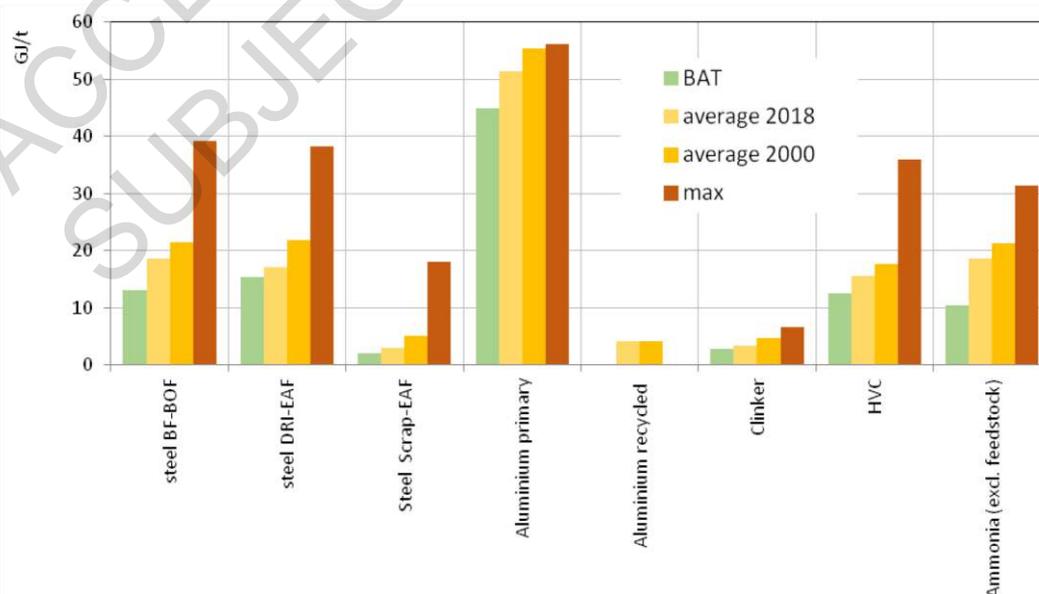

1 solid waste streams, these activities only lead to a resource use reduction of only 18% (Steger et al.
 2 2019). In general, the identification of the most appropriate CE method for different countries requires
 3 understanding and information exchange on background conditions, local policies and myriad other
 4 factors influencing material flows from the local up to the global level (Tapia Carlos et al. 2019). Also,
 5 an information platform should be created at the national level so that all the stakeholders can share
 6 their CE technologies and expertise, information (such as materials/energy/water consumption data),
 7 and identify the potential synergy opportunities.

9 11.3.4 Energy Efficiency

10 Energy efficiency in industry is an important mitigation option and central in keeping 1.5°C within
 11 reach (IPCC SR1.5). It has long been recognized as the first mitigation option in industry (Yeen Chan
 12 and Kantamaneni 2016; Nadel and Ungar 2019; IEA 2021a). It allows reduction of the necessary scale
 13 of deployment for low-carbon energy supplies and associated mitigation costs (Energy Transitions
 14 Commission 2018). The efficiency potentials are greatest in the non-energy intensive industries and
 15 often relatively limited in energy intensive ones, such as steel (Pardo and Moya 2013; Arens et al. 2017;
 16 Kuramochi 2016). Deep decarbonisation in these subsectors requires fundamental process changes but
 17 energy efficiency remains important to reduce costs and the need for low-carbon energy supplies.

18 Below, we focus mainly on the technical progress and on new options that are reflected in the literature
 19 since AR5 and refer the reader there for a broader and deeper treatment of energy efficiency.
 20 Digitalisation and the development of industrial high-temperature heat pumps are two notable
 21 technology developments that can facilitate energy efficiency improvements.

22 Industrial energy efficiency can be improved through multiple technologies and practices (Tanaka 2011;
 23 Fawkes et al. 2016; Crijns-Graus et al. 2020; IEA 2020a; Lovins 2018). There are two parallel processes
 24 in improvement of SEC: progress in energy-efficient BAT, and moving the SEC of industrial plants
 25 towards BAT. Both slow down as theoretical thermodynamic minimums are approached (Gutowski et
 26 al. 2013). For the last several decades the focus has been on effective spreading of BAT technologies
 27 through application of policies for worldwide diffusion of energy-saving technologies (see 11.6). As a
 28 result the SEC for many basic primary materials is approaching BAT and there are signs that energy
 29 efficiency improvements have been slowing down over recent decades (IEA 2019d, 2020a, 2021a)
 30 (Figure 11.8).

31

1 **Figure 11.8 Energy efficiency indicators for basic material production. Energy accounting is based on**
2 **final energy use. Sectoral boundaries for steel are as defined in (IEA 2020c).**

3 Sources: Calculated based on (IEA 2017, 2018b; IEA and WBCSD 2018; IEA 2020b; Hasanbeigi et al. 2012;
4 UNIDO 2010; Saygin et al. 2011; WBCSD 2016; Crijns-Graus et al. 2020; Napp et al. 2014; Moya and Pardo
5 2013; International Aluminium Institute 2020; IEA 2019b, 2020c)

6
7 **11.3.4.1 Heat use energy efficiency improvement**

8 While about 10% of global GHG emissions originate from combustion to produce high temperature
9 heat for basic material production processes (Sandalow et al. 2019), limited efforts have been made to
10 decarbonize heat production. There is still a large potential for using various grades of waste heat and
11 the development of high-temperature heat pumps facilitates its use. NEDO (2019) applies a ‘Reduce,
12 Reuse, and Recycle’ concept for improved energy efficiency, and we use this frame our discussion of
13 heat efficiency.

14 *Reduce* refers to reducing heat needs via improved thermal insulation, for example, where porous type
15 insulators have been developed with thermal conductivity half of what is traditionally achieved by heat
16 resistant bricks under conditions of high compressive strength (Fukushima and Yoshizawa 2016). *Reuse*
17 refers to waste heat recovery. A study for the EU identified a waste heat potential of about 300 TWh·yr⁻¹,
18 corresponding to about 10 % of total energy use in industry. About 50% of this was below 200°C,
19 about 25% at temperatures 200–500°C, and 25% at temperatures of 500°C and above (Papapetrou et al.
20 2018). A survey conducted in Japan showed that 9% of the input energy is lost as waste heat, of which
21 heat below 199°C accounts for 68% and that below 149°C was 29% (NEDO 2019). McBrien et al.
22 (2016) identified that in steel sector process heat recovery presently saves 1.8 GJ per tonne of hot rolled
23 steel, while integrated across all production processes heat recovery with conventional heat exchange
24 could save 2.5 GJ per tonne, and it scales up to 3.0 GJ per tonne using an alternative heat exchange that
25 recovers energy from hot steel. High temperature industrial heat pumps represent a new and important
26 development for upgrading waste heat and at the same time the facilitate electrification. One recent
27 example is a high temperature heat pump that can raise temperatures up to 165°C at a coefficient of
28 performance (COP) of 3.5 by recovering heat from unused hot water (35–65°C) (Arpagaus et al. 2018).
29 Commercially available heat pumps can deliver 100–150°C but at least up to 280°C is feasible
30 (Zühlsdorf et al. 2019). Mechanical vapor recompression avoids the loss of latent heat by condensation,
31 then it acts as a highly efficient heat pump with a 5–10 COP (Philibert 2017a).

32 Waste heat to power (WHP), or *Recycle* in NEDO’s terms, is also an underutilised option. For example,
33 a study for the cement, glass and iron industries in China showed that current technology enables only
34 7–13% of waste heat to be used for power generation. With improved technologies, potentially 40–57%
35 of waste heat with temperatures above 150°C could be used for power generation via heat recovery.
36 Thermal power fluctuations can be a challenge and negatively affect the operation and economic
37 feasibility of heat recovery power systems such as Steam and/or Organic Rankine Cycle. In such cases,
38 latent heat storage technology and intermediate storage units may be applied (Jiménez-Arreola et al.
39 2018). The development of thermoelectric conversion materials that produce power from unused heat
40 and energy harvested from higher temperature environment is also progressing, with several possible
41 applications in industrial processes (Ohta et al. 2018; Jood et al. 2018; Lv et al. 2018; Gayner and Kar
42 2016). A potential early application in industry is to power wireless sensors, a niche that uses microwatts
43 or milliwatts, and avoid power cables (Champier 2017).

44
45 **11.3.4.2 Smart energy management**

46 Energy management systems to reduce energy costs in an integrated and systematic manner were first
47 developed in the 1970s, mainly in low energy resource countries, for example, by establishing energy

1 managers and institutionalizing management targets (Tanaka 2011). Strategic energy management has
2 since then evolved and been promoted through the establishment of dedicated organizational
3 infrastructures for energy use optimization, such as ISO-50001 which specifies the requirements for
4 establishing, implementing, maintaining, and improving an energy management system (Biel and Glock
5 2016; Tunnessen and Macri 2017). Digitalisation, sometimes referred to as Industry 4.0, facilitates
6 further improvements in process control and optimisation through technology development involving
7 sensors, communications, analytics, digital twins, machine learning, virtual reality, and other simulation
8 and computing technologies (Rogers 2018), all of which can improve energy efficiency. One example
9 is combustion control systems, where big data analysis of factors affecting boiler efficiency, operation
10 optimization and load forecasting have been shown that it can lead to energy savings of 9% (Wang et
11 al. 2017).

12 Smart energy systems with real time monitoring allow for optimization of innovative technologies,
13 energy demand response, balancing of energy supply and demand including that on real time pricing,
14 and product quality management, and prediction and reduction of idle time for workers and robots
15 (Legorburu and Smith 2018; Pusnik et al. 2016; Ferrero et al. 2020; ISO 2018; ERIA 2016; Nimbalkar
16 et al. 2020). IEA estimated that smart manufacturing could deliver 15 EJ in energy savings between
17 2014 and 2030 (IEA 2019d). Smart manufacturing systems that integrate manufacturing intelligence in
18 real time through the entire production operation have not been yet widely spread in the industry.
19 Examples have been demonstrated and integrated in real operation in the electrical appliance assembly
20 industry (Yoshimoto 2016). Combining process controls and automation allows cost optimization and
21 improved productivity (Edgar and Pistikopoulos 2018).

22 23 **11.3.5 Electrification and fuel switching**

24 The principle of electrification and fuel switching as a GHG mitigation strategy is that industries, to the
25 extent possible, switch their end uses of energy from a high GHG intensity energy carrier to a lower or
26 zero intensity one, including both its direct and indirect production and end-use GHG emissions. In
27 general, and non-exclusively, this implies a transition from coal ($\sim 0.09 \text{ tCO}_2\text{-GJ}^{-1}$ on combustion),
28 refined petroleum products ($\sim 0.07 \text{ tCO}_2\text{-GJ}^{-1}$), and natural gas ($\sim 0.05 \text{ tCO}_2\text{-GJ}^{-1}$) to biofuels, direct solar
29 heating, electricity, hydrogen, ammonia, or net zero synthetic hydrocarbon fuels. Switching to these
30 energy carriers is not necessarily lower emitting, however; how they are made matters.

31 Fuel switching has already been observed to reduce direct combustion CO_2 emissions in many
32 jurisdictions. There are significant debates about the net effect of upstream fossil fuel production and
33 fugitive emissions, but observers have noted that in the case of US power generation it would take a
34 leakage rate of $\sim 2.7\%$ from natural gas production to undo the direct fuel switching from coal mitigation
35 effect, and the value is likely higher in most cases (Alvarez et al. 2012; Hausfather 2015). Coal mine
36 methane emissions are also estimated to be substantially higher than previously assessed (Kholod et al.
37 2020). Alvarez et al. (2018) estimated US fugitive emissions (not including the Permian) at 2.3% of
38 supply, 60% more than previously estimated, while recent Canadian papers indicate fugitive emissions
39 are at least 50% more than reported (Chan et al. 2020; MacKay et al. 2021). However, given the
40 potential for energy supply infrastructure lock-in effects (Tong et al. 2019), purely fossil fuel to fossil
41 fuel switching is a limited and potentially dangerous strategy unless it is used very carefully and in a
42 limited way.

43 Biofuels come in many forms, including ones that are nearly identical to fossil fuels but sourced from
44 biogenic sources. Solid biomass, either from direct from wood chips, lignin or processed pellets are the
45 most commonly used renewable fuel in industry today and are occasionally used in cement kilns and
46 boilers. Biomethane, biomethanol, and bioethanol are all commercially made today using fermentation
47 and anaerobic digestion techniques and are mostly “drop-in” compatible with fossil fuel equivalents. In

1 principle they cycle carbon in and out of the atmosphere, but their life cycle GHG intensities are
2 typically not GHG neutral due to land use changes, soil carbon depletion, fertilizer use, and other
3 dynamics (Hepburn et al. 2019), and are highly case specific. Most commercial biofuel feedstocks come
4 from agricultural (e.g. corn) and food waste sources, and the feedstock is limited; to meet higher levels
5 of biomass use a transition to using higher cellulose feedstocks like straw, switchgrass and wood waste,
6 available in much larger quantities, must be fully commercialized and deployed. Significant efforts have
7 been made to make ethanol from cellulosic biomass, which promises much higher quantities, lower
8 costs, and lower intensities, but commercialization efforts, with a few exceptions, have largely not
9 succeeded (Padella et al. 2019). The IEA estimates, however, that up to 20% of today's fossil methane
10 use, including by industry, could be met with biomethane (IEA 2020g) by 2040, using a mixture of
11 feedstocks and production techniques. Biofuel use may also be critical for producing negative emissions
12 when combined with carbon capture and storage, i.e. BECCS. Most production routes for biofuels,
13 biochemicals and biogas generate large side streams of concentrated CO₂ which is easily captured, and
14 which could become a source of negative emissions (Sanchez et al. 2018) (See section 11-3511.3.6).
15 Finally, it should be noted that biofuel combustion can, if inadequately controlled, have substantial
16 negative local air quality effects, with implications for SDGs 3, 7 and 11.

17 There is a large identified potential for direct solar heating in industry, especially in regions with strong
18 solar insolation and sectors with lower heat needs (<180°C), for example, food and beverage processing,
19 textiles, and pulp and paper (Schoeneberger et al. 2020). The key challenges to adoption are site and
20 use specificity, capital intensity, and a lack of standardized, mass manufacturing for equipment and
21 supply chain to provide them.

22 Switching to electricity for end-uses, or “direct electrification”, is a highly discussed strategy for net
23 zero industrial decarbonisation (Palm et al. 2016; Lechtenböhmer et al. 2016; Davis et al. 2018; Bataille
24 et al. 2018a; UKCCC 2019b; Åhman et al. 2017; Axelson et al. 2018; Material Economics 2019).
25 Electricity is a flexible energy carrier that can be made from many forms of primary energy, with high
26 potential process improvements in terms of end-use efficiency (Eyre 2021), quality and process
27 controllability, digitizability, and no direct local air pollutants (Deason et al. 2018; McMillan et al.
28 2016; Jadun et al. 2017; Mai et al. 2018). The net GHG effect of electrification is contingent on how
29 the electricity is made, and because total output increases can be expected for full effect it should be
30 made with a very low GHG intensity primary sources (i.e. <50 grams CO₂·kWh⁻¹: e.g. hydroelectricity,
31 nuclear energy, wind, solar photovoltaics, or fossil fuels with 95+% carbon capture and storage (IPCC
32 2014)). This has strong implications for the electricity sector and its generation mix when the goal is a
33 net zero emissions electricity system. Despite their falling costs, progressively higher mixes of variable
34 wind and solar on a given grid will require support from grid flexibility sources, including demand
35 response, more transmission, storage on multiple time scales, or firm low to negative emissions
36 generation sources (e.g. nuclear energy, hydrogen fuel cells or turbines, biofuels, fossil or biofuels with
37 CCS, geothermal) to moderate costs (Jenkins et al. 2018; Sepulveda et al. 2018; Williams et al. 2021).
38 Regions that may be slower to reduce the GHG intensity of their electricity production will likely need
39 to consider more aggressive use of other measures, like energy and material efficiency or bioenergy.

40 The long-term potential for full process electrification is a very sector by sector and process by process
41 phenomenon, with differing energy and capacity needs, load profiles, stock turnover, capacity for
42 demand response, and characteristics of decision makers. Industrial electrification is most viable in the
43 near term in cases with: minimal retrofitting and rebuild in processes; with relatively low local
44 electricity costs; where the degree of process complexity and process integration is more limited and
45 extensive process re-engineering would not be required; where combined heat and power is not used;
46 where induction heating technologies are viable; and where process heating temperatures are lower
47 (Deason et al. 2018).

1 For these reasons, lighter, manufacturing orientated industries are more readily electrifiable than heavier
2 industry like steel, cement, chemicals and other sectors with high heat and feedstock needs. Steam
3 boilers, curing, drying and small-scale process heating, with typically lower maximum heat temperature
4 needs (<200-250°C) are readily electrifiable with appropriate fossil fuel to electricity price ratios
5 (accounting for capital costs and efficiencies), and direct induction and infrared heating are available
6 for higher temperature needs. These practices are uncommon outside regions with ample hydroelectric
7 power due to the currently relatively low cost of coal, natural gas and heating oil, and especially when
8 there is no carbon combustion cost. Madeddu et al. (2020) argue up to 78% of Europe's industrial
9 energy requirements are electrifiable through existing commercial technologies. In contrast (Mai et al.
10 2018) saw only a moderate industrial heat supply electrification in their high electrification scenario for
11 the US.

12 Electrification has also been explored in: raw and recycled steel (Fischedick et al. 2014b; Vogl et al.
13 2018); ammonia (Philibert 2017a; Bazzanella and Ausfelder 2017); and chemicals (Palm et al. 2016;
14 Bazzanella and Ausfelder 2017). While most chemical production of feedstock chemicals (e.g. H₂, NH₃,
15 CO, CH₃OH, C₂H₄, C₂H₆, C₂H₅OH) is done thermo-catalytically today, it is feasible to use direct
16 electrocatalytic production, by itself or in combination with utilization of previously captured carbon
17 sources if a fossil fuel feedstock is used, or well-known bio-catalytic (e.g. fermentation) and thermo-
18 catalytic processes (De Luna et al. 2019; Kätelhön et al. 2019; Bazzanella and Ausfelder 2017). It may
19 even be commercially possible to electrify cement sintering and calcination through plasma or
20 microwave options (Material Economics 2019).

21 Increased electrification of industry will result in increased overall demand for electricity. For example,
22 75 TWh of electricity was used by steel in the EU in 2015 (out of 1000 TWh total used by industry),
23 Material Economics (2019), varying between their new process, circularity and CCUS scenarios,
24 projects increased demand to 355 (+373%), 214 (+185%) and 238 (+217%) TWh. These values are
25 consistent with (Vogl et al. 2018), which projects a tripling of electricity demand in the German or
26 Swedish steel industries if hydrogen direct reduced iron and electric arc furnace steel making (DRI
27 EAFs) replaces BF-BOFs. Material Economics (2019) was conservative with its use of electricity in
28 chemical production, making preferential use of biofeedstocks and some CCUS, and electricity demand
29 still rose from 118 TWh to 510, 395 and 413 TWh in their three scenarios. (Bazzanella and Ausfelder
30 2017), exploring deeper reductions from the chemical sector using more electrochemistry, projected
31 scenarios with higher electricity demands of 960–4900 TWh (140% of projected available clean
32 electricity at the time) with maximum electricity use. In counterpoint, however, with revised wind
33 capabilities and costs, the (IEA 2019e) Offshore Wind Outlook indicates that ten times current EU
34 electricity use could be produced if necessary. Greater use of electro-catalytic versus thermo-catalytic
35 chemistry, as projected by (De Luna et al. 2019), could greatly reduce these electricity needs, but the
36 technology readiness levels are currently low. Finally, the (UKCCC 2019b), which focussed primarily
37 on CCS for industry in its “Further Ambition” scenario (the UK currently consumes about 300 TWh),
38 in its supplementary “Further electrification” scenario projects an additional 300 TWh for general
39 electrolysis needs and another 200 TWh for synthetic fuel production.

40 While it has been demonstrated that almost any heating end use can be directly electrified, this would
41 imply very high instantaneous thermal loads for blast furnace-basic oxygen furnace (BF-BOF) steel
42 production, limestone calcination for cement and lime production, and other end-uses where flame front
43 (1000°C–1700°C) temperatures are currently needed. This indicates a possible need for another energy
44 carrier to minimize instantaneous generation and transmission needs. These needs can be met at varying
45 current and potential future costs using: bioliquids or gases hydrogen, ammonia, or net zero synthetic
46 hydrocarbons or alcohols.

47 Broadly speaking, **hydrogen** can contribute to a cleaner energy system in two ways. 1) Existing
48 applications of hydrogen (e.g., nitrogen fertilizer production, refinery upgrading) can use hydrogen

1 produced using alternative, cleaner production methods. 2) New applications can use low GHG
2 hydrogen as an alternative to current fuels and inputs, or as a complement to the greater use of electricity
3 in these applications. In these cases—for example in transport, heating, industry (e.g. hydrogen direct
4 reduced iron steel production) and electricity—hydrogen can be used in its pure form, or be converted
5 to hydrogen-based fuels, including ammonia, or synthetic net zero hydrocarbons & alcohols like
6 methane or methanol (IEA 2019f). The IEA states that **hydrogen** could be used to help integrate more
7 renewables, including by enhancing storage options and “exporting sunshine & wind” from places with
8 abundant resources; decarbonize steel, chemicals, trucks, ships and planes; and boost energy security
9 by diversifying the fuel mix & providing flexibility to balance grids (IEA 2019f).

10 Around 70 Mtonne·yr⁻¹ of pure hydrogen is produced today, 76% from natural gas and 23% from coal,
11 resulting in emissions of roughly 830 MtCO₂·yr⁻¹ in 2016/17 (IEA 2019f), or 4.7% of global industrial
12 direct and indirect emissions (waste excluded, see Table 11.1) . Fuels refining (~410 MtCO₂·yr⁻¹) and
13 production of ammonia (420 MtCO₂·yr⁻¹) largely dominate its uses. Another 45 Mtonnes hydrogen is
14 being produced along with other gases, on purpose or as by-products, and used as fuel, to make
15 methanol or as a chemical reactant (IEA 2019f). Very low and potentially zero GHG (depending on the
16 energy source) **hydrogen** can be made via: electrolysis separation of water into hydrogen and oxygen
17 (Glenk and Reichelstein 2019), also known as “green H₂”; electrothermal separation of water, as done
18 in some nuclear plants (Bicer and Dincer 2017); partial oxidation of coal or naphtha or steam/auto
19 methane reforming (SMR/ATR) combined with CCS (Leeson et al. 2017), or “blue H₂”; methane
20 pyrolysis, where the hydrogen and carbon are separated thermally and the carbon is left as a solid (Ashik
21 et al. 2015; Abbas and Wan Daud 2010), or via biomass gasification (Ericsson 2017) (which could be
22 negative emissions if the CO₂ from the gasification process is sequestered). All these processes would
23 in turn need to be run using very low or zero GHG energy carriers for the resulting hydrogen to also be
24 low GHG emissions.

25 **Ammonia production**, made from hydrogen and nitrogen using the Haber-Bosch process, is the most
26 voluminous chemical produced from fossil fuels, being used as feedstock for nitrogen fertilizers and
27 explosives, as well as a cleanser, refrigerant and for other uses. Most ammonia is made today using
28 methane as the hydrogen feedstock and heat source but has been made using electrolysis-based
29 hydrogen in the past, and there are several announced investments to resume doing so. If ammonia is
30 used as a combustion fuel care must be taken to avoid N₂O as a GHG and NO_x in general as a local air
31 pollutant.

32 Hydrogen can also be combined with low to zero net GHG carbon (see 11.3.6 and oxygen and made
33 into **methane, methanol** and other potential net zero **synthetic hydrocarbons & alcohol** energy
34 carriers using methanation, steam reforming and Fischer-Tropsch processes, all of which can provide
35 higher degrees of storable and shippable high temperature energy using known industrial processes in
36 novel combinations (Davis et al. 2018; Bataille et al. 2018a). If the hydrogen and oxygen is accessed
37 via electrolysis the terms “power-to-fuel” or “e-fuels” are often used (Ueckerdt et al. 2021). Given their
38 carbon content, if used as fuels, their carbon will eventually be oxidized and emitted as CO₂ to the
39 atmosphere. This makes their net GHG intensity dependent on the carbon source (Hepburn et al. 2019),
40 with recycled fossil fuels, biocarbon and direct air capture carbon all having very different net CO₂
41 impacts - see the next section on CCS and CCU for elaboration.

42

43 **START BOX 11.1 HERE**

44

45

Box 11.1 Hydrogen in industry

46 The “hydrogen economy” is a long-touted vision for the energy and transport sectors, and one that has
47 gone through hype-cycles since the energy crises in the 1970s (Melton et al. 2016). The widely varying

1 visions of hydrogen futures have mainly been associated with fuel cells in vehicles, small-scale
2 decentralized cogeneration of heat and electricity, and to a certain extent energy storage for electricity
3 (Eames et al. 2006; Syniak and Petrov 2008). However, nearly all hydrogen currently produced is used
4 in industry, mainly for hydrotreating in oil refineries, to produce ammonia, and in other chemical
5 processes, and it is mostly made using fossil fuels.

6 In the context of net zero emissions new visions are emerging in which hydrogen has a central role to
7 play in decarbonizing industry. Near-term industrial applications for hydrogen includes feeding it into
8 ammonia production for fertilizers, while a novel application would be as a replacement for coal as
9 the reductant in steelmaking, being piloted by the HYBRIT project in Sweden 2020-2021, and many
10 companies have initiated hydrogen steelmaking projects. As shown in sections 11.3.5 and 11.3.6 there
11 are many other potential applications of hydrogen, some of which are still relatively unexplored.
12 Hydrogen can also be used to produce various lower GHG hydrocarbons and alcohols for fuels and
13 chemical feedstocks using carbon from biogenic sources or direct air capture of CO₂ (Ericsson 2017;
14 Huang et al. 2020).

15 The geographical distribution of the potential for hydrogen from electrolysis powered by renewables
16 like solar and wind, nuclear electrothermally produced hydrogen, and hydrogen from fossil gas with
17 CCS may reshape where heavy industry is located, how value chains are organized, and what gets
18 transported in international shipping (Gielen et al. 2020; Bataille et al. 2021a; Saygin and Gielen 2021;
19 Bataille 2020a). Regions with bountiful renewables resources, nuclear, or methane co-located with CCS
20 geology may become exporters of hydrogen or hydrogen carriers such as methanol and ammonia, or
21 home to the production of iron and steel, organic platform chemicals, and other energy intensive basic
22 materials. This in turn may generate new trade patterns and needs for bulk transport.

23
24 **END BOX 11.1 HERE**

25 **11.3.6 CCS, CCU, carbon sources, feedstocks, and fuels**

27 Carbon is an important and highly flexible building block for a wide range of fuels, organic chemicals
28 and materials including methanol, ethanol, olefins, plastics, textiles, and wood and paper products. In
29 this chapter we define CCS as requiring return of CO₂ from combustion or process gases or ambient air
30 to the geosphere for geological time periods, i.e. thousands of years (IEA 2009; IPCC 2005; IEA 2019g;
31 Bruhn et al. 2016). CCU is defined as being where carbon (as CO or CO₂) is captured from one process
32 and reused for another, reducing emissions from the initial process, but is then potentially but not
33 necessarily released to the atmosphere in following processes (Tanzer and Ramírez 2019; Detz and van
34 der Zwaan 2019; Bruhn et al. 2016). In both cases the net effect on atmospheric emissions depends on
35 the initial source of the carbon, be it from a fossil fuel, from biomass, or from direct air capture (Cuéllar-
36 Franca and Azapagic 2015; Hepburn et al. 2019) and the duration of storage or use, which can vary
37 from days to millennia.

38 While CCS and CCU share common capture technologies, what happens to the CO₂ and therefore the
39 strategies that will employ them can be very different. CCS can help maintain near CO₂ neutrality for
40 fossil CO₂ that passes through the process, with highly varying partially negative emissions if the source
41 is biogenic (Hepburn et al. 2019), and fully negative emissions if the source is air capture, all not
42 considering the energy used to drive the above processes. CCS has been covered in other IPCC
43 publications at length, for example, IPCC (2005), and in most mitigation oriented assessments since,
44 for example, the IEA's ETP 2020 and Net Zero scenario reports (IEA 2021a, 2020a). The potentials
45 and costs for CCS in industry vary considerably due to the diversity of industrial processes (Leeson et
46 al. 2017), as well as the volume and purity of different flows of carbon dioxide (Naims 2016); Kearns

1 et al. (2021) provide a recent review. As a general rule it is not possible to capture all the carbon dioxide
2 emissions from an industrial plant. To achieve zero or negative emissions, CCS would need to be
3 combined with some use of sustainably sourced biofuel or -feedstock, or the remaining emissions would
4 need to be offset by CDR elsewhere.

5 For concentrated CO₂ sources (e.g. cleaning of wellhead formation gas to make it suitable for the
6 pipeline network, hydrogen production using steam methane reforming, ethanol fermentation, or from
7 combustion of fossil fuels with oxygen in a nitrogen free environment, i.e. “oxycombustion”) CCS is
8 already amenable to commercial oil and gas reinjection techniques used to eliminate hydrogen sulphide
9 gas and brines at prices of 10–40 USD·tCO₂-eq⁻¹ sequestered (Wilson et al. 2003; Leeson et al. 2017).
10 Most currently operating CCS facilities take advantage of concentrated CO₂ flows, for example, from
11 formation gas cleaning on the Snoevit and Sleipner platforms in Norway, from syngas production for
12 the Al Reyadah DRI steel plant in Abu Dhabi, and from SMR hydrogen production on the Quest
13 upgrader in Alberta. Since concentrated process CO₂ emissions are often exempted from existing cap
14 and trade systems, these opportunities for CCS have largely gone unexploited. Many existing projects
15 partially owe their existence to the utilization of the captured CO₂ for enhanced oil recovery, which in
16 many cases counts as both CCS and CCU because of the permanent nature of the CO₂ disposal upon
17 injection if sealed properly (Mac Dowell et al. 2017). There are several industrial CCS strategies and
18 pilot projects working to take advantage of the relative ease of concentrated CO₂ disposal (e.g. LEILAC
19 for limestone calcination process emissions from cement production, HISARNA direct oxycombustion
20 smelting for steel) (Bataille 2020a). An emerging option for storing carbon is methane pyrolysis by
21 which methane is split into hydrogen and solid carbon that may subsequently be stored (Schneider et
22 al. 2020).

23 There are several post-combustion CCS projects underway globally (IEA 2019g), generally focussed
24 on energy production and processing rather than industry. Their costs are higher but evolving downward
25 – (Giannaris et al. 2020) suggest 47 USD·tCO₂⁻¹ for a follow up 90% capture power generation plant
26 based on learnings from the Saskpower Boundary Dam pilot – but crucially these costs are higher than
27 implicit and explicit carbon prices almost everywhere, resulting in limited investment and learning in
28 these technologies. A key challenge with all CCS strategies, however, is building a gathering and
29 transport network for CO₂, especially from dispersed existing sites; hence most pilot are built near
30 EOR/geological storage sites, and the movement towards industrial clustering in the EU and UK
31 (UKCCC 2019b), and as suggested in (IEA 2019f).

32 In the case of CCU, CO and CO₂ are captured and subsequently converted into valuable products (e.g.
33 building materials, chemicals, synthetic fuels) (Daggash et al. 2018; Styring et al. 2011; Vreys et al.
34 2019; Artz et al. 2018; Breyer et al. 2019; Brynolf et al. 2018; Bruhn et al. 2016; Kätelhön et al. 2019).
35 CCU has been envisioned as part of the “circular economy” but conflicting expectations on CCU and
36 its association or not with CCS leads to different and contested framings (Palm and Nikoleris 2021).
37 The duration of the CO₂ storage in these products varies from days to millennia according to the
38 application, potentially but not necessarily replacing new fossil, biomass or direct air capture
39 feedstocks, before meeting one of several possible fates: permanent burial, decomposition, recycling or
40 combustion, all with differing GHG implications. While the environmental assessment of CCS projects
41 is relatively straight forward, however, this is not the case for CCU technologies. The net GHG
42 mitigation impact of CCU depends on several factors (e.g. the capture rate, the energy requirements,
43 the lifetime of utilization products, the production route that is substituted, and associated room for
44 improvement along the traditional route) and has to be determined by life cycle CO₂ or GHG analysis
45 (e.g. Nocito and Dibenedetto (2020) and Bruhn et al. (2016)). For example, steel mill gases containing
46 carbon monoxide and carbon dioxide can be used as feedstock together with hydrogen for producing
47 chemicals. In this way, the carbon originally contained in the coke used in the blast furnace is used
48 again, or cascaded, and emissions reduced but not brought to zero. If fossil sourced CO₂ is only reused

1 once and then emitted, the maximum reduction is 50% (Tanzer and Ramírez 2019). The logic of using
2 steel mill CO and CO₂ could equally be applied to gasified biomass, however, with a far lower net GHG
3 footprint, likely negative, which CCU fed by fossil fuels cannot be if end-use combustion is involved.

4 Partly because of the complexity of the life cycle analysis accounting, the literature on CCU is not
5 always consistent in terms of the net GHG impacts of strategies. For example, Artz et al. (2018),
6 focussed not just on GHG mitigation but multi-attribute improvements to chemical processes from
7 reutilization of CO₂, suggests the largest reduction in the absolute amount of GHGs from CO₂
8 reutilization could be achieved by coupling of highly concentrated CO₂ sources with carbon-free
9 hydrogen or electrons from low GHG power in so called “Power-to-fuel” scenarios. From the point of
10 view of maximizing GHG mitigation using surplus “curtailed” renewable power, however, Daggash et
11 al. (2018) instead indicates the best use would be for direct air capture and CCS. These results depend
12 on what system is being measured, and what the objective is.

13 There are several potential crucial transitional roles for synthetic hydrocarbons & alcohols (e.g.
14 methane, methanol, ethanol, ethylene, diesel, jet fuel) constructed using fossil, biomass or direct carbon
15 capture (DAC) and CCU (Fasihi et al. 2017; Sternberg and Bardow 2015; Breyer et al. 2015; Dimitriou
16 et al. 2015; Bataille 2020a; Bataille et al. 2018a). They can allow reductions in the GHG intensity of
17 high value legacy transport, industry and real estate that currently runs on fossil fuels but cannot be
18 easily or readily retrofitted. They can be used by existing long lived energy and feedstock infrastructure,
19 transport and storage, which can compensate for seasonal supply fluctuations and contribute to
20 enhancing energy security (Ampelli et al. 2015). Finally, they can reduce the GHG intensity of end-
21 uses that are very difficult to run on electricity, hydrogen or ammonia (e.g., long haul aviation).
22 However, their equivalent mitigation cost today would be very high (USD 960–1440 tCO₂-eq⁻¹), with
23 the potential to fall to USD 24–324 tCO₂-eq⁻¹) with commercial economies of scale, with very high
24 uncertainty (Hepburn et al. 2019; Ueckerdt et al. 2021; IEA 2020a).

25 A very large and important uncertainty is the long-term demand for hydrocarbon and alcohol fuels
26 (whether fossil, biomass or DAC based), chemical feedstocks (e.g., methanol and ethylene) and
27 materials, and competition for biomass feedstock with other priorities, including agriculture,
28 biodiversity and other proximate land use needs, as well as need for negative emissions through BECCS.
29 The current global plastics production of around 350 Mt·yr⁻¹ is almost entirely based on petroleum
30 feedstock and recycling rates are very low. If this or future demand were to be 100% biomass based it
31 would require tens of exajoules of biomass feedstock (Meys et al. 2021). If demand can be lowered and
32 recycling increased (mechanical as well as chemical) the demand for biomass feedstock can be much
33 lower (Material Economics 2019). Promising routes in the short term would be to utilise CO₂ from
34 anaerobic digestion for biogas and fermentation for ethanol in the production of methane or methanol
35 (Ericsson 2017); methanol can be converted into ethylene and propylene in a methanol-to-olefins
36 process and used in the production of plastics (Box 11.2). New process configurations where hydrogen
37 is integrated into biomass conversion routes to increase yields and utilise all carbon in the feedstock are
38 relatively unexplored (Ericsson 2017; De Luna et al. 2019).

39 There are widely varying estimates of the capacity of CCU to reduce GHG emissions and meet the net-
40 zero objective. According to Hepburn et al. (2019), the estimated potential for the scale of CO₂
41 utilisation in fuels varies widely, from 1 to 4.2 GtCO₂·yr⁻¹, reflecting uncertainties in potential market
42 penetration, requiring carbon prices of around USD 40 to 80 tCO₂⁻¹, increasing over time. The high end
43 represents a future in which synthetic fuels have sizeable market shares, due to cost reductions and
44 policy drivers. The low end—which is itself considerable—represents very modest penetration into the
45 methane and fuels markets, but it could also be an overestimate if CO₂-derived products do not become
46 cost competitive with alternative clean energy vectors such as hydrogen or ammonia, or with direct
47 sequestration. Brynolf et al. (2018) indicates that a key cost variable will be the cost of electrolyzers for
48 producing hydrogen. Kästelhön et al. (2019) estimate that up to 3.5 GtC·yr⁻¹ could be displaced from

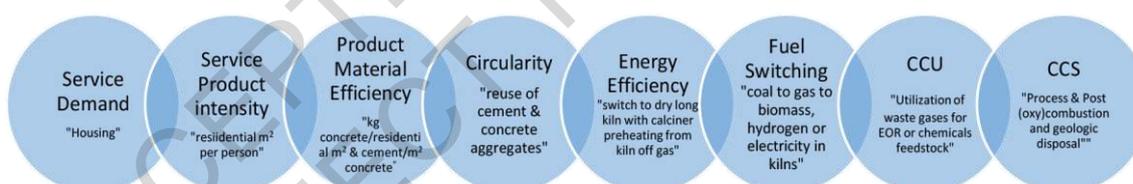

1 chemical production by 2030 using CCU, but this would require clean electricity equivalent to 55% of
 2 estimated global power production, at the same time other sectors' demand would also be rising. Mac
 3 Dowell et al. (2017) suggest that while CCU, and specifically CO₂ based enhanced oil recovery, may
 4 be an important economic incentive for early CCS projects (up to 4–8% of required mitigation by 2050),
 5 it is unlikely the chemical conversion of CO₂ for CCU will account for more than 1% of overall
 6 mitigation.

7 Finally, there is another class of CCU activities associated with carbonation of alkaline industrial wastes
 8 (including iron and steel slags, coal fly ash, mining and mineral processing wastes, incinerator residues,
 9 cement and concrete wastes, and pulp and paper mill wastes) using waste or atmospheric CO₂. Given
 10 the large volume of alkaline wastes produced by industry, capture estimates are as high at 4 GtCO₂·yr⁻¹
 11 (Pan et al. 2020; Huang et al. 2019c; Kaliyavaradhan and Ling 2017; Cuéllar-Franca and Azapagic
 12 2015; Pasquier et al. 2018; Ebrahimi et al. 2017; Zhang et al. 2020) However, as some alkaline wastes
 13 are already used directly as supplementary cementitious materials to reduce clinker-to-cement ratios, and
 14 their abundant availability in the future is questionable (e.g. steel blast furnace slag and coal fly ash),
 15 there will be a strong competition between mitigation uses (see 11.4.2), and the potential for direct
 16 removal by carbonation is estimated at about 1 GtCO₂·yr⁻¹ (Renforth 2019).

17 The above CCU literature has identified that there may be a highly unpredictable competition between
 18 fossil, biogenic and direct air capture carbon to provide highly uncertain chemical feedstock, material
 19 and fuel needs. Fossil waste carbon will likely initially be plentiful but will add to net atmospheric CO₂
 20 when released. Biogenic carbon is variably, partially net-negative, but the available stock will be finite
 21 and compete with biodiversity and agriculture needs for land. Direct air capture carbon will require
 22 significant amounts of low GHG electricity or methane with high capture rate CCS (Keith et al. 2018).
 23 There are clearly strong interactive effects between low carbon electrification, switching to biomass,
 24 hydrogen, ammonia, synthetic hydrocarbons via CCU, and CCS.

25

26 11.3.7 Strategy interactions and integration

27

28 **Figure 11.9 Fully interactive, non-sequential strategies for decarbonising industry**

29

30 In this section we conceptually address interactions between service demand, service product intensity,
 31 product material efficiency, energy efficiency, electrification and fuel switching, CCU and CCS, and
 32 what conflicts and synergies may exist. Post AR5 a substantial literature has emerged, see Rissman et
 33 al. (2020), that addresses integrated and interactive technical deep decarbonization pathways for GHG
 34 intense industrial sectors, and how they interact with the rest of the economy (Denis-Ryan et al. 2016;
 35 Wesseling et al. 2017; Davis et al. 2018; Axelson et al. 2018; Åhman et al. 2017; Bataille et al. 2018a;
 36 Bataille 2020a). It is a common finding across this literature and a related scenario literature (Energy
 37 Transitions Commission 2018; Material Economics 2019; IEA 2021a; CAT 2020; UKCCC 2019a,b;
 38 IEA 2019b, 2020a) that deep decarbonisation of industry requires integrating all available options.
 39 There is no 'silver bullet' and so all behavioural and technological options have to be mobilized, with
 40 more emphasis required on the policy mechanisms necessary to engage a challenging transition in the

1 coming decades in highly competitive, currently GHG intense, price sensitive sectors with long lived
2 capital stock (Wesseling et al. 2017; Bataille et al. 2018a; Bataille 2020a), discussed in the final section
3 of this chapter.

4 While the strategies are not sequential and interact strongly, we discuss them in the order given.
5 Reduced demand through reduced service demand and product intensity per service unit (van Vuuren
6 et al. 2018; Grubler et al. 2018) reduces the need for the next five strategies. Greater material efficiency
7 (see earlier sections) reduces the need for the next four, and so on – see Figure 11.9 above.

8 Circular economy introduces itself throughout, but mainly at the front end when designing materials
9 and processes to be more materially efficient, efficient in use, and easy to recycle, and at the back end,
10 when a material or product's services life has come to end, and it is time for recycling or sustainable
11 disposal (Korhonen et al. 2018; Murray et al. 2017). The entire chain's potential will be maximized
12 when these strategies are designed in ahead of time instead of considered on assembly, or as a retrofit
13 (Material Economics 2019; Allwood et al. 2012; Gonzalez Hernandez et al. 2018a; IEA 2019b; Bataille
14 2020a). For example, when designing a building: 1) Is the building shell, interior mass and ducting
15 orientated for passive heating and cooling, and can the shell and roof have building integrated solar PV
16 or added easily, with hard-to-retrofit wiring already incorporated? 2) Are steel and high quality concrete
17 only used where really needed (i.e. for shear, tension and compression strength), can sections be
18 prefabricated off-site, can other materials be substituted, such as wood? 3) Can the interior fittings be
19 built with easy to recycle plastics or other sustainably disposable materials (e.g. wood)? 4) Can this
20 building potentially serve multiple purposes through its anticipated lifetime, are service conduits
21 oversized and easy to access for retrofitting? 5) When it is time to be taken apart, can pieces be reused,
22 and all components recycled at high purity levels, for example, can all the copper wiring be easily be
23 found and removed, are the steel beams clearly tagged with their content? The answers to these
24 questions will be very regionally and site specific, and require revision of educational curricula for the
25 entire supply chain, as well as revision of building codes.

26 Energy efficiency is a critical strategy for net zero transitions and enabling clean electrification (IEA
27 2021a). Improving the efficiency of energy services provision reduces the need for material intensive
28 energy supply, energy storage, CCU and CCS infrastructure, and limits generation and transmission
29 expansion to meet an ever-higher power demand, with associated generation, transmission, and
30 distribution losses. Using electricity efficiently can help reduce peak demand and the need for peaking
31 plants (currently often powered by fossil fuels), and energy storage systems.

32 Electrification and final energy efficiency are deeply entangled, because switching to electricity from
33 fossil fuels in most cases improves GJ for GJ end-use energy efficiency: resistance heaters are almost
34 100% efficient, heat pumps can be 300–400% efficient, induction melting can improve mixing and
35 temperature control, and electric vehicle motors typically translate 90-95% of input electricity to motor
36 drive in contrast to 35–45% for a large, modern internal combustion engine. Overall, the combined
37 effect could be 40 % lower global final energy demand assuming renewable electricity is used (Eyre
38 2021).

39 There are potentially complicated physical and market **fuel switching** relationships between low GHG
40 electricity, bioliquids and gases, hydrogen, ammonia, and synthetic hydrocarbons constructed using
41 **CCU**, with remaining CO₂ potentially being disposed of using **CCS**. Whether or not they compete for
42 a wide range of end uses and primary demand needs will be regional and whether or not infrastructure
43 is available to supply them. Regions with less than optimal renewable energy resources, or not sufficient
44 to meet growing needs, could potentially indirectly import them as liquid or compressed hydrogen,
45 ammonia or synthetic hydrocarbon feedstocks made in regions with abundant resources (Armijo and
46 Philibert 2020; Bataille 2020a). Large scale CCU and CCS applications needs additional basic materials
47 to build corresponding infrastructure and energy to operate it thus reducing overall material and energy
48 efficiencies.

- 1 There are different roles for different actors in relation to the different mitigation strategies (exemplified
- 2 in Table 11.2), with institutions and supply chains developed to widely varying levels, for example,
- 3 while energy efficiency is a relatively mature strategy with an established supply chain, material
- 4 efficiency is not.

1 **Table 11.2 Examples of the potential roles of different actors in relation to different mitigation strategies indicating the importance of engaging a wide set of actors**
2 **across all mitigation strategies.**

Sectors	Demand control measures (DM)	Materials Efficiency (ME)	Circular Economy	Energy Efficiency	Electrification, hydrogen and fuel switching	CCU	CCS
Architectural, and engineering firms	Build awareness on the material demand implications of e.g., building codes, urban planning, and infrastructure.	Education of designers, architects, engineers, etc. Develop design tools. Map material flows.	Design and build for e.g., repurpose, reuse, and recycle. Improve transparency on volumes and flows.	Maintain high expertise, knowledge sharing, transparency, and benchmarking.	Support innovation. Share best practice. Design for dynamic demand response for grid balancing.	Develop allocation rules, monitoring and transparency. Coordination and collaboration across sectors.	Transparency, monitoring and labelling. Coordination and collaboration for transport and disposal infrastructure.
Industry and service sector	Digital solutions to reduce office space and travel. Service oriented business models for lower product demand.	Design for durability and light weight. Minimize industry scrap.	Design for reuse and recycling. Use recycled feedstock and develop industrial symbiosis.	Maintain energy management systems.	Develop and deploy new technologies in production, engage with lead markets.	Develop new technologies. Engage in new value chains and collaborations for sourcing carbon.	Plan for CCS where possible and phase-out of non-retrofitable plants where necessary.
International bodies	Best practice sharing. Knowledge building on demand options.	Progressivity in international standards (e.g., ISO).	Transparency and regulation around products, waste handling, trade, and recycling.	Maintain efforts for sharing good practice and knowledge.	Coordinate innovation efforts, technology transfer, lead markets, and trade policies.	Coordinate and develop accounting and standards. Ensure transparency.	Align regulation to facilitate export, transport, and storage.
Regional and national government, and cities	Reconsider spatial planning and regulation that has demand implications.	Procurement guidelines and better indicators. Standards and building codes.	Regulation on product design (e.g., Ecodesign directive) Collect material flow data.	Continue energy efficiency policies such as incentives, standards, labels, and disclosure requirements.	R&D and electricity infrastructure. Policy strategies for making investment viable (including carbon pricing instruments).	Align regulation to facilitate implementation and ensure accountability for emissions.	Develop regulation and make investment viable. Resolve long term liabilities.

Civil society and consumer organizations	Information and advocacy related to social norms.	Strengthen lobby efforts and awareness around e.g., planned obsolescence.	Engage in standards, monitoring and transparency.	Monitor progress.	Information on embodied emissions. Assess renewable electricity and grid expansion.	Develop standards and accounting rules.	Ensure transparency and accountability

1 **11.4 Sector mitigation pathways and cross sector implications**

2 This section continues the discussion of the various mitigation options and strategy elements introduced
3 in section 11.3 and makes them explicit for the most relevant industry sectors. For the various sectors
4 11.4.1 concludes with a tabular overview of key technologies and processes, their technology readiness
5 level (TRL), potential timing of market penetration, mitigation potential and assessment of associated
6 mitigation costs.

7 An integrated sequencing of mature short-term actions and less mature longer-term actions is crucial to
8 avoid lock-in effects. Temporal implementation and discussion of the general quantitative role of the
9 different options to achieve net zero emissions in the industrial sectors is core to the second part of the
10 section (11.4.2), where industry wide mitigation pathways are analysed. This comprises the collection
11 and discussion of mitigation scenarios available in the literature with a high technological resolution
12 for the industry sector in addition to a set of illustrative global and national GHG mitigation scenarios
13 selected from chapter 3 and 4 representing different GHG mitigation ambitions and different pathways
14 to achieve certain mitigation targets. Comparing technology focussed sector-based scenarios with more
15 top-down oriented scenario approaches allows for a reciprocal assessment of both perspectives and
16 helps to identify robust elements for the transformation of the sector. Comparison of real-world
17 conditions within the sector (e.g., industry structure and logics, investment cycles, market behaviour,
18 power, and institutional capacity) and the transformative pathways described in the scenarios helps
19 researchers, analysts, governments, and all stakeholders understand the need not only for technological
20 change, but for structural (e.g., new value chains, markets, infrastructures, and sectoral couplings) and
21 behavioural (e.g., design practices and business models) change at multiple levels.

22 When undergoing a transformative process, it is obvious that interactions occur, within the sector but
23 also on a cross-sectoral basis. Relevant interactions are identified and discussed in the third and fourth
24 part of the sub-section. Changes are induced along the whole value chains, i.e., switching to an
25 alternative (climate-friendly, e.g., low GHG hydrogen based) steel making process has substantial
26 impacts on the value chain, associated sub-suppliers, and electricity and coal outputs. In addition, cross-
27 sectoral interactions are discussed. This includes feedback loops with other end-use chapters, for
28 example, higher material demand through market penetration of some GHG mitigation technologies or
29 measures (e.g., insulation materials for buildings, steel for windmills) and lower demand through others
30 (e.g., less steel for fossil fuel extraction, transport and processing), or substantial additional demand of
31 critical materials (e.g., the widely varying demands for copper, lithium, nickel, cobalt and rare earths
32 for producing windmills, solar panels, and batteries). Generally, if consumption (or behaviour) driven
33 additional material demand creates scarcity it becomes important to increase efforts on material
34 efficiency, substitution, recycling/re-use, and sustainable consumption patterns.

35

36 **11.4.1 Sector specific mitigation potential and costs**

37 Based on the general discussion of strategies across industry in Section 11.3 this sub-section focuses on
38 the sector perspective and provides insights into the sector specific mitigation technologies and
39 potentials. As industry is comprised of many different sub-sectors, the discussion here has its focus on
40 the most important sources of GHG emissions, that is, steel, cement and concrete, as well as chemicals,
41 before other sectors are discussed.

42

43 **11.4.1.1 Steel**

44 For the period leading up to 2020, in terms of end-use allocation globally, approximately 40% of steel
45 is used for structures, 20% for industrial equipment, 18% for consumer products, 13% for infrastructure,

1 and 10% for vehicles (Bataille 2020b). The global production of crude steel increased by 41 % between
2 2008 and 2020 (World Steel Association 2021) and its GHG emissions depending on the scope covered
3 is 3.7–4.1 GtCO₂-eq. It represented 20% of total global direct industrial emissions in 2019 accounting
4 for coke oven and blast furnace gases use Figure 11.4 and Table 11.1 (Crippa et al. 2021; Lamb et al.
5 2021; Minx et al. 2021; Olivier and Peters 2018; World Steel Association 2021; IEA 2020a). Steel
6 production can be divided into primary production based on iron ore and secondary production based
7 on steel scrap. The blast furnace to basic oxygen furnace route (BF-BOF) is the main primary steel route
8 globally, while the electric arc furnace (EAF) is the preferred process for the less energy and emissions-
9 intensive melting and alloying of recycled steel scrap. The direct reduced iron (DRI) route is a lesser
10 used route that replaces BFs for reducing iron ore, usually followed by an EAF. In 2019, 73% of global
11 crude steel production was produced in BF-BOFs, while 26% was produced in EAFs, a nominal 5.6%
12 of which is DRI (World Steel Association 2021) .

13 An estimated 15% energy efficiency improvement is possible within the BF-BOF process (Figure 11.8).
14 Several options exist for deep GHG emissions reductions in steel production processes (Leeson et al.
15 2017; Axelson et al. 2018; Fan and Friedmann 2021; Fishedick et al. 2014b; Wang et al. 2021; Holappa
16 2020; Bataille 2020a; Vogl et al. 2018; Rissman et al. 2020). Each could reduce specific CO₂ emissions
17 of primary steel production by 80% or more relative to today's dominant BF-BOF route if input streams
18 are based on carbon-free energy and feedstock sources or if they deploy high capture CCS:

- 19 • *Increasing the share of the secondary route* can bring down emissions quickly and potential
20 emissions savings are significant, from a global average 2.3 tCO₂⁻¹ per tonne steel in BF-BOFs
21 down to 0.3 (or less) tCO₂⁻¹ per tonne steel in EAFs (Pauliuk et al. 2013a; Zhou et al. 2019), the
22 latter depending scrap preheating and electricity GHG intensity. However, realising this
23 potential is dependent on the availability of regional and global scrap supplies and requires
24 careful sorting and scrap management, especially to eliminate copper contamination (Daehn et
25 al. 2017). There is significant uncertainty how much new scrap will be available and usable
26 (IEA 2019b; Xylia et al. 2018; Wang et al. 2021). Most steel is recycled already; the gains are
27 mainly to be made in quality, i.e. separation from contaminants like copper. End of life scrap
28 availability and its contribution to steel production will increase as in use stock saturates in
29 many countries (Xylia et al. 2016).
- 30 • *BF-BOFs with CCU or CCS*. Abdul Quader et al. (2016) and Fan and Friedmann (2021)
31 indicate that it would be difficult to retrofit BF-BOFs beyond 50% capture, which is insufficient
32 for long term emission targets, but may be useful in some cases for avoiding cumulative
33 emissions where other options are not available. However, BF-BOFs need their furnaces relined
34 every 15–25 years (IEA 2021a; Vogl et al. 2021b), at a cost 80–100% of a new build, and this
35 would be an opportunity to build a new facility designed for 90%+ capture (e.g. fewer CO₂
36 outlets). This would depend upon access to transport to geology appropriate for CCS.
- 37 • *Methane based syngas (hydrogen and carbon monoxide) direct reduced iron (DRI) with CCS*.
38 Most DRI facilities currently use a methane-based syngas of H₂ and CO as both reductant and
39 fuel (some use coal). A syngas DRI-EAF steel making facility has been operating in Abu Dhabi
40 since 2016 that captures carbon emitted from the DRI furnace (where it is a co-reductant with
41 hydrogen) and sends it to a nearby oil field for enhanced oil recovery.
- 42 • *Hydrogen-based direct reduced iron (H-DRI)* is based on the already commercialized DRI
43 technology but using only hydrogen as the reductant; pure hydrogen has already been used
44 commercially by Circored in Trinidad 1999-2008. The reduction process of iron ore is typically
45 followed by an EAF for smelting. During a transitional period, DRI could start with methane
46 or a mixture of methane and hydrogen as some of the methane (<=30% hydrogen can be
47 substituted with green or blue hydrogen without the need to change the process). If the hydrogen
48 is produced based on carbon-free sources, this steel production process can be nearly CO₂
49 neutral (Vogl et al. 2018).

- 1 • In the *aqueous electrolysis* route (small scale piloted as Siderwin during the EU ULCOS
2 program), the iron ore is bathed in an electrolyte solution and an electric current is used to
3 remove the oxygen, followed by an electric arc furnace for melting and alloying. In the *molten*
4 *oxide electrolysis* route, an electric current is used to directly reduce and melt the iron ore using
5 electrolysis in one step, followed by alloying. These processes both promise a significant
6 increase in energy efficiency compared with the direct reduced iron and blast furnace routes
7 (Cavaliere 2019). If the electricity used is based on carbon-free sources, this steel production
8 process can be nearly CO₂ neutral. Both processes would require supplemental carbon, but this
9 is typically only up to 0.05% per tonne steel, with a maximum of 2.1%. Aqueous electrolysis
10 is possible with today's electrode technologies, while molten oxide electrolysis would require
11 advances in high temperature electrodes.
- 12 • The *HIsarna*® process is a new type of coal-based smelting reduction process, which allows
13 certain agglomeration stages (coking plant, sintering/pelletizing) to be dispensed with. The iron
14 ore, with a certain amount of steel scrap, is directly reduced to pig iron in a single reactor. This
15 process is suitable to be combined with CCS technology because of its relatively easy to capture
16 and pure CO₂ exhaust gas flow. CO₂ emission reductions of 80% are believed to be realisable
17 relative to the conventional blast furnace route (Abdul Quader et al. 2016). The total GHG
18 balance also depends on the further processing in a basic oxygen furnace or in an EAF. The
19 HIsarna process was small scale piloted under the EU ULCOS program.
- 20 • *Hydrogen co-firing* in BF-BOFs can potentially reduce emission by 30-40%, referring to
21 experimental work by the Course50 projects and Thyssen Krupp, but coke is required to
22 maintain stack integrity beyond that.

23 Reflecting the different conditions at existing and potential future plant sites, when choosing one of the
24 above options a combination of different measures and structural changes (including electricity,
25 hydrogen and CCU or CCS infrastructure needs) will likely be necessary in the future to achieve deep
26 reductions in CO₂ emissions of steel production.

27 In addition, increases in material efficiency (e.g., more targeted steel use per vehicle, building or piece
28 of infrastructure) and increases in the intensity of product use (e.g. sharing cars instead of owning them)
29 can contribute significantly to reduce emissions by reducing the need for steel production. The IEA
30 (2019b) suggested that up to 24% of cement and 40% of steel demand could be plausibly reduced
31 through strong material efficiency efforts by 2060. Potential material efficiency contribution for the EU
32 is estimated to be much higher—48% (Material Economics 2019). Recycling would cut the average
33 CO₂ emissions per tonne of steel produced by 60% (Material Economics 2019), but globally by 2050
34 secondary steel production is limited to 40–56% in various scenarios (IEA 2019b), with 46% in the IEA
35 (2021a) and up to 56% in 2050 in Xylia et al. (2016). It may scale up to 68% by 2070 (Xylia et al.
36 2016). CCU and more directly CCS are other options to reduce GHG emissions but depend on the full
37 life cycle net GHGs that can be allocated to the process (see 11.3.6). Bio-based fuels can also substitute
38 for some of the coal input, but due to other demands for biomass this strategy is likely to be limited to
39 specific cases.

40 Abatement costs for these strategies vary considerably from case to case and for each a plausible cost
41 range is difficult to establish; cf. **Table 11.3** (Leeson et al. 2017; Axelson et al. 2018; Fishedick et al.
42 2014b; Wang et al. 2021; Vogl et al. 2018; Fan and Friedmann 2021). A key point is that while cost of
43 production increases are significant, the effect on final end-uses is typically very small (Rootzén and
44 Johnsson 2016), with significant policy consequences (See Section 11.6 on public and private lead
45 markets for cleaner materials).

46

1 *11.4.1.2 Cement and concrete*

2 The cement sector is regarded as a sector where mitigation options are especially narrow (Energy
3 Transitions Commission 2018; Habert et al. 2020). Cement is used as the glue to hold together sand,
4 gravel and stone aggregates to make concrete, the most consumed manufactured substance globally.
5 The production of cement has been increasing faster than the global population since the middle of the
6 last century (Scrivener et al. 2018). Despite significant improvements in energy efficiency over the last
7 couple of decades (e.g. a systematic move from wet to dry kilns with calciner preheaters feeding off the
8 kilns) the direct emissions of cement production (sum of energy and process emissions) are estimated
9 to be 2.1–2.5 GtCO₂-eq in 2019 or 14–17% of total global direct industrial GHG emissions (Figure
10 11.4) (Crippa et al. 2021; Lehne and Preston 2018; Hertwich 2021; Sanjuán et al. 2020; Lamb et al.
11 2021; Bataille 2020a). Typically, about 40% of these direct emissions originates from process heating
12 (e.g. for calcium carbonate (limestone) decomposition into calcium oxide at 850°C or higher, directly
13 followed by combination with cementitious materials at about 1,450°C to make clinker), while 60% are
14 process CO₂ emissions from the calcium carbonate decomposition (Kajaste and Hurme 2016; IEA and
15 WBCSD 2018; Andrew 2019). Some of the CO₂ is reabsorbed into concrete products and can be seen
16 as avoided during the decades long life of the products; estimates of this flux vary between 15 and 30%
17 of the direct emissions (Schneider 2019; Stripple et al. 2018; Andersson et al. 2019; GCCA 2021a; Cao
18 et al. 2020). Some companies are mixing CO₂ into hardening concrete, both to dispose of the CO₂ and
19 more importantly reduce the need for binder (Lim et al. 2019).

20 One of the simplest and most effective ways to reduce cement and concrete emissions is to make
21 stronger concrete through better mixing and aggregate sizing and dispersal; poorly and well-made
22 concrete can vary in strength by a factor of 4 for a given volume (Fechner and Kray 2012; Habert et al.
23 2020). This argues for a refocus of the market away from “one size fits all”, often bagged, cements to
24 professionally mixed clinker, cementitious material and filler mixtures appropriate to the needs of the
25 end use.

26 Architects, engineers and contractors also tend to overbuild with cement because it is cheap as well as
27 corrosion and water resistant. Buildings and infrastructure can be purposefully designed to minimize
28 cement use to its essential uses (e.g. compression strength and corrosion resistance), and replace its use
29 with other materials (e.g. wood, stone, other fibres) for non-essential uses. This could reduce cement
30 use by 20–30% (D’Alessandro et al. 2016; Imbabi et al. 2012; Brinkerhoff and GLDNLV 2015; Lehne
31 and Preston 2018; Shanks et al. 2019; IEA 2019b; Habert et al. 2020).

32 Because so much of the emissions from concrete come from the limestone calcination to make clinker,
33 anything that reduces use of clinker for a given amount of concrete reduces its GHG intensity. While
34 95% Portland cement is common in some markets, it is typically not necessary for all end-use
35 applications, and many markets will add blast furnace slag, coal fly ash, or natural pozzolanic materials
36 to replace cement as supplementary cementitious materials; 71% was the global average clinker content
37 of cement in 2019 (IEA 2020a). All these materials are limited in volume, but combination of roughly
38 2–3 parts ground limestone and one part specially selected, calcined clays can also be used to replace
39 clinker (Fechner and Kray 2012; Lehne and Preston 2018; Habert et al. 2020). Local building codes
40 determine what mixes of cementitious materials are allowed for given uses, and would need to be
41 modified to allow these alternative mixtures where appropriate.

42 Ordinary Portland cement process CO₂ emissions cannot be avoided or reduced through the use of non-
43 fossil energy sources. For this reason, CCS technology, which could capture just the process emissions
44 (e.g. the EU LEILAC project, which concentrates the process emissions from the limestone calciner,
45 see following paragraph) or both the energy and process-related CO₂ emissions, is often mentioned as
46 a potentially important element of an ambitious mitigation strategy in the cement sector. Different types
47 of CCS processes can be deployed, including post-combustion technologies such as amine scrubbing
48 and membrane-assisted CO₂-liquefaction, oxycombustion in a low to zero nitrogen environment (full or

1 partial) to produce a concentrated CO₂ stream for capture and disposal, or calcium-looping (Dean et al.
2 2011). The IEA puts cement CCS technologies at the TRL 6-8 level (IEA 2020h). These approaches
3 have different strengths and weaknesses concerning emission abatement potential, primary energy
4 consumption, costs and retrofittability (Voldsund et al. 2019; Gardarsdottir et al. 2019; Hills et al. 2016).
5 Use of biomass energy combined with CCS has the possibility of generating partial negative emissions,
6 with the caveats introduced in 11.3.6 (Hepburn et al. 2019).

7 The energy-related emissions of cement production can also be reduced by using bioenergy solids,
8 liquids or gases (TRL 9) (IEA and WBCSD 2018), hydrogen or electricity (TRL 4 according to (IEA
9 2020h)) for generating the high-temperature heat at the calciner – hydrogen and bioenergy co-burning
10 could be complementary due to their respective fast vs slow combustion characteristics. In an approach
11 pursued by the LEILAC research project, the calcination process step is carried out in a steel vessel that
12 is heated indirectly using natural gas (Hills et al. 2017). The LEILAC approach makes it possible to
13 capture the process-related emissions in a comparatively pure CO₂ stream, which reduces the energy
14 required for CO₂ capture and purification. This technology (LEILAC in combination with CCS) could
15 reduce total furnace emissions by up to 85% compared with an unabated, fossil fuelled cement plant,
16 depending on the type of energy sources used for heating (Hills et al. 2017). In principle, the LEILAC
17 approach allows the eventual potential electrification of the calciner by electrically heating the steel
18 enclosure instead of using fossil burners.

19 In the long run, if some combination of material efficiency, better mixing and aggregate sizing,
20 cementitious material substitution and 90%+ capture CCS with supplemental bioenergy are not feasible
21 in some regions or at all to achieve near zero emissions, alternatives to limestone based ordinary
22 Portland cement may be needed. There are several highly regional alternative chemistries in use that
23 provide partial reductions (Fechner and Kray 2012; Lehne and Preston 2018; Habert et al. 2020), for
24 example, carbonatable calcium silicate clinkers, and there have been pilot projects with magnesium
25 oxide based cements, which could be negative emissions. Lower carbon cement chemistries are not
26 nearly as widely available as limestone deposits (Material Economics 2019), and would require new
27 materials testing protocols, codes, pilots and demonstrations.

28 Any substantial changes in cement and concrete material efficiency or production decarbonisation,
29 however, will require comprehensive education and continuing re-education for cement producers,
30 architects, engineers, contractors and small, non-professional users of cements. It will also require
31 changes to building codes, standards, certification, labeling, procurement, incentives, and a range of
32 policies to help create the market will be needed, as well as those for information disclosure, and
33 certification for quality. Even an end-of-pipe solution like CCS will require infrastructure for transport
34 and disposal. Abatement costs for these strategies vary considerably from case to case and for each a
35 plausible cost range is difficult to establish but are summarized in **Table 11.3** from the following
36 literature and other sources (Moore 2017; Fechner and Kray 2012; Leeson et al. 2017; IEA 2019f;
37 Wilson et al. 2003; Lehne and Preston 2018; Habert et al. 2020).

39 *11.4.1.3 Chemicals*

40 The chemical industry produces a broad range of products that are used in a wide variety of applications.
41 The products range from plastics and rubbers to fertilisers, solvents, and specialty chemicals such as
42 food additives and pharmaceuticals. The industry is the largest industrial energy user and its direct
43 emissions were about 1.1–1.7 GtCO₂-eq or about 10% of total global direct industrial emissions in 2019
44 (Figure 11.4 and Table 11.1) (Crippa et al. 2021; Lamb et al. 2021; Olivier and Peters 2018; IEA 2019f;
45 Minx et al. 2021). With regard to energy requirements and CO₂ emissions, ammonia, methanol, olefins,
46 and chlorine production are of great importance (Boulamanti and Moya Rivera 2017). Ammonia is

1 primarily used for nitrogen fertilisers, methanol for adhesives, resins, and fuels, whereas olefins and
2 chlorine are mainly used for the production of polymers, which are the main components of plastics.

3 Technologies and process changes that enable the decarbonisation of chemicals production are specific
4 to individual processes. Although energy efficiency in the sector has steadily improved over the past
5 decades (Figure 11.8; (Boulamanti and Moya Rivera 2017; IEA 2018a) a significant share of the
6 emissions is caused by the need for heat and steam in the production of primary chemicals (Box 11.2)
7 (Bazzanella and Ausfelder 2017). This energy is currently supplied almost exclusively through fossil
8 fuels which could be substituted with bioenergy, hydrogen, or low or zero carbon electricity, for
9 example, using electric boilers or high-temperature heat pumps (Thunman et al. 2019; Bazzanella and
10 Ausfelder 2017; Saygin and Gielen 2021). The chemical industry has among the largest potentials for
11 industrial energy demand to be electrified with existing technologies, indicating the possibility for a
12 rapid reduction of energy related emissions (Madeddu et al. 2020).

13 The production of ammonia causes most CO₂ emissions in the chemical industry, about 30% according
14 to IEA (2018a) and nearly one third according to (Crippa et al. 2021; Lamb et al. 2021; Minx et al.
15 2021). Ammonia is produced in a catalytic reaction between nitrogen and hydrogen – the latter most
16 often produced through natural gas reforming (Stork et al. 2018; Material Economics 2019) and in some
17 regions through coal gasification, which has several times higher associated CO₂ emissions. Future low-
18 carbon options include hydrogen from electrolysis using on low or zero-carbon energy sources
19 (Philibert 2017a), natural gas reforming with CCS, or methane pyrolysis, a process in which methane
20 is transformed into hydrogen and solid carbon (Material Economics 2019; Bazzanella and Ausfelder
21 2017) (see also Section 11.3.5 and Box 11.1). Electrifying ammonia production would lead to a decrease
22 in total primary energy demand compared to conventional production, but a significant efficiency
23 improvement potential remains in novel synthesis processes (Wang et al. 2018; Faria 2021). Combining
24 renewable energy sources and flexibility measures in the production process could allow for low-carbon
25 ammonia production on all continents (Fasihi et al. 2021). Steam cracking of naphtha and natural gas
26 liquids for the production of olefins, i.e. ethylene, propylene and butylene, and other high value
27 chemicals is the second most CO₂ emitting process in the chemical industry, accounting for another
28 almost 20% of the emissions from the subsector (IEA 2018a). Future lower-carbon options include
29 electrifying the heat supply in the steam cracker as described above, although this will not remove the
30 associated process emissions from the cracking reaction itself or from the combustion of the by-
31 products. Further in the future, electrocatalysis of carbon monoxide, methanol, ethanol, ethylene and
32 formic acid could allow direct electric recombination of waste chemical products into new intermediate
33 products (De Luna et al. 2019).

34 A ranking of key emerging technologies with likely deployment dates from the present to 2025 relevant
35 for the chemical industry identified different carbon capture processes together with electrolytic
36 hydrogen production as being of very high importance to reach net zero emissions (IEA 2020a).
37 Methane pyrolysis, electrified steam cracking, and the biomass based routes for ethanol-to-ethylene and
38 lignin-to-BTX were ranked as being of medium importance. While macro-level analyses show that
39 large-scale use of carbon circulation through CCU is possible in the chemical industry as primary
40 strategy, it would be very energy intensive and the climate impact depend significantly on the source of
41 and process for capturing the CO₂ (Kätelhön et al. 2019; Müller et al. 2020; Artz et al. 2018). Significant
42 synergies can be found when combining circular CCU approaches with virgin carbon feedstocks from
43 biomass (Bachmann et al. 2021; Meys et al. 2021).

44 In a net zero world carbon will still be needed for many chemical products, but the sector must also
45 address the life-cycle emissions of its products which arise in the use phase, for example, CO₂ released
46 from urea fertilisers, or at the end-of-life, for example, incineration of waste plastics which was
47 estimated to emit 100 Mt globally in 2015 (Zheng and Suh 2019). Reducing life-cycle emissions can
48 partly be achieved by closing the material cycles starting with material and product design planning for

1 re-use, re-manufacturing, and recycling of products – ending up with chemical recycling which yields
2 recycled feedstock that substitutes virgin feedstocks for various chemical processes (Smet and Linder
3 2019; Rahimi and García 2017). However, the chemical recycling processes which are most well
4 studied are pyrolytic processes which are energy intensive and have significant losses of carbon to off-
5 gases and solid residues (Dogu et al. 2021; Davidson et al. 2021). They are thus associated with
6 significant CO₂ emissions, which can even be larger in systems with chemical recycling than energy
7 recovery (Meys et al. 2020). Further, the products from many pyrolytic chemical recycling processes
8 are primarily fuels, which then in their subsequent use will emit all contained carbon as CO₂ (Vollmer
9 et al. 2020). Achieving carbon neutrality would thus require this CO₂ either to be recirculated through
10 energy-consuming synthesis routes or to be captured and stored (Lopez et al. 2018; Material Economics
11 2019; Geyer et al. 2017; Thunman et al. 2019). As all chemical products are unlikely to fit into chemical
12 recycling systems, CCS can be used to capture and store a large share of their end-of-life emissions
13 when combined with waste combustion plants or heat-demanding facilities like cement kilns (Tang and
14 You 2018; Leeson et al. 2017).

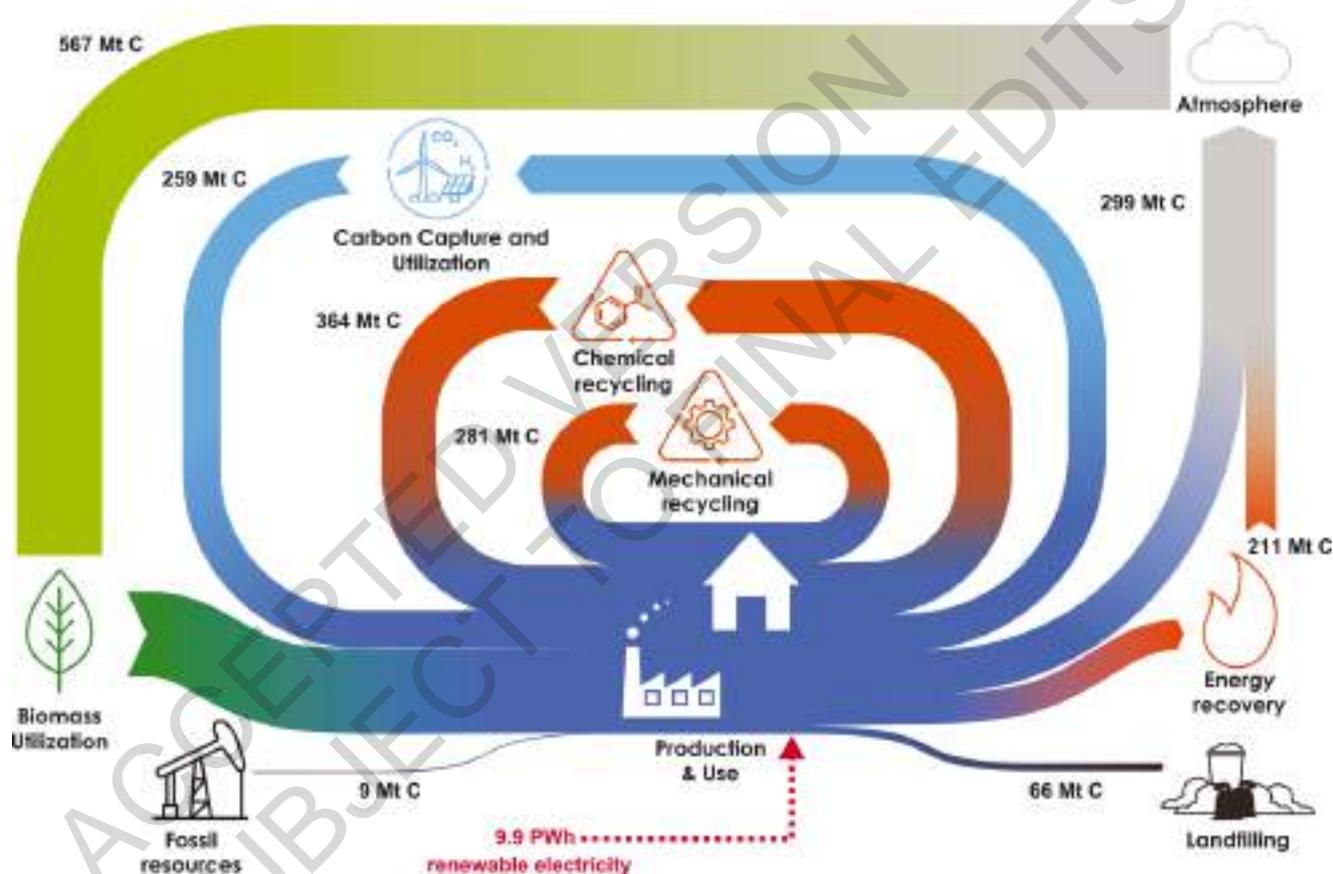

15 Reducing emissions involves demand-side measures, for example, efficient end-use, materials
16 efficiency and slowing demand growth, as well as recycling where possible to reduce the need for
17 primary production. The following strategies for primary production of organic chemicals which will
18 continue to need a carbon source are key in avoiding the GHG emissions of chemical products
19 throughout their life cycles:

- 20 • Recycled feedstocks: *chemical recycling* of plastics unsuitable for mechanical recycling was
21 already mentioned. Through *pyrolysis* of old plastics, both gas and a naphtha-like pyrolysis oil
22 can be generated, a share of which could replace fossil naphtha as a feedstock in the steam
23 cracker (Honus et al. 2018a,b). Alternatively, waste plastics could be *gasified* and combined
24 with low-carbon hydrogen to a syngas, for example, the production and methanol and
25 derivatives (Stork et al. 2018; Lopez et al. 2018). Other chemical recycling options include
26 polymer selective chemolysis, catalytic cracking, and hydrocracking (Ragaert et al. 2017).
27 Carbon losses and process emissions must be minimized and it may thus be necessary to
28 combine chemical recycling with CCS to reach near-zero emissions (Smet and Linder 2019;
29 Thunman et al. 2019; Meys et al. 2021).
- 30 • Biomass feedstocks: Substituting fossil carbon at the inception of a product life-cycle for
31 carbon from renewable sources processed in designated biotechnological processes (Hatti-Kaul
32 et al. 2020; Lee et al. 2019) using specific biomass resources (Isikgor and Becer 2015) or
33 residual streams already available (Abdelaziz et al. 2016). Routes with thermochemical and
34 catalytic processes, such as pyrolysis and subsequent catalytic upgrading, are also available
35 (Jing et al. 2019).
- 36 • Synthetic feedstocks: carbon captured with direct air capture or from point sources (bioenergy,
37 chemical recycling, or during a transition period from industrial processes emitting fossil CO₂)
38 can be combined with low-GHG hydrogen into a syngas for further valorisation (Kätelhön et
39 al. 2019). Thus, low-carbon methanol can be produced and used in methanol-to-
40 olefins/aromatics (MTO/MTA) processes, substituting the steam cracker (Gogate 2019) or a
41 Fischer-Tropsch processes could produce synthetic hydrocarbons.

42 Reflecting the diversity of the sector the listed options can only be illustrative. The above listed
43 strategies all rely on low-carbon energy to reach near zero emissions. In considering mitigation
44 strategies for the sector it will be key to focus on those for which there is a clear path towards (close to)
45 zero emissions, with high (carbon) yields over the full product value chain and minimal fossil resource
46 use for both energy and feedstocks (Saygin and Gielen 2021), with CCU and CCS employed for all
47 remnant carbon flows. The necessity of combining mitigation approaches in the chemicals industry with
48 low-carbon energy was recently highlighted in an analysis (see Figure 11.10) which showed how the

1 combined use of different recycling options, carbon capture, and biomass feedstocks was most effective
 2 at reducing global life-cycle emissions from plastics (Meys et al. 2021). While most of the chemical
 3 processes for doing all the above are well-known and have been used commercially at least partly, they
 4 have not been used at large scale and in an integrated way. In the past external conditions (e.g.
 5 availability and price of fossil feedstocks) have not set the necessary incentives to implement alternative
 6 routes and to avoid emitting combustion and process related CO₂ emissions to atmosphere. Most of
 7 these processes will very likely be more costly than using fossil fuels and full scale commercialisation
 8 would require significant policy support and the implementation of dedicated lead markets (Wyns et al.
 9 2019; Material Economics 2019; Wesseling et al. 2017; Bataille et al. 2018a). As in other sub-sectors
 10 abatement costs for the various strategies vary considerably across regions and products making it
 11 difficult to establish a plausible cost range for each (Philibert 2017b; Bazzanella and Ausfelder 2017;
 12 Philibert 2017a; Axelson et al. 2018; IEA 2018a; Saygin and Gielen 2021; De Luna et al. 2019).

21

Box 11.2 Plastics and climate change

22 The global production of plastics has increased rapidly over the past 70 years, with a compound annual
 23 growth rate (CAGR) of 8.4 %, about 2.5 times the growth rate for global GDP (Geyer et al. 2017) and
 24 higher than other materials since 1970 (IEA 2019b). Global production of plastics is now more than

1 400 million tonnes, including synthetic fibres (ibid.) The per capita use of plastics is still up to 20 times
2 higher in developed countries than in developing countries with low signs of saturation and the potential
3 for an increased use is thus still very large (IEA 2018a). Plastics is the largest output category from the
4 petrochemical industry, which as a whole currently uses about 14 % of petroleum and 8 % of natural
5 gas (IEA 2018a). Forecasts for plastic production assuming continued growth at recent rates of about
6 3.5% point towards a doubled production by 2035, following record-breaking investments in new and
7 increased production capacity based on petroleum and gas in recent years (CIEL 2017; Bauer and
8 Fontenit 2021). IEA forecasts show that even in a world where transport demand for oil falls
9 considerably by 2050 from the current ~100 mbpd, feedstock demand for chemicals will rise from ~12
10 mbpd to 15–18 mbpd (IEA 2019b). Projections for increasing plastic production as well as petroleum
11 use together with the lack of investments in break-through low-emission technologies do not align with
12 necessary emission reductions.

13 About half of the petroleum that goes into the chemical industry is used for producing plastics, and a
14 significant share of this is combusted or lost in the energy intensive production processes, primarily the
15 steam cracker. GHG emissions from plastic production depend on the feedstock used (ethane based
16 production is associated with lower emissions than naphtha based), the type of plastic produced
17 (production of simple polyolefins is associated with lower emissions than more complex plastics such
18 as polystyrene), and the contextual energy system (e.g. the GHG intensity of the electricity used) but
19 weighted averages have been estimated to be 1.8 tCO₂-eq-t⁻¹ for North American production (Daniel
20 Posen et al. 2017) and 2.3 tCO₂-eq-t⁻¹ for European production (Material Economics 2019). In regions
21 more dependent on coal electricity production the numbers are likely to be higher, and several times
22 higher for chemical production using coal as a feedstock - coal-based MTO has 7 times higher emissions
23 than olefins from steam cracking (Xiang et al. 2014). Coal-based plastic and chemicals production has
24 over the past decade been developed and deployed primarily in China (Yang et al. 2019). The
25 production of plastics was thus conservatively estimated to emit 1085 MtCO₂-eq-yr⁻¹ in 2015 (Zheng
26 and Suh 2019). Downstream compounding and conversion of plastics was estimated to emit another
27 535 MtCO₂-eq-yr⁻¹, while end-of-life treatment added 161 MtCO₂-eq-yr⁻¹. While incineration of plastic
28 waste was the cause of only 5% of global plastic life cycle emissions, in regions with waste-to-energy
29 infrastructures this share is significantly larger, for example, 13% of life cycle emissions in Europe (Ive
30 Vanderreydt et al. 2021). The effective recycling rate of plastics remains low relating to a wide range
31 of issues such as insufficient collection systems, sorting capacity, contaminants and quality deficiencies
32 in recycled plastics, design of plastics integrated in complex products such as electronics and vehicles,
33 heterogenous plastics used in packaging, and illegal international trade.

34

35 **END BOX 11.2 HERE**

36

37 *11.4.1.4 Other industry sectors*

38 The other big sources of direct global industrial combustion and process CO₂ emissions are light
39 manufacturing and industry (9.7% in 2016), non-ferrous metals like aluminium (3.1%), pulp and paper
40 (1.1%), and food and tobacco (1.9%) (Bataille 2020a; Crippa et al. 2021; Lamb et al. 2021).

41 **Light manufacturing and industry**

42 Light manufacturing and industry represent a very diverse sector in terms of energy service needs (e.g.,
43 motive power, ventilation, drying, heating, compressed air, etc.) and it comprises both small and large
44 plants in different geographical contexts. Most of the direct fossil fuel use is for heating and drying, and
45 it can be replaced with low GHG electricity, through direct resistance, high temperature heat pumps
46 and mechanical vapour recompression, induction, infrared, or other electrothermal processes
47 (Bamigbetan et al. 2017; Lechtenböhmer et al. 2016). Madeddu et al. (2020) argue up to 78% of

1 Europe's industrial energy requirements are electrifiable through existing commercial technologies and
2 99% with addition of new technologies currently under development. Direct solar heating is possible
3 for low temperature needs (<100°C) and concentrating solar for higher temperatures. Commercially
4 available heat pumps can deliver 100-150°C but at least up to 280°C is feasible (Zühlsdorf et al. 2019).
5 Plasma torches using electricity can be used where high temperatures (>1000°C) are required, but
6 hydrogen, biogenic or synthetic combustible hydrocarbons (methane, methanol, ethanol, LPG, etc.) can
7 also be used (Bataille et al. 2018a).

8 There is also a large potential for energy savings through cascading in industrial clusters similar to the
9 one at Kalundborg, Denmark. Waste heat can be passed at lower and lower temperatures from facility
10 to facility or circulated as low-grade steam or hot water, and boosted as necessary using heat pumps
11 and direct heating. Such geographic clusters would also enable lower cost infrastructure for hydrogen
12 production and storage as well as CO₂ gathering, transport and disposal (IEA 2019f).

13 **Aluminium and other non-ferrous metals**

14 Demand for aluminium comes from a variety of end-uses where a reasonable cost, light-weight metal
15 is desirable. It has historically been used in aircraft, window frames, strollers, and beverage containers.
16 As fuel economy has become more desirable and design improvements have allowed crush bodies made
17 of aluminium instead of steel, aluminium has become progressively more attractive for cars. Primary
18 aluminium demand is total demand (100 Mtonnes·yr⁻¹ in 2020) net of manufacturing waste reuse (14%
19 of virgin and recycled input) and end-of-life recycling (about 20% of what reaches market). Primary
20 aluminium consumption rose from under 20 Mtonnes·yr⁻¹ in 1995 to over 66 Mtonnes primary ingot
21 production in 2020 (International Aluminium Institute 2021). International Aluminium Institute (2021a)
22 expects total aluminium consumption to reach 150–290 Mtonnes·yr⁻¹ by 2050 with primary aluminium
23 contributing 69–170 Mtonnes and secondary recycled 91–120 Mtonnes (as in-use stock triples or
24 quadruples). OECD forecasts increases in demand by 2060 for primary aluminium to 139 Mt·yr⁻¹ and
25 for secondary aluminium to 71 Mtonnes (OECD 2019a). Primary (as opposed to recycled) aluminium
26 is generally made in a two-stage process, often geographically separated. In the first stage aluminium
27 oxide is extracted from bauxite ore (often with other trace elements) using the Bayer hydrometallurgical
28 process, which requires up to 200°C heat when sodium hydroxide is used to leach the aluminium oxide,
29 and up to 1000°C for kilning. This is followed by electrolytic separation of the oxygen from the
30 elemental aluminium using the Hall-Héroult process, by far the most energy intense part of making
31 aluminium. This process has large potential emissions from the electricity used (12.5 MWh per tonne
32 aluminium BAT, 14–15 MWh per tonne average). From bauxite mine to aluminium ingot, reported
33 total global average emissions are between 12 and 17.6 tCO₂-eq per tonnes of aluminium, depending
34 on estimates and assumptions made²³ (Saevarsdottir et al. 2020). About 10 % of this, 1.5 tonnes of direct
35 CO₂ per tonne aluminium are currently emitted as the graphite electrodes are depleted and combine
36 with oxygen, and if less than optimal conditions are maintained perfluorocarbons can be emitted with
37 widely varying GHG intensity, up to the equivalent of 2 tCO₂-eq per tonne aluminium. PFC emissions,
38 however, have been greatly reduced globally and almost eliminated in well-run facilities. Aluminium,
39 if is not contaminated, is highly recyclable and requires 1/20 of the energy required to produce virgin
40 aluminium; increasing aluminium recycling rates from the 20–25% global average is a key emissions
41 reduction strategy (Haraldsson and Johansson 2018).

42 The use of low and zero GHG electricity (e.g. historically from hydropower) can reduce the indirect
43 emissions associated with making aluminium. A public-private partnership with financial support from
44 the province of Québec and the Canadian federal government has recently announced a fundamental

FOOTNOTE²³ According to International Aluminium Institute (2021b), scope 3 (cradle to gate) emissions from aluminium industry in 2018 reached 1.127 GtCO₂-eq or 17.6 tCO₂-eq per tonne of primary aluminium. In Low carbon B2DS it expected to be reduced to 2.5 tCO₂-eq per tonne.

1 modification to the Hall-Héroult process by which the graphite electrode process emissions can be
2 eliminated by substitution of inert electrodes. This technology is slated to be available in 2024 and is
3 potentially retrofittable to existing facilities (Saevarsdottir et al. 2020).

4 Smelting and otherwise processing of other non-ferrous metals like nickel, zinc, copper, magnesium
5 and titanium with less overall emissions have relatively similar emissions reduction strategies (Bataille
6 and Stiebert 2018): 1) Increase material efficiency. 2) Increase recycling of existing stock. 3) Pursue
7 ore extraction processes (e.g. hydro- and electro-metallurgy) that allow more use of low carbon
8 electricity as opposed to pyrometallurgy, which uses heat to melt and separate the ore after it has been
9 crushed. These processes have been used occasionally in the past but have generally not been used due
10 to the relatively inexpensive nature of fossil fuels.

11 **Pulp and Paper**

12 The pulp and paper industry is a small net-emitter of CO₂, assuming the feedstock is sustainably sourced
13 (see Chapter 7), but it has large emissions of biogenic CO₂ from feedstock (700–800 Mtonne·yr⁻¹
14 (Tanzer et al. 2021). It includes pulp mills, integrated pulp and paper mills and paper mills using virgin
15 pulpwood and other fibre sources, residues and co-products from wood products manufacturing, and
16 recycled paper as feedstock. Pulp mills typically have access to bioenergy in the chemical pulping
17 processes to cover most or all of heat and electricity needs, for example, through chemicals recovery
18 boilers and steam turbines in the kraft process. Mechanical pulping mainly uses electricity for energy;
19 decarbonisation thus depends on grid emission factors. With the exception of the lime kiln in kraft pulp
20 mills, process temperature needs are typically less than or equal to 150°C to 200°C, mainly steam for
21 heating and drying. This means that this sector can be relatively easily decarbonised through continued
22 energy efficiency, fuel switching and electrification, including use of high temperature heat pumps
23 (Ericsson and Nilsson 2018). Electrification of pulp mills could, in the longer term, make bio-residues
24 currently used internally for energy available as a carbon source for chemicals (Meys et al. 2021). The
25 PPI also has the capabilities, resources and knowledge, to implement these changes. Inertia is mainly
26 caused by equipment turn-over rates, relative fuel and electricity prices, and the profitability of
27 investments.

28 A larger and more challenging issue is how the forestry industry can contribute to the decarbonisation
29 of other sectors and how biogenic carbon will be used in a fossil-free society, for example, through
30 developing the forest based bioeconomy (Bauer 2018; Pülzl et al. 2014). In recent years the concept of
31 biorefineries has gained increasing traction. Most examples involve innovations for taking by-products
32 or diverting small streams to produce fuels, chemicals and bio-composites that can replace fossil-based
33 products, but there is little common vision on what really constitutes a biorefinery (Bauer et al. 2017).
34 Some of these options have limited scalability and the cellulose fibre remains the core product even in
35 the relatively large shift from paper production to textiles fibre production.

36 Pulp mills have been identified as promising candidates for post-combustion capture and CCS
37 (Onarheim et al. 2017), which could allow some degree of net negative emissions. For deep
38 decarbonisation across all sectors, notably switching to biomass feedstock for fuels, organic chemicals
39 and plastics, the availability of biogenic carbon (in biomass or as biogenic CO₂, Chapter 7) becomes an
40 issue. A scenario where biogenic carbon is CCU as feedstock implies large demands for hydrogen,
41 completely new value chains and more closed carbon loops, all areas which are as yet largely
42 unexplored (Ericsson 2017; Meys et al. 2021).

43

44

45

1 **11.4.1.5 Overview of estimates of specific mitigation potential and abatement costs of key technologies**
2 **and processes for main industry sectors**

3 Climate policy related literature focusing on deep industrial emission reductions has expanded rapidly
4 since AR 5. An increasing body of research proposes deep decarbonisation pathways for energy
5 intensive industries (Figure 11.13). (Bataille et al. 2018a) address the question of whether it is possible
6 to reduce GHG emissions to very low, zero, or negative levels, and identifies preliminary technological
7 and policy elements that may allow the transition, including the use of policy to drive technological
8 innovation and uptake. Material Economics (2019); IEA (2019b), Energy Transitions Commission
9 (2018) and Climate Action Tracker CAT (2020) take steps to identify pathways integrating energy
10 efficiency, material efficiency, circular economy and innovative technologies options to cut GHG
11 emissions across basic materials and value chains. The key conclusion is that net zero CO₂ emissions
12 from the largest sources (steel, plastics, ammonia, and cement) could be achieved by 2050 by deploying
13 already available multiple options packaged in different ways (Material Economics 2019; UKCCC
14 2019b; Davis et al. 2018). The studies assume that for those technologies that have a kind of
15 breakthrough technology status further technological development and significant cost reduction can
16 be expected.

17 **Table 11.3**, modified from Bataille (2020a) and built from (Material Economics 2019; Bazzanella and
18 Ausfelder 2017; Axelson et al. 2018; McMillan et al. 2016; Wesseling et al. 2017; UKCCC 2019b;
19 Energy Transitions Commission 2018; Philibert 2017a; Davis et al. 2018; IEA 2019f, 2020c; Bataille
20 et al. 2018a), presents carbon intensities that could be achieved by implementing mitigation options in
21 major basic material industries, mitigation potential, estimates for mitigation costs, TRL and potential
22 year of market introduction (see also Figure 11.13).

23 **Table 11.3** acknowledges that for many carbon intensive products a large variety of novel processes,
24 inputs and practices capable of providing very deep emission reductions are already available and
25 emerging. However, their application is subject to different economic and structural limitations,
26 therefore in the scenarios assuming deep decarbonisation by 2050–2060 different technological mixes
27 can be observed (section 11.4.2).

Table 11.3 Technological potentials and costs for deep decarbonisation of basic industries. Percentages of maximum reduction are multiplicative, not additive

Sector	Current Intensity (tCO ₂ -eq t ⁻¹)	Potential GHG reduction	NASA TRL	Cost per tonne CO ₂ -eq (2019 USD tCO ₂ -eq ⁻¹ for % of emissions) ? = Unknown	Year available assuming policy drivers
Iron and Steel					
Current intensity – all steel (Worldsteel)	1.83				
Current intensity – ~BF-BOF/ Best BF-BOF & NG-DRI (with near zero GHG electricity)	2.3/1.8 & 0.7				
Current intensity – EAF (depends on electricity intensity & pre-heating fuel)	>=0	Up to 99%			
Material efficiency (IEA 2019 “Material Efficiency...”)		Up to 40%	9	Subject to supply chain building codes and education	Today
More recycling; depends on available stock, recycling network, quality of scrap, availability of DRI for dilution		Highly regional, growing with time	9	Subject to logistical, transport, sorting, & recycling equipment costs	Today
BF-BOF w/ top gas recirculation & CCU/S ⁱ		60%	6–7	70–130 USD/t	2025-‘30
Syngas (H ₂ & CO) DRI EAF with concentrated flow CCU/S		90%+	9	>=40 USD/t	Today
Hisarna with concentrated CO ₂ capture ⁱⁱ		80–90%	7	40–70 USD/t	2025
Hydrogen DRI EAF ⁱⁱⁱ - Fossil hydrogen with CCS is in operation, electrolysis based hydrogen scheduled for 2026		Up to 99%	7	34–68 EUR/t & 40 EUR/MWh	2025
Aqueous (e.g. SIDERWIN) or Molten Oxide (e.g. Boston Metals) Electrolysis ^{iv}		Up to 99%	3–5	?	2035-‘40
Cement & Concrete					
Current intensity, about 60% is limestone calcination	0.55				
Building design to minimize concrete (IEA 2019b, 2020a)		Up to 24%	9	Low, education, design and logistics related	2025
Alternative lower GHG fuels, e.g. waste (biofuels and hydrogen see above)		40%	9	Cost of alt. fuels	Today

	CCUS for process heating & CaCO ₃ calcination CO ₂ (e.g. LEILAC, possible retrofit) ^v		99% calc., <=90% heat	5–7	<=40 USD/t calc. <=120 USD/t heat	2025
	Clinker substitution (e.g. limestone + calcined clays) ^{vi}		40–50%	9	Near zero, education, logistics, building code revisions	Today
	Use of multi sized and well dispersed aggregates ^{vi}		Up to 75%	9	Near zero	Today
	Magnesium or ultramafic cements ^{vi}		Negative?	1–4	?	2040
Aluminium & other non-ferrous						
	Current Al intensity, from hydro to coal based electricity production. 1.5 tonne CO ₂ are produced by graphite electrode decay	1.5 t/t + electricity req., i.e. 10/t (NG) to 18 t/t (Coal)				
	Inert electrodes + green electricity ^{vii}		100%	6–7	Relatively low	2024
	Hydro/Electrolytic smelting (w/CO ₂ CCUS if necessary)		Up to 99%	3–9	Ore specific	<2030
Chemicals (see also crosscutting feedstocks above) ^{viii}						
	Catalysis of ammonia from low/zero GHG hydrogen H ₂	1.6 (NG), 2.5 (naptha) 3.8 (coal)	<=99%	9	Cost of H ₂	Today
	Electrocatalysis: CH ₄ , CH ₃ OH, C ₂ H ₅ OH, CO, olefins ^{ix}		Up to 99%	3	Cost: Elec., H ₂ , CO _x	2030
	Catalysis of olefins from: (m)ethanol; H ₂ & CO _x directly		9%	9,3	Cost: H ₂ & CO _x	<2030
	End-use plastics, mainly CCUS and recycling	1.3–4.2, about 2.4	94%	5–6	150–240 USD/t	2030?
Pulp & Paper						
	Full biomass firing, inc. lime kilns		60-75%	9	About 50 USD/t	Today
Other manufacturing						
	Electrification using current tech (boilers, 90°C–140°C heat pumps		99%	9	Cost: Elec. vs. NG	2025
	" using new tech (induction, plasma heating)		99%	3–6		2025
Cross-cutting (CCUS, H ₂ , net zero C _o O _x H _y fuels/feedstocks)						
	CCUS of post-combustion CO ₂ diluted in nitrogen ^v		Up to 90%	6–7	<=120 USD/t	2025
	CCUS of concentrated CO ₂ ^v		99%	9	<=40 USD/t	Today
	H ₂ prod: Steam or auto-thermal CH ₄ reforming w/ CCS ^v		SMR<=90% ATR >90%	6*, 9**	56% @<=40 USD/t chem**, <=120 USD heat*,+20%/kg	<=2025
	H ₂ prod: coal with CCUS ^v		<=90%	6	“,+25-50%/kg	<=2025

	H ₂ prod: Alkaline or PEM Electrolysis ^x		99%	9	about 50 USD/t or <20-30 USD/MWh	Today
	H ₂ prod: Reversible solid oxide fuel electrolysis ^x		99%	6–8	about 40 USD/t or <40 USD/MWh	2025
	H ₂ prod: CH ₄ pyrolysis or catalytic cracking ^{xi}		99%	5	?	2030?
	Hydrogen as CH ₄ replacement		<=10%	9	See above	Today
	Biogas or liquid replacement hydrocarbons		60–90%	9	Biomass USD/GJ; >=50 USD/t, uncertain	Today
	Anaerobic digestion/fermentation: CH ₄ , CH ₃ OH, C ₂ H ₅ OH ^{xii}		Up to -99%	9	Biomass cost	Today
	Methane or methanol from H ₂ & CO _x (CCUS for excess). Maximum -50% reduction if C source is FF		50–99%	6–9	Cost: H ₂ & CO _x	Today
	850°C woody biomass gasification w/ CCS for excess carbon: CO, CO ₂ , H ₂ , H ₂ O, CH ₄ , C ₂ H ₄ & C ₆ H ₆ ^{xiii}		Could be negative	7–8	about 50–75 USD/t, uncertain	Today
	Direct air capture for short and long chain C _o O _x H _y ^{xiv}		Up to 99%	3	Cost: E, H ₂ , CO _x about 94–232 USD/t	<=2030

1

ⁱ Data for CCS costs for steel making: Birat (2012); Axelson et al. (2018) and Leeson et al. (2017);

ⁱⁱ Data for Hisarna: Axelson et al. (2018);

ⁱⁱⁱ Data for hydrogen DRI electric arc furnaces: Fishedick et al. (2014b) and Vogl et al. (2018);

^{iv} Data for molten oxide electrolysis (also known as SIDERWIN): (Axelson et al. 2018; Fishedick et al. 2014b). The TRLs differ by source, the value provided is from Axelson et al. (2018) based on UCLOS SIDERWIN;

^v Data for making hydrogen from SMR and ATR with CCUS: Moore (2017), Leeson et al. (2017) and IEA (2019f). The cost of CCS disposal of concentrated sources of CO₂ at 15–40 USD·tCO₂-eq⁻¹ is well established as commercial for direct or EOR purposes and is based on the long standing practise of disposing of hydrogen sulfide and oil brines underground: Wilson et al. (2003) and Leeson et al. (2017). There is a wide variance, however, in estimated tCO₂-eq⁻¹ breakeven prices for industrial post-combustion capture of CO₂ from sources highly diluted in nitrogen (e.g. Leeson et al. (2017) at 60–170 USD·tCO₂-eq⁻¹), but most fall under 120 USD·tCO₂-eq⁻¹;

^{vi} Data for clinker substitution and use of well mixed and multi sized aggregates: (Fechner and Kray 2012; Lehne and Preston 2018; Habert et al. 2020);

^{vii} Rio Tinto, Alcoa and Apple have partnered with the governments of Québec and Canada to formed a coalition to commercialize inert as opposed to sacrificial graphite electrodes by 2024, thereby making the standard Hall Heroult process very low emissions if low carbon electricity is used;

^{viii} Data and other information: Bazzanella and Ausfelder (2017); Axelson et al. (2018); IEA (2018a); De Luna et al. (2019) and Philibert (2017b,a);

^{ix} See De Luna et al. (2019) for a state of the art review of electrocatalysis, or direct recombination of organic molecules using electricity and catalysts;

^x Data for hydrogen production from electrolysis: Bazzanella and Ausfelder (2017); Philibert (2017a); Armijo and Philibert (2020); IEA (2019f); Philibert (2017b);

^{xi} Data for methane pyrolysis to make hydrogen: Abbas and Wan Daud (2010). Data for hydrogen production from methane catalytic cracking: Amin et al. (2011) and Ashik et al. (2015);

^{xii} Data for anaerobic digestion or fermentation for the production of methane, methanol and ethanol: De Luna et al. (2019);

^{xiii} Data for woody biomass gasification: Li et al. (2019) and van der Meijden et al. (2011);

^{xiv} Data on direct air capture of CO₂: Keith et al. (2018) and Fasihi et al. (2019).

1 While deep GHG emissions reduction potential is assessed for various regions, assessment of associated
2 costs is limited to only a few regions; nevertheless those analyses may be illustrative at the global scale.
3 UKCCC (2019b) provides costs assessments for different industrial subsectors (see **Table 11.3**) for the
4 UK. They provide three ranges: core, more ambitious and when energy and material efficiency are
5 limited. The core options range from 2–85 GBP 2019 tCO₂-eq⁻¹ (e.g., reduction in GHG emissions by
6 about 50% by 2050 applying energy efficiency (EE), ME, CCS, biomass and electrification). The more
7 ambitious options are estimate at 32–119 GBP 2019 tCO₂-eq⁻¹ (e.g., 90% emissions reduction via
8 widespread deployment of hydrogen, electrification or bioenergy for stationary industrial
9 heat/combustion). Finally, costs range from 33–299 GBP tCO₂-eq⁻¹ when energy and material
10 efficiency are limited.

11 In Material Economics (2019) costs are provided for separate technologies and subsectors, and also by
12 pathways, each including new industrial processes, circular economy and CCS components in different
13 proportions allowing for the transition to net zero industrial emission in the EU by 2050. That means
14 that the study provides information about the three main mid- to long-term options which could enable
15 a widely abatement of GHG emissions. Given different electricity price scenarios, average abatement
16 costs associated with the circular economy-dominated pathway are 12–75 EUR 2019 tCO₂-eq⁻¹, for the
17 carbon capture-dominated pathway 79 euro 2019 tCO₂-eq⁻¹, and for the new processes dominated
18 scenario 91 euro 2019 tCO₂-eq⁻¹. Consequently, net zero emission pathways are about 3–25% costlier
19 compared to the baseline (Material Economics 2019). According to Energy Transitions Commission
20 (2018), cement decarbonisation would cost on average 110–130 USD tCO₂⁻¹ depending on the cost
21 scenario. Rootzén and Johnsson (2016) state that CO₂ avoidance costs for the cement industry vary
22 from 25 to 110 EUR·tCO₂⁻¹, depending on the capture option considered and on the assumptions made
23 with respect to the different cost items involved. According to Energy Transitions Commission (2018),
24 steel can be decarbonised on average at 60 USD tCO₂⁻¹, with highly varying costs depending on low
25 carbon electricity prices..

26 For customers of final products, information on the potential impact of supply side decarbonization on
27 final prices may be more useful than that of CO₂ abatement costs. A different approach has been
28 developed to assess the costs of mitigation by estimating the potential impacts of supply-side
29 decarbonization on final products prices. Material Economics (2019) shows that with deep
30 decarbonization, depending on the pathway, steel costs grow by 20–30%; plastics by 20–45%; ammonia
31 by 15–60% and cement (not concrete) by 70–115%. While these are large and problematic costs
32 increases for material producers working with low margins in a competitive market, final end-use
33 product price increases are far less, for example, a car becomes 0.5% more expensive, supported by
34 both Rootzén and Johnsson (2016) and Energy Transitions Commission (2018). For comparison,
35 Rootzén and Johnsson (2017) found that decarbonizing cement making, while doubling the cost of
36 cement, would add <1% to the costs of a residential building; the Energy Transitions Commission
37 (2018) found concrete would be 10-30% more expensive, adding 15,000 USD or 3% to the price of a
38 house includign land value. Finally, IEA (2020a) estimated the impact on end-use prices are rather
39 small, even in a net zero scenario; they find price increases of 0.2% for a car and 0.6% for a house based
40 on higher costs for steel and cement respectively.

41 Thus, the price impact scales down going across the value chain and might be acceptable for a
42 significant share of customers. However, it has to be reflected that the cumulative price increase could
43 be more significant if several different zero-carbon materials (e.g., steel, plastics, aluminium) in the
44 production process of a certain product have to be combined, indicating the importance of material
45 efficiency being applied along with production decarbonisation.

46

1 **11.4.2 Transformation pathways**

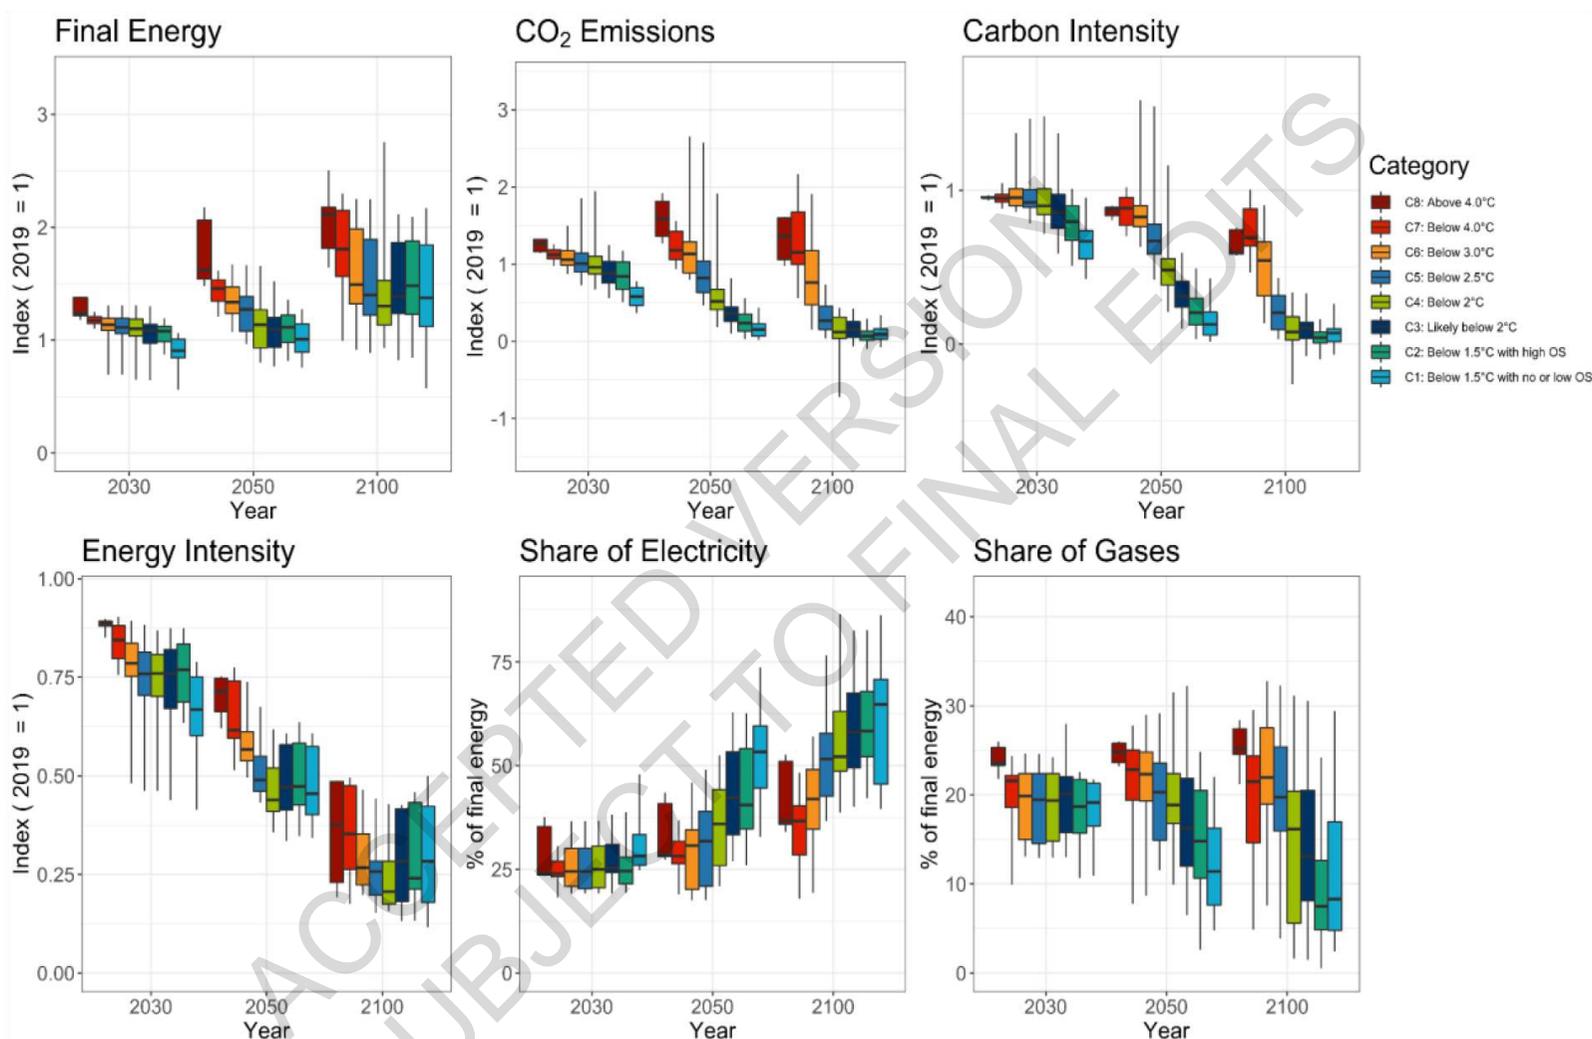

2 To discuss the general role and temporal implementation of the different options for achieving a net-
3 zero GHG emissions industry, mitigation pathways will be analyzed. This starts with showing the
4 results of IAM based scenarios followed by specific studies which provide much higher technological
5 resolution and allow a much deeper look into the interplay of different mitigation strategies. The
6 comparison of more technology-focused sector-based scenarios with top-down oriented scenarios
7 provides the opportunity for a reciprocal assessment across different modelling philosophies and helps
8 to identify robust elements for the transformation of the sector. Only some of the scenarios available in
9 the literature allow for at least rough estimates of the necessary investments and give direction about
10 relevant investment cycles and potential risks of stranded or depreciated assets. In some specific cases
11 cost comparisons can be translated into expected difference costs not only for the overall sector, but
12 also for relevant materials or even consumer products.

13

14 *11.4.2.1 Central results from (top down) scenarios analysis and illustrative mitigation pathways* 15 *discussion*

16 Chapter 3 conducted a comprehensive analysis of scenarios based on IAMs. The resulting database
17 comprises more than 1000 model-based scenarios published in the literature. The scenarios span a broad
18 range along temperature categories from rather baseline like scenarios to the description of pathways
19 that are compatible with the 1.5°C target. Comparative discussion of scenarios allows some insights
20 with regard to the relevance of mitigation strategies for the industry sector (Figure 11.11).

1

2 The main results from the Chapter 3 analysis from an industry perspective are:

3 • While all scenarios show a decline in energy and carbon intensity over time final energy
4 demand and associated industry related CO₂ emissions increase in many scenarios. Only
5 ambitious scenarios (category C1) show significant reduction in final energy demand in 2030,
6 more or less constant demand in 2050, but increasing demand in 2100, driven by growing
7 material use throughout the 21st century. While carbon intensity shrinks over time energy
8 related CO₂-emissions decline after 2030 even in less ambitious scenarios, but particularly in
9 those pursuing a temperature increase below 2°C.10 • Reduction of CO₂-emissions in the sector are achieved through a combination of technologies
11 which includes nearly all options that have been discussed in this chapter (Section 11.3 and
12 11.4.1). However, there are big differences with regard to the intensity the scenarios implement
13 the various options. This is particularly true for CCS for industrial applications and material
14 efficiency and material demand management (i.e., service demand, service product intensity).
15 The latter options are still underrepresented in many global IAMs.16 • There are only a few scenarios which allow net-negative CO₂-emissions for the industry for the
17 second half of the century while most scenarios assessed (including the majority of 1.5°C
18 scenarios) end up with still significant positive CO₂-emissions. In comparison to the whole
19 system most scenarios expect a slower decrease of industry related emissions.20 • There is a great - up to a factor of two - difference in assumptions about the GHG mitigation
21 potential associated with different carbon cost levels between IAMs and sector specific industry
22 models. Consequently, IAMs pick up mitigation options slower or later (or not at all) than
23 models which are more technologically detailed. Due to their top-down perspective IAMs to
24 date have not been able to represent the high complexity of industries in terms of the broad
25 variety of technologies and processes (particularly circularity aspects) and to fully reflect the
26 dynamics of the sector. In addition, as energy and carbon price elasticities are still not
27 completely understood, primarily cost driven models have their limitations. However, there are
28 several ongoing activities to bring in more engineering knowledge and technological details
29 into the IAM models (Kermeli et al. 2021).30 In addition to the more aggregated discussion, the IAMs illustrative mitigation pathways (IMPs) allow
31 a deeper look into the transformation pathways related to the scenarios. For the illustrative mitigation
32 pathways (IMPs) approach sets of scenarios have been selected which represent different levels of GHG
33 mitigation ambitions, scenarios which rely on different key strategies or even exclude some mitigation
34 options, represent delayed actions or SDG oriented pathways. For more detailed information about the
35 selection see Chapter 3.3.2. Figure 11.12 compares for a selected number of key variables the results of
36 IMPs and puts them in the context of the whole sample of IAMs scenario results for three temperature
37 categories.

Figure 11.12 Comparison of industry sector related CO₂-emissions (including process emissions), final energy demand, share of electricity and hydrogen in the final energy mix, and industrial CCS for different mitigation scenarios representing illustrative mitigation pathways and the full sample of IAM scenario results for three temperature categories (figure based on scenario data base). Indicators in the Illustrative Mitigation Pathways (lines) and the 5-95% range of Reference, 1.5°C and 2°C scenarios (shaded areas). The selected IMPs reflect the following characteristics: opportunities for reducing demand (IMP-LD; low demand), the role of deep renewable energy penetration and electrification (IMP-Ren; renewables), extensive use of CDR in the industry and the energy sectors to achieve net negative emissions (IMP-Neg), insights how shifting development can lead to deep emission reductions and achieve sustainable development goals (IMP-SP; shifting pathways), and insights how slower short term emissions reductions can be compensated by very fast emission reductions later on (IMP-GS; gradual

- 1 **strengthening). Furthermore, two scenarios were selected to illustrate the consequences of current policies and pledges; these are CurPol (Current Policies) and**
2 **ModAct (Moderate Action) and are referred to as Pathways Illustrative of Higher Emissions**

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1

2 With growing mitigation ambition final energy demand is significantly lower in comparison of a current
3 policy pathway (CurPol) and a scenario that explores the impact of further moderate actions (ModAct).
4 Based on the underlying assumptions, scenarios IMP-SP and IMP-LD are characterized by the lowest
5 final energy demand, triggered by high energy efficiency improvement rates as well as additional
6 demand side measures while a scenario with extensive use of CDR in the industry and the energy sectors
7 to achieve net negative emissions (IMP-Neg) leads to a significant increase in final energy demand.
8 Scenario IMP-GS represents a pathway where mitigation action is gradually strengthened by 2030
9 compared to pre-COP 26 NDCs shows the lowest final energy demand. All ambitious IMPs show
10 substantially increasing contributions from electricity, with electricity's end-use share more than
11 doubling for some of them by 2050 and more than tripling by 2100. The share of hydrogen shows a
12 flatter curve for many scenarios, reaching 5% (IMP-Ren) in 2050 and up to 20% in 2100 for some
13 scenarios (Ren, LD). Those scenarios that have a strong focus on renewable energy electrification show
14 high shares of hydrogen in the sector. In comparison to sector specific and national studies which show
15 typically a range between 5 and 15% by 2050, many IAM IMPs expect hydrogen to play a less important
16 role. Results for industrial CCS show a broad variety of contributions, with the GS scenario (where
17 hydrogen is not relevant as mitigation option) representing the upper bound to 2050, with almost 2
18 GtCO₂-yr⁻¹ captured and stored by 2050. Beyond 2050 the upper bound is associated with scenario IMP-
19 Neg associated with extensive use of CDR in the industry and energy sectors to achieve net negative
20 emissions in the second half of the century - more than 6 GtCO₂-yr⁻¹ is captured and stored in 2100
21 (this represents roughly 60% of 2018 direct CO₂ emissions of the sector).

22

23 *11.4.2.2 In-depth discussion and “reality” check of pathways from specific sector scenarios*

24 Since AR5 a number of studies providing a high technological level of detail for the industry sector
25 have been released which describe how the industry sector can significantly reduce its GHG emissions
26 until the middle of the century. Many of these studies try to specifically reflect the particular industry
27 sector characteristics and barriers that hinder industry to follow an optimal transformation pathway.
28 They vary in respect to different characteristics. In respect to their geographical scope, some studies
29 analyse the prospects for industry sector decarbonisation on a global level (Tchung-Ming et al. 2018;
30 IEA 2017a; Grubler et al. 2018; Energy Transitions Commission 2018; IEA 2020a, 2019b, 2020c);
31 regional level, for example, European Commission (2018); Material Economics (2019), or country level
32 - studies for China, from where most industry related emissions come, (e.g. Zhou et al. (2019)).²⁴ In
33 regard sectoral scope, some studies include the entire industry sector, while others focus on selected
34 GHG emission intensive sectors, such as steel, chemicals and/or concrete. Most of the scenarios focus
35 solely on CO₂ emissions, that is non-CO₂ emissions of the industrial sector are neglected.²⁵

36 Industry sector mitigation studies also differ in regard to whether they develop coherent scenarios or
37 whether they focus on discussing and analysing selected key mitigation strategies, without deriving full

FOOTNOTE²⁴ In addition, there are many other studies available which have developed country-specific, technologically detailed scenarios for industry decarbonisation e.g. (Gerbert et al. 2018) and a few which have investigated the decarbonisation prospects of individual industrial clusters (Schneider 2019), but these types of studies are not discussed here.

FOOTNOTE²⁵ Most of the global mitigation scenarios solely focus on CO₂ emissions. Non-CO₂ emissions make up only a small share of the industry sector's current CO₂-eq. emissions and include N₂O emissions (e.g. from nitric and adipic acid production), CH₄ emissions (e.g. from chemical production and iron and steel production) and various F-gases (such as perfluorocarbons from primary aluminium production and semiconductor manufacturing) (Gambhir et al. 2017; USEPA and ICF 2012). Mitigation options for these non-CO₂ emissions are discussed in (Gambhir et al. 2017).

1 energy and emission scenarios. Coherent scenarios are developed in (IEA 2017; Energy Transitions
2 Commission 2018; Tchung-Ming et al. 2018; Grubler et al. 2018; IEA 2021a; IRENA 2021; IEA 2019b,
3 2020a,c) on the global level and in Climact (2018); European Commission (2018); Material Economics
4 (2019) on the European level. Recent literature analysing selected key mitigation strategies, for example
5 IEA (2019b) and Material Economics (2019) has focused either exclusively or to a large extent on
6 analysing the potential of materials efficiency and circular economy measures to reduce the need for
7 primary raw materials relative to a business-as-usual development. IEA (2021a, 2020a) also provides
8 deep insides in single mitigation strategies for the industry sector, particularly the role of CCS.

9 The following discussion mainly concentrates on scenarios from IEA. It has to be acknowledged that
10 they only represent a small segment of the huge scenario family (cf. scenario data base in chapter 3),
11 but this approach enables to show the chronological evolution of scenarios coming from the same
12 institution, using the same modelling approach (which allows a technology-rich analytical backcasting
13 approach), but reflect additional requests that emerge over time (Table 11.5). In the 2DS scenario from
14 the “Energy Technology Perspectives (ETP)” study (IEA 2017), which intends to describe in great
15 technological detail how the global energy system could transform by 2060 so as to be in line with
16 limiting global warming to below 2°C, total CO₂ emission are 74 % lower in 2060 than in 2014, while
17 only 39% lower in the industry sector. The B2DS scenario of the same study intends to show how far
18 known clean energy technologies (including those that lead to negative emissions) could go if pushed
19 to their practical limits, allowing the future temperature increase to be limited to “well below” 2°C and
20 lowering total CO₂ emissions by 100% by 2060 and by 75% relative to 2014 in the industry sector.

21 Technologies penetration assumed in the CTS scenario by 2060 allows for an industrial emission cut of
22 45% from 2017 level and a 50% cut against projected 2060 emissions in the Reference Technology
23 Scenario (RTS) from the same study (IEA 2019b) similar to IEA’s 2DS scenario. Energy efficiency
24 improvements and deployment of BATs contribute 46% to cumulative emission reduction in 2018–
25 2060, while fuel switch (15%), material efficiency (19%) and deployment of innovative processes
26 (20%) provide the rest. IEA (2020a,c) which continuous the Energy Technology Perspectives series
27 include the new Sustainable Development Scenario (SDS) to describe a trajectory for emissions
28 consistent with reaching global “net zero” CO₂ emissions by around 2070.²⁶ In 2070 the net zero balance
29 is reached through a compensation of the remaining CO₂-emissions (fossil fuel combustion and
30 industrial processes still lead to around 3 GtCO₂) by a combination of BECCS and to a lesser degree
31 Direct Air Capture and storage. In IEA (2020c) the Faster Innovation Case (FIC) shows a possibility to
32 reach net zero emissions level globally already in 2050, assuming that technology development and
33 market penetration can be significantly accelerated. Innovation plays a major role in this scenario as
34 almost half of all the additional emissions reductions in 2050 relative to the reference case would be
35 from technologies that are in an early stage of development and have not yet reached the market today
36 (IEA 2020c). The most ambitious IEA scenario NZE2050 (IEA 2021a) describes a pathway reaching
37 net zero emissions at system level by 2050. With 0.52 GtCO₂ industry related CO₂-emissions (including
38 process emissions) it ends up 94% below 2018 level in 2050. Remaining emissions in the industry sector
39 have to be compensated by negative emissions (e.g. via DAC).

FOOTNOTE²⁶ Following the description of IEA SDS 2020 would limit the global temperature rise to below 1.8°C with a 66% probability if CO₂ emissions remain at net zero after 2070. If CO₂ emissions were to fall below net zero after 2070, then this would increase the possibility of reaching 1.5°C by the end of the century (IEA 2020c).

1

Table 11.4 Perspectives on industrial sector mitigation potential (comparison of different IEA scenarios)

Reduction of direct CO ₂ emissions	Scenario assumptions ⁱ	IEA (2017, 2020c,i, 2021a)		IEA (2019b)	IEA (2020a,c)	
		2030	2050	2060	2050	2070
Baseline direct emissions from industrial sector						
Reference Technology Scenario (RTS)	Industry sector improvements in energy consumption and CO ₂ emissions are incremental, in line with currently implemented and announced policies and targets.	9.8 GtCO ₂	10.4 GtCO ₂	9.7 GtCO ₂		
Emission reduction potential						
2°C Scenario (2DS)	Assumes the decoupling of production in industry from CO ₂ emissions growth across the sector that would be compatible with limiting the rise in global mean temperature to 2°C by 2100.	-7% vs 2014 ⁱⁱ -20% vs RTS ⁱⁱ	-39% vs 2014 ⁱⁱ -50% vs RTS ⁱⁱ			
Beyond 2°C Scenario (B2DS)	Pushes the available CO ₂ abatement options in industry to their feasible limits in order to aim for the “well below 2°C” target.	-28% vs 2014 -38% vs RTS	-75% vs 2014 -80% vs RTS			
Clean Technology Scenario (CTS)	Strong focus on clean technologies. Energy efficiency and deployment of BATs contribute 46% to cumulative emission reduction in 2018–2060; fuel switch -15%; material efficiency -19%; deployment of innovative processes -20%.			5 Gt CO ₂ or -45% vs 2017 level and -50% from 2060 RTS level		
Sustainable Development Scenario 2020 (SDS 2020)	Leads to net zero emissions globally by 2070. Remaining emissions in some sectors (including industry) in 2070 will be compensated by negative emissions in other areas (e.g. through BECCS and DAC)				~ 4.0	~ 0.6
Net-zero emissions across all sectors	-23% (i.e. 2.1 GtCO ₂) vs. 2018	-94% (i.e. 8.4 GtCO ₂) vs. 2018	Net-zero emissions across all			

Reduction of direct CO ₂ emissions	Scenario assumptions ⁱ	IEA (2017, 2020c,i, 2021a)		IEA (2019b)	IEA (2020a,c)	
		2030	2050	2060	2050	2070
are reached already by 2050.			sectors are reached already by 2050.			
Faster Innovation Case (FIC)	Achieves net zero emissions status already by 2050 based on accelerated development and market penetration of technologies which have currently not yet reached the market.				0.8 Gt CO ₂ (mainly steel and chemical industry)	

1

ⁱ Based on bottom-up technology modelling of five energy-intensive industry subsectors (cement, iron and steel, chemicals and petrochemicals, aluminium and pulp and paper).

ⁱⁱ Industrial direct CO₂ emissions reached 8.3 GtCO₂ in 2014, 24% of global CO₂ emissions.

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1 Two studies complement the discussion of the IEA scenarios and are related to IEA data base.²⁷ The
2 ETC Supply Side scenario builds on the ETP 2017 study, investigating additional emission reduction
3 potentials in the emissions intensive sectors such as heavy industry and heavy-duty transport so as to
4 be able to reach net zero emission by the middle of the century. The LED scenario (Grubler et al. 2018)
5 also builds on the ETP 2017 study, but focuses on the possible potential of very far-reaching efforts to
6 reduce future material demand.

7 A comparison of the different mitigation scenarios shows that they depend on how individual mitigation
8 strategies in the industry sector (see Figure 11.13) are assessed, . The use of CCS for example is in many
9 scenarios assessed as very important, while other scenarios indicate that ambitious mitigation level can
10 be achieved without CCS in the industry sector. CCS plays a major role in the B2DS scenario (3.2
11 GtCO₂ in 2050), the ETC Supply Side scenario (5.4 GtCO₂ in 2050) and the IEA (2020a), IEA (2021a)
12 scenarios (e.g. 2.8 Gt CO₂ in NZE2050 in 2050, roughly one half of the captured CO₂ is related to
13 cement production), while it is explicitly excluded in the LED scenario. In the latter scenario, on the
14 other hand, considerable emission reductions are assumed to be achieved by far-reaching reductions in
15 material demand relative to a baseline development. In other words, the analysed scenarios also suggest
16 that to reach very strong emission reductions from the industry sector either CCS needs to be deployed
17 to a great extent or considerable material demand reductions will need to be realised. Such demand
18 reductions only play a minor role in the 2DS scenario and no role in the ETC Supply Side scenario. The
19 SDS described in IEA (2020a) provides a pathway where both CCS and material efficiency contribute
20 significantly. In SDS material efficiency is a relevant factor in several parts of industry, explicitly steel,
21 cement, and chemicals. Combining the different material efficiency options including to a substantial
22 part lifetime extension (particularly of buildings) leads to 29% less steel production by 2070, 26% less
23 cement production, and 25% less chemicals production respectively in comparison to the reference line
24 used in the study (Stated Policy Scenario: STEPS). Sector or sub-sector specific analysis support the
25 growing role of material efficiency. For the global chemical and petrochemical sector (Saygin and
26 Gielen 2021) point out that circular economy (including recycling) has to cover 16% of the necessary
27 reduction that is need for the implementation of a 1.5°C scenario.

28 In all scenarios, the relevance of biomass and electricity in industrial final energy demand increases,
29 especially in the more ambitious scenarios NZE2050, SDS, ETC Supply Side and LED. While in all
30 scenarios, electrification becomes more and more important hydrogen or hydrogen-derived fuels, on
31 the other hand, do not contribute to industrial final energy demand by the middle of the century in 2DS
32 and B2DS, while LED (1% final energy share in 2050) and particularly ETC supply side (25% final
33 energy share in 2050) consider hydrogen or hydrogen-derived fuels as a significant option. In the
34 updated IEA scenarios hydrogen and hydrogen-based fuels already play a more important role. In the
35 SDS share in industry final energy is around 10% (IEA 2020a) and in the Faster Innovation Case around
36 12% (IEA 2020c) in 2050. In the latter case this is based on the assumption that by 2050 on average
37 each year 22 hydrogen-based steel plants come into operation (IEA 2020c). In SDS around 60% of the
38 hydrogen is produced onsite via water electrolysis while the remaining 40% is generated in fossil fuel
39 plants (methane reforming) coupled with CCS facilities. In the NZE2050 scenario biomass/biomethane
40 (13%/3%), hydrogen (3%), natural gas with CCUS (4%) and coal with CCUS (4%) are responsible for
41 27% of the final energy demand of the sector. This is much more than in 2018, starting here from
42 roughly 6% (only biomass). Direct use of electricity still plays a bigger role in the analysis, as share of

FOOTNOTE²⁷ Several other two global mitigation scenarios (e.g. from Tchung-Ming et al. (2018), Shell Sky Scenario from Shell (2018)) are not included in the following scenario comparison as the study's energy and emission base year data on the industry sector deviates considerably from the other three studies included in the comparison, which all use IEA data. Furthermore, unlike the other studies, Tchung-Ming et al. (2018) do not provide detailed information on the steel, chemicals and concrete sub-sectors. Not included here but worth to be mentioned are many other sector specific studies, for example Napp et al. (2019, 2014), which consider more technologically advanced decarbonisation routes for the sector.

1 electricity increases in NZE2050 from 22% in 2018 to 28% in 2030 and 46% in 2050 (in 2050 with
2 15% a part of the electricity is used to produce hydrogen). This is reflecting the effect that since
3 publication of older IEA reports more direct electric applications for the sector become available. In
4 NZE2050 approx. 25% of total heat used in the sector is electrified directly with heat pumps or
5 indirectly with synthetic fuels already by 2030.

6 For B2DS it is assumed that most of the available abatement options in the industry sector are pushed
7 to their feasible limits. That leads to cumulative direct CO₂ emissions reductions compared to 2DS
8 which come from: energy efficiency improvements and BAT deployment (42%), innovative processes
9 and CCS (37%), switching to lower carbon fuels and feedstocks (13%) and material efficiency strategies
10 in manufacturing processes (8%). Energy efficiency improvements are particular important in the first
11 time period.

12 IEA World Energy Outlook indicates energy efficiency improvement in the 2020-2030 period as major
13 basis to switch from STEPS (stated policies) to the SDS (net zero emissions by 2070) pathway (IEA
14 2020i, 2021c). For many energy-intensive industries annual efficiency gains have to be almost doubled
15 (e.g., from 0.6% yr⁻¹ to 1.0 % yr⁻¹ for cement production) to contribute sufficiently to the overall goal.
16 If net zero CO₂-emissions should be achieved already by 2050 as pursued in the NZE2050 scenario IEA
17 (2020i) and (2021c) further accelerating energy efficiency improvements are necessary (e.g., for cement
18 annual efficiency gains of 1.75%) leading to the effect, that in 2030 many processes are implemented
19 closely to their technological limits. In total, sector final energy demand can be held nearly constant at
20 2018 level until 2050 and decoupled from product demand growth

21 The comparative analysis leads to the point that the relevance of individual mitigation strategies in
22 different scenarios depends not only on a scenario's level of ambition. Instead, implicit or explicit
23 assumptions about: a) the costs associated with each strategy, b) future technological progress and
24 availability of individual technologies and c) the future public or political acceptance of individual
25 strategies are likely to be main reasons for the observed differences between the analysed scenarios. For
26 many energy-intensive products technologies capable of deep emission cuts are already available. Their
27 application is subject to different economic and resources constrains (incremental investments needs,
28 products prices escalation, requirements for escalation of new low carbon power generation). To fully
29 exploit potential availability of carbon-free energy sources (e.g., electricity or hydrogen and related
30 derivatives) is a fundamental prerequisite and marks the strong interdependencies between the industry
31 and the energy sector.

32 Assessment of the scenario literature allows to conclude that under specific conditions strong CO₂
33 emission reductions in the industry sector by 2050–2070 and even net zero emission pathways are
34 possible. However, there is no consensus on the most plausible or most desirable mix of key mitigation
35 strategies to be pursued. In addition it has to be stressed that suitable pathways are very country-specific
36 and depend on the economic structure, resource potentials, technological competences, and political
37 preferences and processes of the country or region in question (Bataille 2020a).

38 There is a consensus among the scenarios that a significant shift is needed from a transition process in
39 the past mainly based on marginal (incremental) changes (with a strong focus on energy efficiency
40 efforts) to a one based on transformational change. To limit the barriers that are associated with
41 transformational change, besides overcoming the valley of death for technologies or processes with
42 breakthrough character, it is required to carefully identify structural change processes which are
43 connected with substantial changes of the existing system (including the whole process chain). This has
44 to be done at an early stage and has to be linked with considerations about preparatory measures which
45 are able to flank the changes and to foster the establishment of new structures (Section 11.6). The right
46 sequencing of the various mitigation options and building appropriate bridges between the different
47 strategies are important. Rissman et al. (2020) proposes three phases of technologies deployment for
48 the industry sector: (1) energy/material efficiency improvement (mainly incremental) and electrification

1 in combination with demonstration projects for new technologies potentially important in subsequent
2 phases (2020-2035), (2) structural shifts based on technologies which reach maturity in phase (1) such
3 as CCS and alternative materials (2035-2050) (3) widespread deployment for technologies that are
4 nascent today like molten oxide electrolysis based steel making. There are no strong boundaries
5 between the different phases and all phases have to be accompanied by effective policies like R&D
6 programs and market pull incentives.

7 Taking the steel sector as an illustrative example, sector specific scenarios examining the possibility to
8 reach GHG reduction beyond 80% (CAT 2020; IEA 2021a; Vogl et al. 2021b; Bataille et al. 2021b)
9 indicate that robust measures comprise direct reduction of iron (DRI) with hydrogen in combination
10 with efforts to further close the loops and increase availability of scrap metal (reducing the demand for
11 primary steel). As hydrogen based DRI might not be a fully mature technology before 2030 (depending
12 on further developments of the policy framework and technological progress), risk of path dependencies
13 has to be taken into consideration when reinvestments in existing production capacities will be required
14 in the coming years. For existing plants, implementation of energy efficiency measures (e.g. utilization
15 of waste heat, improvement of high temperature pumps) could build a bridge for further mitigation
16 measures, but have only limited unexhausted potential. As many GHG mitigation measures are
17 associated with high investment costs and missing operating experience, a step by step implementing
18 process might be an appropriate strategy to avoid investment leakage (given the mostly long operation
19 times, investment cycles have to be used so as not to miss opportunities) and to gain experience. In the
20 case of steel, companies can start with the integration of a natural gas based direct reduced iron furnace
21 feeding the reduced iron to an existing blast furnace, blending and later replacing the natural gas by
22 hydrogen in a second stage, and later transitioning to a full hydrogen DRI EAF or molten oxide
23 electrolysis EAF, all without disturbing the local upstream and downstream supply chains.

24 It is worth mentioning the flexibility of implementing transformational changes not the least depends
25 on the age profile and projected longevity of existing capital stock, especially the willingness to accept
26 the intentional or market-based stranding of high GHG intensity investments. This is a relevant aspect
27 in all producing countries, but particularly in those countries with a rather young industry structure (i.e.
28 comparative low age of existing facilities on average). Tong et al. (2019) suggest that in China using
29 the survival rate as a proxy less than 10% of existing cement or steel production facilities will reach
30 their end of operation time by 2050. Vogl et al. (2021b) argue that the mean blast furnace campaign is
31 considerably shorter than used in Tong et al (2019), at only 17 years between furnace relining, which
32 suggests there is more room for retrofitting with clean steel major process technologies than generally
33 assumed. Bataille et al. (2021b) found if very low carbon intensity processes were mandatory starting
34 in 2025, given the lifetimes of existing facilities, major steel process lifetimes of up to 27 years would
35 still make a full retrofit cycle with low carbon processes possible.

36 In general, early adoption of new technologies plays a major role. Considering the long operation time
37 (lifetime) of industrial facilities (e.g., steel mills, cement kilns) early adoption of new technologies is
38 needed to avoid lock-in. For the SDS 2020 scenario, IEA (2020h) calculated the potential cumulative
39 reduction of CO₂-emissions from the steel, cement and chemicals sector to be around 57 GtCO₂ if
40 production technology is changed at its first mandatory retrofit, typically 25 years, rather than at 40
41 years (typical retrofitted lifetime) (Figure 11.13). Net zero pathways require that the new facilities are
42 based on zero- or near zero emissions technologies from 2030 onwards (IEA 2021c).

43 Another important finding is that material efficiency and demand management are still not well
44 represented in the scenario literature. Besides IEA (2020a) two of the few exceptions are Material
45 Economics (2019) for the EU and Zhou et al. (2019) for China. Zhou et al. (2019) describe a consistent
46 mitigation pathway (Reinventing Fire scenario) for China where in 2050 CO₂-emissions are at a level
47 42% below 2010 emissions. Around 13% of the reduction is related to less material demand, mainly
48 based on extension of building and infrastructure lifetime as well as reduction of material losses in the

1 production process and application of higher quality materials particularly high-quality cement (Zhou
2 et al. 2019). For buildings and cars, Pauliuk et al. (2021) analyzed the potential role of material
3 efficiency and demand management strategies on material demand to be covered by the industry sector.

4 For the three most important sub-sectors in industry Table 11.5 shows results from Material Economics
5 (2019) for the EU. The combination of circularity, material and energy efficiency, fossil and waste fuels
6 mix, electrification, hydrogen, and biomass use varies from scenario to scenario with no of these options
7 ignored. On the contrary, for CCS the authors set a strong default - in all scenarios CCS is not included
8 as a mitigation option. Scenario studies for Germany Samadi and Barthel (2020) support the Material
9 Economics (2019) findings and show deep mitigation s and even net zero emissions can be reached
10 without application of CCS and with limited contribution of synthetic carbon neutral fuels. In those
11 scenarios there are large contributions from material efficiency, circular economy, material substitution
12 as well as life-style changes.

13
14 **Table 11.5 Contribution to emission reduction of different mitigation strategies for net zero emission**
15 **pathways (range represents three different pathways for the industry sector in Europe; each related**
16 **scenario focus on different key strategies)²⁸**

	Steel	Plastics	Ammonia	Cement
	Contribution to emission reduction (%) (range represents the three different pathways of the study)			
Circularity	5–27	7–27		10–44
Energy efficiency	5–23	2–9		1–5
Fossil fuels and waste fuels	9–41	0–27		0–51
Decarbonised electricity	36–59	16–22		29–71
Biomass for fuel or feedstock	5–9	18–22		0–9
End-of-life plastic		16–35		
	Required electrification level			
Growth of electricity demand (times compared with 2015)	3–5	3–4		2–5
	Investments and production costs escalation			
Investment needs growth (% versus BAU)	25–65	122–199	6–26	22–49
Cost of production (% versus BAU)	2–20	20–43	15–111	70–115

17 Source: Material Economics (2019).
18

19 The analysis of net zero emission pathways require significantly higher investments compared to
20 business as usual (BAU), 25% to 65% for steel, 6–26% for Ammonia, 22–49% for cement and with
21 122–199% the highest number for plastics (Material Economics 2019).

22 While sector specific cost analysis are rare in general, there are scenarios indicating that pathways to
23 net zero CO₂ emissions in the emissions intensive sectors can be realized with limited additional costs.
24 According to Energy Transitions Commission (2018) deep decarbonization from four major industry
25 subsectors (plastics, steel, aluminium and cement) is achievable on a global level with cumulative
26 incremental capital investments (2015–2050) limited to about 0.1% of aggregate GDP over that period.
27 UKCCC (2019a) assesses that total incremental costs (compared to a theoretical scenario with no
28 climate change policy action at all) for cutting industrial emissions by 90% by 2050 is 0.2% of expected
29 2050 UK GDP (UKCCC 2019a). The additional investment is 0.2% of gross fixed capital formation
30 (Material Economics 2019). The IEA (2020a) indicates the required annual incremental global
31 investment in heavy industry is approximately 40 billion 2019 USD yr⁻¹ moving from (STEPS) to the

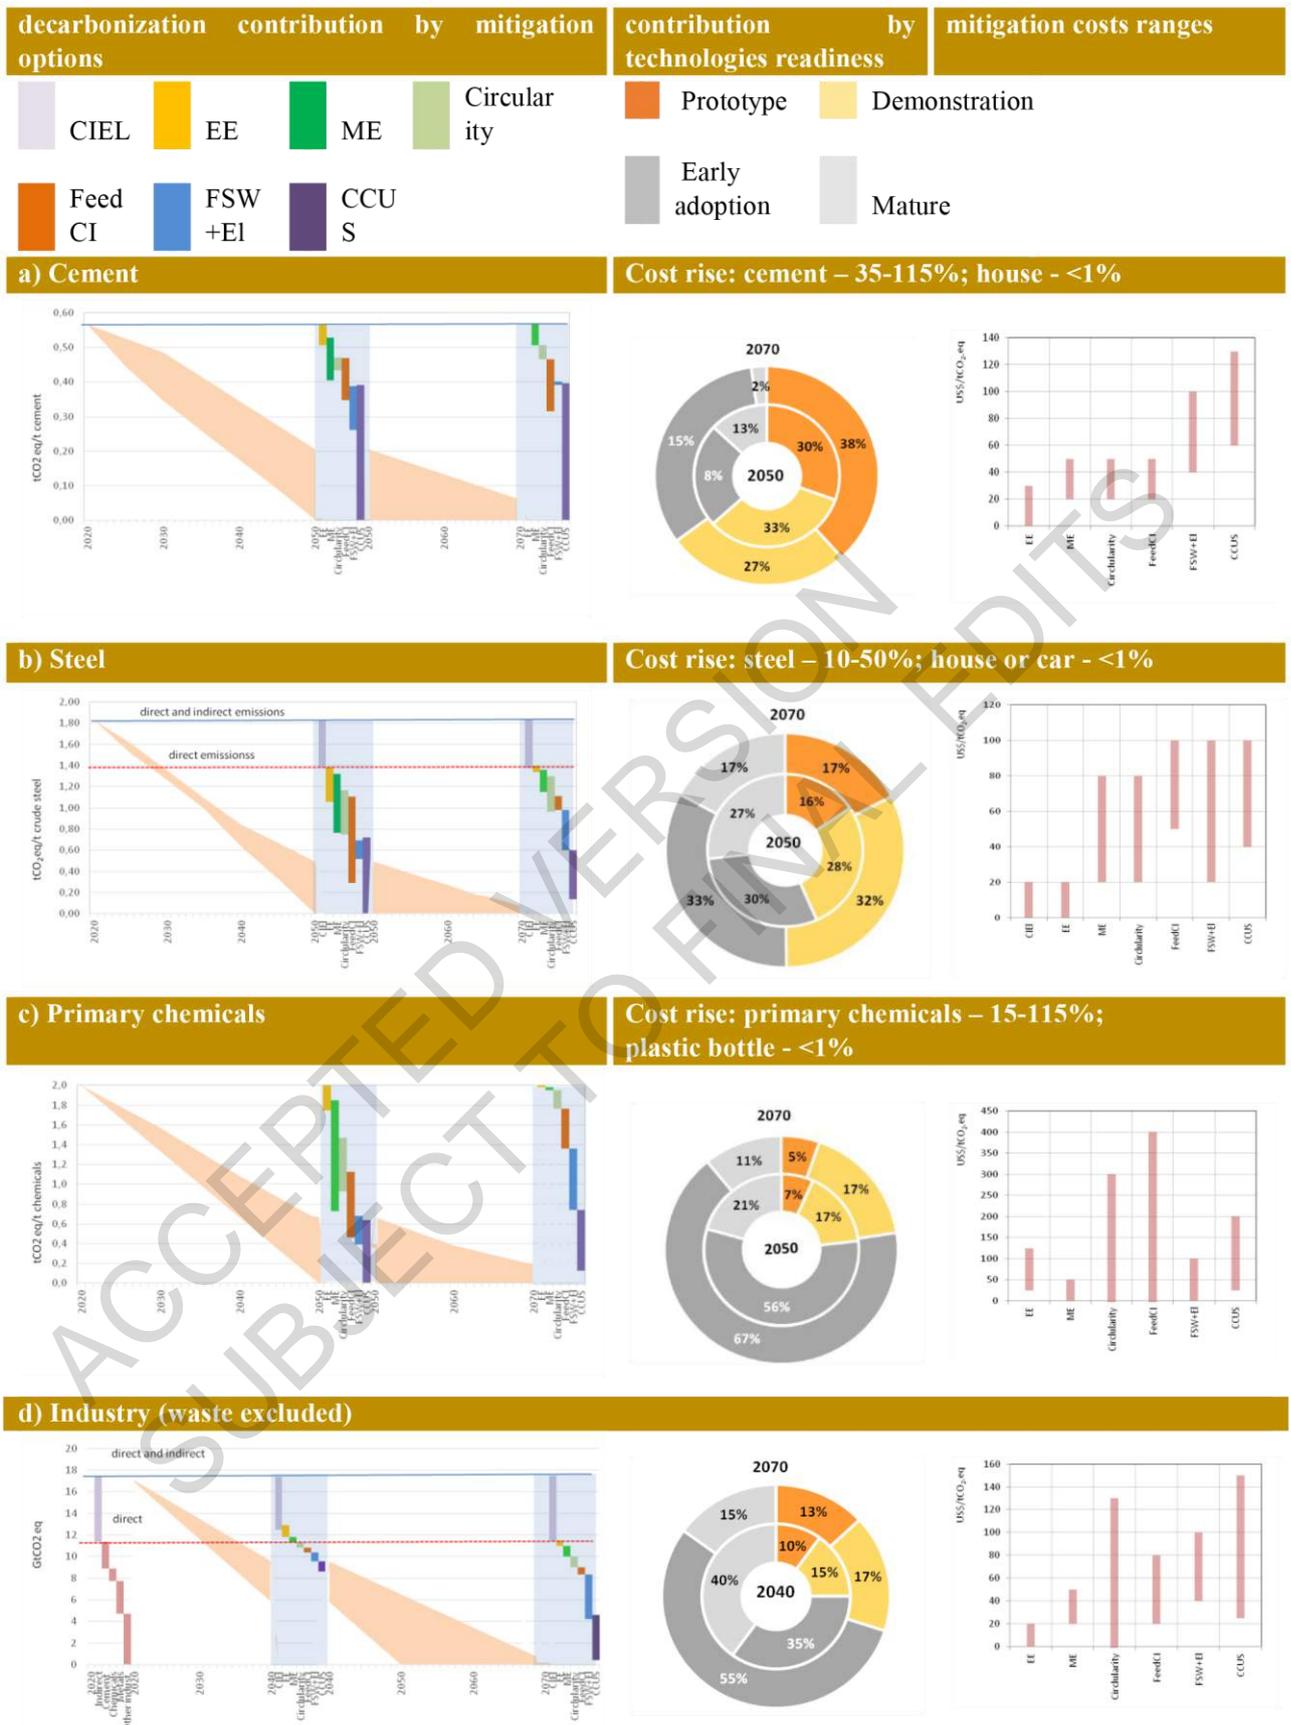

FOOTNOTE²⁸ Note: In the described scenarios CCS was not taken into consideration as a mitigation option by the authors.

1 SDS scenario (2020–2040), rising to 55 billion USD yr⁻¹ (2040–2070), effectively 0.05-0.07% of global
2 annual GDP today.

3 Finally, a new literature is emerging, based on the new sectoral electrification, hydrogen and CCS based
4 technologies listed in previous sections, considering the possibility of rearranging standard supply and
5 process chains using regional and international trade in intermediate materials like primary iron, clinker
6 and chemical feedstocks, to reduce global emissions by moving production of these materials to regions
7 with large and inexpensive renewable energy potential or CCS geology (Gielen et al. 2020; Bataille et
8 al. 2021a; Saygin and Gielen 2021; Bataille 2020a)

9 In a sequence of sectoral and industry wide figures below (Figure 11.13), it is shown - starting in the
10 present on the left and moving through 2050 to 2070 on the right, how much separate mitigation
11 strategies can contribute and how they are integrated in the literature to reach near zero emissions. For
12 cement, steel and primary chemicals GHG intensities are presented, and for all industry absolute GHG
13 emissions are displayed. Effects of the following mitigation strategies are reflected: energy efficiency,
14 material efficiency, circularity/recycling, feedstock carbon intensity, fuel switching, CCU and CCS.
15 Contributions of technologies split by their readiness for 2050 and 2070 are provided along with ranges
16 of mitigation costs for achieving near zero emissions for each strategy, accompanied by ranges of
17 associated basic materials costs escalations and driven by these final products prices increments.

Figure 11.13 Potentials and costs for zero-carbon mitigation options for industry and basic materials *CIEL* –carbon intensity of electricity for indirect emissions; *EE* – energy efficiency; *ME* – material efficiency; *Circularity* - material flows (clinker substituted by coal fly ash, blast furnace slag or other by-products)

1 and waste, steel scrap, plastic recycling, etc.); *FeedCI* – feedstock carbon intensity (hydrogen, biomass,
2 novel cement, natural clinker substitutes); *FSW+El* – fuel switch and processes electrification with low
3 carbon electricity. Ranges for mitigation options are shown based on bottom-up studies for grouped
4 technologies packages, not for single technologies. In circles contribution to mitigation from technologies
5 based on their readiness are shown for 2050 (2040) and 2070. Direct emissions include fuel combustion
6 and process emissions. Indirect emissions include emissions attributed to consumed electricity and
7 purchased heat. For basic chemicals only methanol, ammonia and high-value chemicals are considered.
8 Total for industry doesn't include emissions from waste. Base values for 2020 for direct and indirect
9 emissions were calculated using 2019 GHG emission data (Crippa et al. 2021) and data for materials
10 production from World Steel Association (2020a) and IEA (2021d). Negative mitigation costs for some
11 options like Circularity are not reflected.

16 2021a).

18 11.4.3 Cross sectorial interactions and societal pressure on industry

19 Mitigation involves greater integration and coupling between sectors. This is widely recognised for
20 example in the case of electrification of transport (see 6.6.2 and 10.3.1) but it has been less explored for
21 industrial decarbonisation. Industry is a complex web of sub-sectors and intersectoral interaction and
22 dependence, with associated mitigation opportunities and co-benefits and costs (OECD 2019b; Mendez-
23 Alva et al. 2021). Implementation of the mitigation options assessed in 11.3 will result in new sectoral
24 couplings, value chains, and business models but also in phasing-out of old ones. Notably,
25 electrification in industry, hydrogen and sourcing of non-fossil carbon involves profound changes to
26 how industry interacts with electricity systems and how industrial sub-sectors interact. For example, the
27 chemicals and forestry industries will become much more coupled if various forms of biogenic carbon
28 become an important feedstock for plastics (Figure 11.10). Clinker substitution with blast furnace slag
29 in the cement industry is well established way of reducing CO₂ emissions (Fechner and Kray 2012) but
30 this slag will no longer be available if blast furnaces are phased-out. Furthermore, additional material
31 demand resulting from mitigation in other sectors, as well as adaptation, and the importance of material
32 efficiency improvements are issues that has attracted increasing attention since AR5 (Hertwich et al.
33 2020; IEA 2019b; Bleischwitz 2020). How future material will be affected under different climate
34 scenarios is underexplored and typically not accounted for in modelling (Bataille et al. 2021a).

35 Using industrial waste heat for space heating, via district heating, is an established practice that still has
36 a large potential with large quantities of low-grade heat being wasted (Fang et al. 2015). For Denmark
37 it is estimated that 5.1% of district heating demand could be met with waste heat (Bühler et al. 2017)
38 and for four towns studied in Austria 3-35% of total heat demand could be met (Karner et al. 2016). A
39 European study shows that temporal heat demand flexibility could allow for up to 100% utilization of
40 excess heat from industry (Karner et al. 2018). A study of a Swedish chemicals complex estimated that
41 30-50% of excess heat generated on-site could be recovered with payback periods below 3 years
42 (Eriksson et al. 2018).

43 A European study found that most of the industrial symbiosis or clustering synergies today are in the
44 chemicals sector with shared streams of energy, water, and carbon dioxide (Mendez-Alva et al. 2021).
45 For future mitigation the UKCCC (2019b) finds that industrial clustering may be essential for achieving
46 the necessary efficiencies of scale and to build the infrastructure needed for industrial electrification;
47 carbon capture, transport and disposal; hydrogen production and storage, heat cascading between
48 industries and to other potential heat users (e.g. residential and commercial buildings).

1 With increasing shares of renewable electricity production there is a growing interest in industrial
2 demand response, storage and hybrid solutions with on-site PV and CHP (Schriever and Halstrup 2018;
3 Scheubel et al. 2017; Shoreh et al. 2016). With future industrial electrification, and in particular with
4 hydrogen used as reduction agent in ironmaking or as feedstock in the chemicals industry, the level of
5 interaction between industry and power systems becomes very high. Large amounts of coking coal, or
6 oil and gas as petrochemical energy and feedstock, are then replaced by electricity. For example, Meys
7 et al. (2021) estimates a staggering future electricity demand of 10,000 TWh in a scenario for a net zero
8 emissions plastics production of 1100 Mt in 2050 (see 11.3.5 for other estimates of electricity demand).
9 Much of this electricity is used to produce hydrogen to allow for CCU and this provides a very large
10 potential flexible demand if electrolysers are combined with hydrogen storage. Vogl et al. (2018)
11 describe how hydrogen DRI and EAF steel plants can be highly flexible in their electricity demand by
12 storing hydrogen or hot-briquetted iron and increasing the share of scrap in EAF. The IEA (2019f)
13 Future of Hydrogen report suggests that hydrogen production and storage networks could be in locations
14 with already existing hydrogen production and storage, for example, chemical industries, and that these
15 could be ideal for system load balancing and demand response, and in case of district heating systems
16 - for heat cascading.

17 The climate awareness that investors, shareholders, and customers demand from companies has been
18 increasing steadily. It is reflected in growing number of environmental management, carbon footprint
19 accounting, benchmarking and reporting schemes (e.g., the Carbon Disclosure Project, Task Force on
20 Climate-Related Financial Disclosures, Environmental Product Declarations and others, e.g., Qian et al.
21 (2018)) requiring companies to disclose both direct and indirect GHG emissions, and creating explicit
22 (for regulatory schemes) as well as implicit GHG liabilities. This requires harmonised and widely
23 accepted methods for environmental and carbon footprint accounting (Bashmakov et al. 2021b). From
24 an investor perspective there are both physical risks (e.g., potential damages from climate change to
25 business) and transition risks (e.g., premature devaluation of assets driven by new policies and
26 technologies deployment and changes in public and private consumer preferences (NGFS 2019a)).
27 Accompanied by reputational risks this leads to increased attention to Sustainable and Responsible
28 Investment (SRI) principles and increased demands from investors, consumers and governments on
29 climate and sustainability reporting and disclosure (NGFS 2019b). For example, Japan's Keidanren
30 promotes a scheme by different each industries to reduce GHG through the global value chain, including
31 material procurement, product use stages, and disposal, regardless of geographical origin, with provided
32 quantitative visualization (Keidanren (Japan Business Federation) 2018). EU adopted a non-financial
33 disclosure Directive in 2014 (Kinderman 2020) and a Taxonomy for Sustainable Finance in 2019 (see
34 also 15.6.1).

35

36 **11.4.4 Links to climate change, mitigation, adaptation**

37 Sectors that are particularly vulnerable to climate change include agriculture, forestry, fisheries and
38 aquaculture, and their downstream processing industries (Bezner et al. 2021). Many of the energy
39 intensive industries are located based on access to fresh water (e.g., pulp and paper) or sea transport
40 (e.g., petrochemicals). Risks of major concern for industry include disrupted supply chains and energy
41 supplies due to extreme weather events, as well as risks associated with droughts, floods with dirty
42 water, sea level rise and storm surges (Dodman et al. 2021). Adaptation measures may in turn affect the
43 demand for basic materials (e.g., steel and cement), for example, increased demand to build sea walls
44 and protect infrastructure, but we have not found any estimates of the potential demand. Increased heat
45 stress is unsafe for outdoor labourers and can reduce worker productivity, for example, in outdoor
46 construction, resource extraction and waste handling (Ranasinghe et al. 2021).

47

1 **11.5 Industrial infrastructure, policy, and SDG contexts**

2 **11.5.1 Existing industry infrastructures**

3 Countries are at different stages of different economic development paths. Some are already
4 industrialised, while developing and emerging economies are on earlier take-off stages or accelerated
5 growth stages and have yet to build the basic infrastructure needed to allow for basic mobility, housing,
6 sanitation, and other services (see 11.2.3). The available in-use stock of material per capita and in each
7 country therefore differs significantly, and transition pathways will require a different mix of strategies,
8 depending on each country's material demand to build, maintain, and operate stock of long-lived assets.
9 Industrialised economies have much greater opportunities for reusing and recycling materials, while
10 emerging economies have greater opportunities to avoid carbon lock-in. The IEA projected that more
11 than 90% of the additional 2050 production of key materials will originate in non-OECD countries (IEA
12 2017). As incomes rise in emerging economies, the industry sector will grow in tandem to meet the
13 increased demand for the manufactured goods and raw materials essential for infrastructure
14 development. The energy and feedstocks needed to support this growth is likely to constitute a large
15 portion of the increase in the emerging economies' GHG emissions in the future unless new low carbon
16 pathways are identified and promoted.

17 Emissions are typically categorised by the territory, sub-sector or group of technologies from which
18 they emanate. An alternative sub-division is that between existing sources that will continue to generate
19 emissions in the future, and those that are yet to be built (Erickson et al. 2015). The rate of emissions
20 from existing assets will eventually tend to zero, but in a timeframe that is relevant to existing climate
21 and energy goals, the cumulative contribution to emissions from existing infrastructure and equipment
22 is likely to be substantial. Aside from the magnitude of the contribution, the distinction between
23 emissions from existing and forthcoming assets is instructive because of the difference in approach to
24 mitigation that may be necessary or desirable in each instance to avoid getting locked into decades of
25 highly carbon-intensive operations (Lecocq and Shalizi 2014).

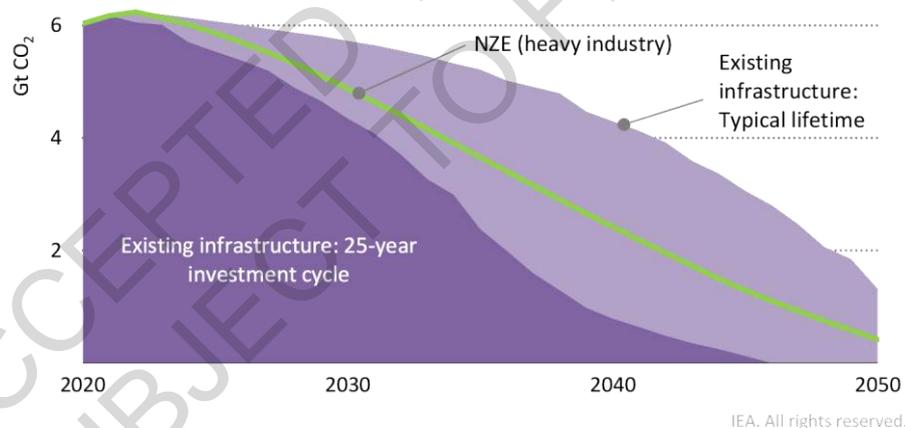

26 Details of the methodologies to assess 'carbon lock-in' or 'committed emissions' differ across studies
27 but the core components of the approaches adopted are common to each: an account of the existing
28 level of emissions for the scope being assessed is established; this level is projected forward with a
29 stylised decay function that is informed by assessments of the current age and typical lifetimes of the
30 underlying assets. From this, a cumulative emissions estimate is calculated. The future emissions
31 intensity of the operated assets is usually assumed to remain constant, implying that nothing is done to
32 retrofit with mitigating technologies (e.g., carbon capture) or alter the way in which the plant is operated
33 (e.g. switching to an alternative fuel or feedstock). While the quantities of emissions derived are often
34 referred to as 'committed' or 'locked-in', their occurrence is of course dependent on a suite of economic,
35 technology and policy developments that are highly uncertain.

36 Data on the current age profile and typical lifetimes of emissions-intensive industrial equipment are
37 difficult to procure and verify and most of the studies conducted in this area contain little detail on the
38 global industrial sector. Two recent studies are exceptions, both of which cover the global energy
39 system, but contain detailed and novel analysis on the industrial sector (Tong et al. 2019; IEA 2020a).
40 Tong et al. (2019) use unpublished unit-level data from China's Ministry of Ecology and Environment
41 to obtain a more robust estimate of the age profile of existing capacity in the cement and iron and steel
42 sectors in the country. The IEA (2020a) uses proprietary global capacity datasets for the iron and steel,
43 cement and chemicals sectors, and historic energy consumption data for the remaining industry sectors
44 as a proxy for the rate of historic capacity build-up.

45 Both studies come to similar estimates on the average age of cement plants and blast furnaces in China
46 of around 10-12 years old, which are the figures for which they have overlapping coverage. Both studies

1 also use the same assumption of the typical lifetime of assets in these sectors of 40 years, whereas the
2 IEA (2020a) study uses 30 years for chemical sector assets and 25 years for other industrial sectors. The
3 studies come to differing estimates of cumulative emissions by 2050 from the industry sector; 196
4 GtCO₂ in the IEA (2020a) study, and 162 GtCO₂ in the Tong et al. (2019) study. This difference is
5 attributable to a differing scope of emissions, with the IEA (2020a) study including industrial process
6 emissions (which for the cement sector in particular are substantial) in addition to the energy-related
7 emissions quantities accounted for in the Tong et al. (2019) study. After correcting for this difference
8 in scope, the emissions estimates compare favourably.

9 The IEA (2020a) study provides supplementary analysis for the industry sector, examining the impact
10 of considering investment cycles alongside the typical lifetimes assumed in its core analysis of
11 emissions from existing industrial assets. For three heavy industry sectors – iron and steel, cement and
12 chemicals – the decay function applied to emissions from existing assets is re-simulated using a 25-year
13 investment cycle assumption (Figure 11.14). This is 15 years shorter than the typical lifetimes assumed
14 for assets in the iron and steel and cement sectors, and 5 years shorter than that considered for the
15 chemical sector. The shorter timeframe for the investment cycle is a simplified way of representing the
16 intermediate investments that are made to extend the life of a plant, such as the re-lining of a blast
17 furnace, which can occur multiple times during the lifetime of an installation. These investments can
18 often be similar in magnitude to that of replacing the installation, and they represent key points for
19 intervention to reduce emissions. The findings of this supplementary analysis are that around 40%, or
20 60 GtCO₂, could be avoided by 2050 if near-zero emissions options are available to replace this
21 capacity, or units are retired, retro-fitted or refurbished in a way that significantly mitigates emissions
22 (e.g. retro-fitting carbon capture, or fuel or process switching to utilise bioenergy or low-carbon
23 hydrogen).

25
26 **Figure 11.14 CO₂ emissions from existing heavy industrial assets in the NZE**

27 Source: IEA (2021a).

28
29 As this review was being finalized several papers were released that somewhat contradict the Tong et
30 al (2010) results (Vogl et al. 2021b; Bataille et al. 2021b). Broadly speaking, these papers argue that
31 while high emitting facilities may last for long time, be difficult to shut down early, and are inherent to
32 local boarder supply chains, individual major processes that are currently highly GHG intense, such as
33 blast furnaces and basic oxygen smelters, could be retired and replaced during major retrofits on much
34 shorter time cycles of 15–25 years.

1 The cost of retrofitting or retiring a plant before the end of its lifetime depends on plant specific
2 conditions as well as a range of economic, technology and policy developments. For industrial
3 decarbonisation it may be a greater challenge to accelerate the development and deployment of zero
4 emission technologies and systems than to handle the economic costs of retiring existing assets before
5 end of life. The ‘lock-in’ also goes beyond the lifetime of key process units, such as blast furnaces and
6 crackers, since they are typically part of large integrated plants or clusters with industrial symbiosis, as
7 well as infrastructures with feedstock storage, ports, and pipelines. Individual industrial plants are often
8 just a small part of a complex network of many facilities in an industrial supply chain. In that sense,
9 current assessments of ‘carbon lock-in’ rely on simplifications due to the high the complexity of
10 industry.

11 Conditions are also sub-sector and context specific in terms of mitigation options, industry structures,
12 markets, value chains and geographical location. For example, the hydrogen steelmaking joint venture
13 in Sweden involves three different companies headquartered in Sweden (in mining, electricity and
14 steelmaking, respectively), two of which are state owned, with a shared vision and access to iron ore,
15 fossil-free electricity and high-end steel markets (Kushnir et al. 2020). In contrast, chemical clusters
16 may consist of several organisations that are subsidiaries to large multinational corporations with
17 headquarters across the world, that also compete in different markets. Even in the presence of a local
18 vision for sustainability this makes it difficult to engage in formalised collaboration or get support from
19 headquarters (Bauer and Fuenfschilling 2019).

20 Furthermore, it is relevant to consider also institutional and behavioural lock-in (Seto et al. 2016). On
21 one side, existing high-emitting practices may be favoured through formal and informal institutions
22 (e.g., regulations and social norms or expectations, respectively), for example around building
23 construction and food packaging. On the other side, mitigation options may face corresponding
24 institutional barriers. Examples include how cars are conventionally scrapped (i.e., crushed, leading to
25 copper contamination of steel) rather than being dismantled, or slow permitting procedures for new
26 infrastructure and industrial installations for reducing emissions.

27

28 **11.5.2 Current industrial and broader policy context**

29 The basic motivation for industrial policy historically has been economic development and wealth
30 creation. Industrial policy can be progressive and promote new developments or be protective to help
31 infant or declining industries. It may also involve the phase-out of industries, including efforts to retrain
32 workers and create new jobs. Industrial policy is not one policy intervention but rather the combined
33 effects of many policy instruments that are coordinated towards an industrial goal. Industrial policies
34 can be classified as being either vertical or horizontal depending on whether singular sectors or
35 technologies are targeted (e.g., through R&D, tariffs and subsidies) or the whole economy (e.g.,
36 education, infrastructure, and general tax policies). The horizontal policies are not always thought of as
37 industrial policy although taking a broad view, including policy coordination and institution building,
38 is important for industrial policy to be effective (see e.g., Andreoni and Chang (2019)).

39 In the past ten years there has been increasing interest and attention to industrial policy. One driver is
40 the desire to retain industry or re-industrialise in regions within Europe and North America where
41 industry has a long record of declining shares of GDP. The need for economic growth and poverty
42 eradication is a key driver in developing countries. An important aspect is the need to meet the “dual
43 challenge of creating wealth for a growing population while staying within planetary boundaries”
44 (Altenburg and Assman 2017). The need for industrial policy that supports environmental goals and
45 green growth has been analysed by Rodrik (2014); Aiginger (2014); Warwick (2013) and Busch et al.
46 (2018). Similar ideas are taken up in OECD reports on green growth (OECD 2011) and system
47 innovation (OECD 2015). However, these approaches to green industrial policy and innovation tend to

1 focus on opportunities for manufacturing industries to develop through new markets for cleaner
2 technologies. They rarely include explicit attention to the necessity of zero emissions and the profound
3 changes in production, use and recycling of basic materials that this entails. This may also involve the
4 phase-out or repurposing of industries that currently rely on fossil fuels and feedstock.

5 The policy implications of zero emissions for heavy industries are relatively unexplored although some
6 analyses in this direction are available (e.g., (Wesseling et al. 2017; Philibert 2017a; Wyns et al. 2019;
7 Fan and Friedmann 2021; Åhman et al. 2017; Bataille 2020a; Bataille et al. 2018a)). For industry, there
8 has been a long time focus on energy efficiency policies through voluntary and negotiated agreements,
9 energy management and audit schemes, and various programs targeting industry (Fischedick et al.
10 2014a). Since AR5, interest in circular economy policies has increased and they have become more
11 prevalent across regions and countries, including EU, China, U.S., Japan and Brazil (e.g. (McDowall et
12 al. 2017; Ranta et al. 2018; Geng et al. 2019)). For electrification and CCUS, efforts are nascent and
13 mainly focused on technology development and demonstrations. Policies for demand reduction and
14 materials efficiency are still relatively unexplored (e.g., Pollitt et al. (2020) and IEA (2019b)). Since
15 zero emissions in industry is a new governance challenge it will be important to build awareness and
16 institutional capacity in industrialised as well as developing countries.

17 In the context of climate change policy, it is fair to say that industry has so far been sheltered from the
18 increasing costs that decarbonisation may entail. This is particularly true for the energy and emissions
19 intensive industries where cost increases and lost competitiveness may lead to carbon leakage, i.e., that
20 industry relocates to regions with less stringent climate policies. Heavy industries typically pay no or
21 very low energy taxes and where carbon pricing exists (e.g., in the European Trading Scheme) they are
22 sheltered through free allocation of emission permits and potentially compensated for resulting
23 electricity price increases. For example, Okereke and McDaniels (2012) shows how the European steel
24 industry was successful in avoiding cost increases and how information asymmetry in the policy process
25 was important for that purpose.

27 **11.5.3 Co-benefits of Mitigation Strategies and SDGs**

28 The deployment of climate change mitigation strategies is primarily influenced by its costs and
29 potential, but also by other broader sustainable development factors such as the SDGs. Mitigation
30 actions therefore are to be considered through the prism of impacts on achieving other economic, social
31 and environmental goals. Those impacts are classified as co-benefits when they are positive or as risk
32 when they are negative. Co-benefits can serve as additional drivers, while risks can inhibit the
33 deployment of available mitigation options. Actions taken to mitigate climate change have direct and
34 indirect interactions with SDGs, both positive (synergies) or negative (trade-off) (Fuso Nerini et al.
35 2019).

36 Given the wide range of stakeholders involved in climate actions and their (often contradictory) interests
37 and priorities, the nature of co-benefits and risk can affect decision-making processes and behaviour of
38 stakeholders (Labella et al. 2020). Co-benefits form an important driver supporting the adoption of
39 mitigation strategies, yet are commonly overlooked in policymaking. Karlsson et al. (2020), based on a
40 review of 239 peer-reviewed articles concluded that diverse co-benefit categories, including air, soil
41 and water quality, diet, physical activity, biodiversity, economic performance, and energy security, are
42 prevalent in the literature.

44 **11.5.3.1 SDGs co-Benefits through Material Efficiency and Demand Reduction**

45 Material efficiency, an important mitigation option (SDG 13 - Climate action) for heavy industries, is
46 yet to be fully acknowledged and leveraged (Gonzalez Hernandez et al. 2018a; Sudmant et al. 2018;

1 Dawkins et al. 2019). Material efficiency directly address SDG 12 (Responsible production and
2 consumption) but also provide opportunities to reduce the pressures and impacts on environmental
3 systems (SDG 6 – Clean water and sanitation) (Olivetti and Cullen 2018). Exploiting material efficiency
4 usually requires new business models and provides potential co-benefits of increased employment and
5 economic opportunities (SDG 8 - Decent work and economic growth).

6 Material efficiency also provides co-benefits through infrastructural development (SDG 9 – Industry,
7 innovation and infrastructure) (Mathews et al. 2018) to support the wide range of potential material
8 efficiency strategies including light-weighting, re-using, re-manufacturing, recycling, diverting scrap,
9 extending product lives, using products more intensely, improving process yields, and substituting
10 materials (Allwood et al. 2011). Worrell et al. (2016) also emphasises how material efficiency
11 improvements, in addition to limiting the impacts of climate change help deliver sustainable production
12 and consumption co-benefits through environmental stewardship. Binder and Blankenberg (2017) and
13 Dhandra (2019) show that sustainable consumption is positively related to life satisfaction and
14 subjective well-being (SDG 3) and Guillen-Royo (2019) adds positive association with happiness and
15 life satisfaction.

16 The reduction in excessive consumption and demand for products and services generates a reduction in
17 post-consumption waste and so enhances clear water and sanitation (SDG 6) (Govindan 2018;
18 Minelgaitė and Liobikienė 2019) and reduces waste along product supply chains and lifecycle (SDG
19 12) (Unstats 2020). Genovese et al. (2017) At the risk side there are possible reduction of employment,
20 incomes, sales taxes from the material extraction and processing activities, considered as excessive for
21 sustainable consumption (Thomas 2003).

23 *11.5.3.2 SDGs co-Benefits from Circular Economy and Industrial Waste*

24 While the circular economy concept first emerged in the context of waste avoidance, resource depletion,
25 closed-loop recycling, etc., it has now evolved as a tool for a broader systemic national policy due to
26 its potential wider benefits (Geng et al. 2013). It represents new circular business models that encourage
27 design for re-use and to improve material recovery and recycling, and so represents a departure from
28 the traditional linear production and consumption systems (with landfilling at the end), with a wide
29 range of potential co-benefits to a wide range of SDGs (Genovese et al. 2017; Schroeder et al. 2019;
30 Unstats 2020; Guo et al. 2016).

31 Genovese et al. (2017) articulates the advantages from an environmental and responsible consumption
32 and production point of view (SDG 12). Many studies have outlined new business models based on the
33 circular economy that fosters sustainable economic growth and the generation of new jobs (SDG 8)
34 (Antikainen and Valkokari 2016), as well as global competitiveness and innovation in business and the
35 industrial sector (Pieroni et al. 2019), such as its potential synergies with industry 4.0 (Garcia-Muiña et
36 al. 2018).

37 Following a review of the literature, Schroeder et al. (2019) identified linkages between circular
38 economy practices and SDGs based on a relationship scoring system and highlighted that such SDGs
39 as SDG 6 (Clean Water and Sanitation), SDG 7 (Affordable and Clean Energy), SDG 8 (Decent Work
40 and Economic Growth), SDG 12 (Responsible Consumption and Production), and SDG 15 (Life on
41 Land) all strongly benefit from circular economy practices. With the potential to impact on all stages of
42 the value chain (micro, meso- and macro-level of the economy), circular economy has also been
43 identified as key industrial strategy to managing waste across sectors.

44 Chatziaras et al. (2016) highlights the co-benefit to SDG 7 (Affordable and Clean Energy) resulting
45 from waste derived fuel for the cement industry. Through the management of industrial waste using
46 circular economy practices, studies such as (Geng et al. 2012; Bonato and Orsini 2017) have pointed

1 out co-benefits to SDGs beyond clear environmental and economic benefits, highlighting how it also
2 benefits SDG 3 and 11 through improved social relations between industrial sectors and local societies,
3 and improved public environmental awareness and public health level.

5 ***11.5.3.3 SDG co-Benefits from Energy Efficiency***

6 Beyond the very direct links between energy and climate change, reliable, clean, and affordable energy
7 (SDG 7) presents a cross-cutting issue, central to all SDGs and fundamental to development, and energy
8 efficiency enables its provision by reducing the direct supply and necessary infrastructure required.
9 Energy efficiency improvements can be delivered through multiple technical options and tested
10 policies, delivering energy and resource savings simultaneously with other socio-economic and
11 environmental co-benefits. At the macro-level, this includes enhancement of energy security (SDG 16
12 – Peace, Justice and Strong Institutions) delivered through clean low carbon energy systems
13 (Fankhauser and Jotzo 2018). Much of the literature, including Sari and Akkaya (2016); Garrett-Peltier
14 (2017) and Allan et al. (2017) points out that energy efficiency improvements deliver superior
15 employment opportunities (SDG 8 - Decent Work and Economic Growth), while a limited number of
16 studies have reported that it can negatively impact employment in fuel supply sectors (Costantini et al.
17 2018).

18 Many studies report that energy efficiency improvements are essential for supporting overall economic
19 growth, contributing to positive changes in multi-factor productivity (SDG 8 - Decent Work and
20 Economic Growth & Industry, Innovation, and Infrastructure) (Bashmakov 2019; Bataille and Melton
21 2017; Stern 2019; Lambert et al. 2014; Rajbhandari and Zhang 2018) through industrial innovation
22 (SDG 9) (Kang and Lee 2016), with some dissent e.g., (Mahmood and Ahmad 2018). Improved energy
23 efficiency against a background of growing energy prices helps industrial plants stay competitive
24 (Bashmakov and Myshak 2018). Energy efficiency allows continued economic growth under strong
25 environmental regulation. Given that energy efficiency measures reduce the combustion of fossil fuels
26 it leads to reduced air pollution at industrial sites (Williams et al. 2012) and better indoor comfort at
27 working places.

28 Since less energy supply infrastructure is needed in cities and less energy is needed to produce materials
29 such as cement & concrete, and metals, energy efficiency indirectly supports Sustainable Cities and
30 Communities (SDG 11) (Di Foggia 2018). In addition, energy efficiency in industry reflects
31 achievements in meeting SDG12 (Responsible Consumption and Production).

33 ***11.5.3.4 SDGs co-Benefits from Electrification and Fuel Switching***

34 A key, generally underappreciated SDG benefit of electrification is improved urban and indoor air
35 quality (at working places as well) and associated health benefits (SDG 3) from clean electrification
36 (SDG 7) of industrial facilities (IEA 2016). With energy being such an important cross-cutting issue to
37 sustainable development, some SDGs, such as SDG 1, 3, 4, 5 (Harmelink et al. 2018) are co-
38 beneficiaries to using electrification and fuel switching as a climate action mitigation option.

40 ***11.5.3.5 SDGs co-Benefits from CCU and CCS***

41 CCU and CCS have been identified as playing key roles in the transition of industry to net zero.
42 Advancements in the development and deployment of both CCS and CCU foster climate action (SDG
43 13). Other co-benefits for CCS include control of non-CO₂ pollutants (SDG 3), direct foreign
44 investment and know-how (SDG 9), enhanced oil recovery from existing resources, and diversified
45 employment prospects and skills (SDG 8) (Bonner 2017). For CCU, the main co-benefit related

1 contributions are expected within the context of energy transition processes, and in societal
2 advancements that are linked to technological progress (Olfe-Kräutlein 2020). Therefore, the
3 expectations are that the deployment of CCU technologies would have least potential for meeting the
4 SDG targets relating to society/people, compared with the anticipated contributions to the pillars of
5 ecology and economy.

6 These mitigation options carry a large number of risks as well. The high cost of the capture and storage
7 process not only limit the technology penetration, but also makes energy and products more expensive
8 (risk to SDG 7), potential leaks from under sea or underground CO₂ storages carries risks for achieving
9 SDG 6, 14 and 15. While there are economic costs involved with the deployment of CCS and CCU
10 (Bataille et al. 2018a), there are also significant economic and developmental costs associated with
11 taking no action, because of the potential negative impact of climate change. CCS and CCU have been
12 argued as providing public good (Bergstrom and Ty 2017) and co-benefits to key SDGs (Schipper et
13 al. 2011). On the other hand, Fan et al. (2018) among others have noted the potential lock-in of existing
14 energy structures due to CCS. Refer to Table 17.1 for CCS and CCU co-benefits with respect to other
15 sector chapters.

17 **11.6 Policy approaches and strategies**

18 Industrial decarbonisation is technically possible on the mid-century horizon, but requires scale up of
19 technology development and deployment, multi-institutional coordination, and sectoral and national
20 industrial policies with detailed sub-sectoral and regional mitigation pathways and transparent
21 monitoring and evaluation processes (Åhman et al. 2017; Wesseling et al. 2017; Nilsson et al. 2021;
22 Rissman et al. 2020; Bataille et al. 2018a). Transitions of industrial systems entail innovations, plant
23 and technology phase-outs, changes across and within existing value-chains, new sectoral couplings,
24 and large investments in enabling electricity, hydrogen, and other infrastructures. Low carbon
25 transitions are likely to be contested, non-linear and require a multi-level perspective policy approach
26 that addresses a large spectrum of social, political, cultural and technical changes as well as
27 accompanying phase-out policies, and involve a wide range of actors, including civil society groups,
28 local authorities, labour unions, industry associations etc. (Geels et al. 2017; Rogge and Johnstone 2017;
29 Yamada and Tanaka 2019; Koasidis et al. 2020). See also cross chapter Box 12.

30 Deployment of the mitigation options presented in this chapter (see 11.3 and 11.4) needs support from
31 a mix of policy instruments including: GHG pricing coupled with border adjustments or other economic
32 signals for trade exposed industries; robust government support for research, development, and
33 deployment; energy, material and emissions standards; recycling policies; sectoral technology
34 roadmaps; market pull policies; and support for new infrastructure (See Figure 11.15) (Creutzig 2019;
35 Flanagan et al. 2011; Tvinnereim and Mehling 2018; Rogge et al. 2017; Rissman et al. 2020; Bataille
36 2020a; Bataille et al. 2018a). The combination of the above will depend on specific sectoral market
37 barriers, technology maturity, and local political and social acceptance (Rogge and Reichardt 2016;
38 Hoppmann et al. 2013). Industrial decarbonization policies need to be innovative and definitive about
39 net zero CO₂ emissions to trigger the level of investment needed for the profound changes in production,
40 use and recycling of basic materials needed (Nilsson et al. 2017). Inclusive and transparent governance
41 that assesses industry decarbonization progress, monitors innovation and accountability, and provides
42 regular recommendations for policy adjustments is also important for progressing (Mathy et al. 2016;
43 Bataille 2020a).

44 The level of policy experience and institutional capacity needed varies widely across the mitigation
45 options. In many countries, energy efficiency is a well-established policy field with decades of
46 experience from voluntary and negotiated agreements, regulations, standards, energy audits, and

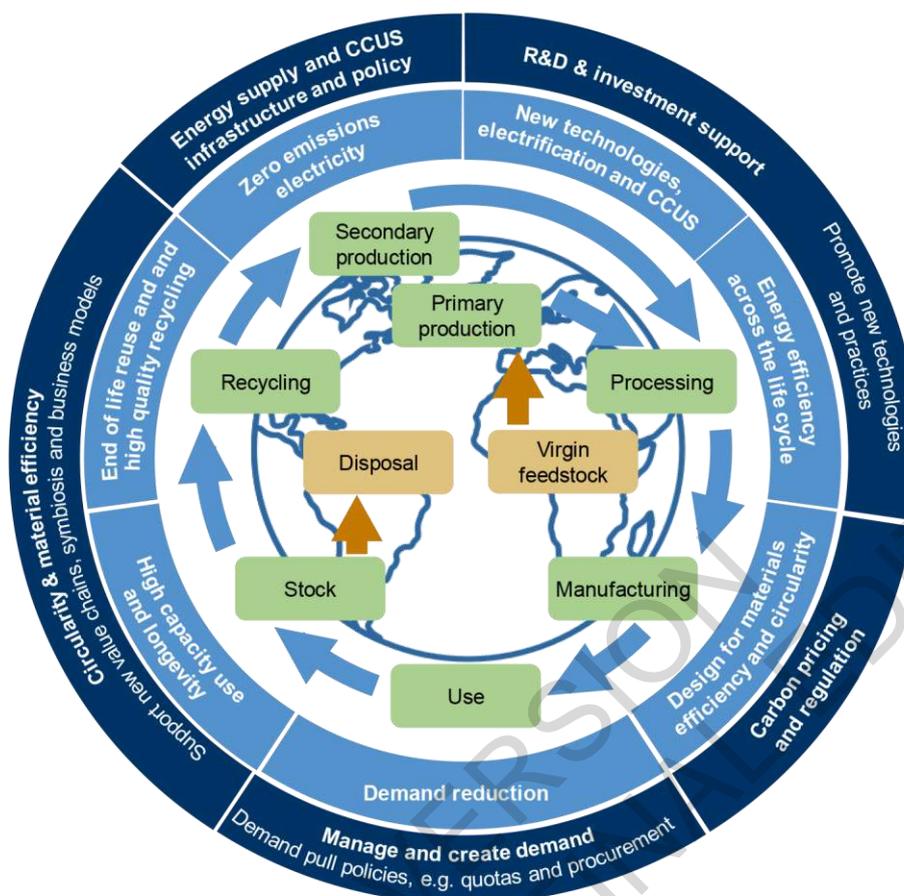

1 demand side management (DSM) programs (see AR5), but there are also many countries where the
2 application of energy-efficiency policy is absent or nascent (See AR5) (García-Quevedo and Jové-
3 Llopis 2021; Tanaka 2011; Saunders et al. 2021; Fishedick et al. 2014a). The application of DSM and
4 load flexibility will also need to grow with electrification and renewable energy integration.

5 Materials efficiency and circular economy are not well understood from a policy perspective and were
6 for a long time neglected in low-GHG industry roadmaps although they may represent significant
7 potential (Allwood et al. 2011; Polverini 2021; Calisto Friant et al. 2021; IEA 2019b; Gonzalez
8 Hernandez et al. 2018b; IEA 2020a). Material efficiency is also neglected in products design,
9 architectural and civil engineering education, infrastructure and building codes, and urban planning (see
10 Ch 5.6) (Orr et al. 2019; Braun et al. 2018). For example, the overuse of steel and concrete in
11 construction is well documented but policies or strategies (e.g., design guidelines, or regulation) for
12 improving the situation are lacking (Shanks et al. 2019; Dunant et al. 2018). Various circular economy
13 solutions are gaining interest from policy makers with examples such as regulations and economic
14 incentives for repair and reuse, initiatives to reduce planned obsolescence, and setting targets for
15 recycling. Barriers that policies need to address are often specific to the different material loops (e.g.,
16 copper contamination for steel and lack of technologies or poor economics for plastics).

17 There is also a growing interest from policymakers in electrification and fuel switching but the focus
18 has been mainly on innovation and on developing technical production-side solutions rather than on
19 creating markets for enabling demand for low carbon products, although the concept of green public
20 procurement is gaining traction. The situation is similar for CCU and CCS. Low carbon technologies
21 adoption represent an additional cost to producers, and this must be handled through fiscal incentives
22 like tax benefits, GHG pricing, green subsidies, regulation and permit procedures. For example, the
23 45Q tax credit provides some incentives to reduce investor risk for CCS and attract private investment
24 in the US (Ochu and Friedmann 2021).

25 Since industrial decarbonisation is only recently emerging as a policy field there is little international
26 collaboration on facilitation (Oberthür et al. 2021). Given that most key materials markets are global
27 and competitive, unless there is much greater global governance to contribute to the decarbonisation of
28 GHG intensive industry through intergovernmental and transnational institutions it is questionable that
29 the world will achieve industry decarbonisation by 2050.

30 As GHG pricing, through GHG taxes or cap and trade schemes, has remained a central avenue for
31 climate policy, this section begins with a review of how the industrial sector has been concerned with
32 these instruments. The rest of the section is then structured into five key topics, following insights on
33 key failures that policy must address to enable and support large-scale transformations as well as the
34 need for complementary mixes of policies to achieve this goal (Grillitsch et al. 2019; Weber and
35 Rohrer 2012; Rogge and Reichardt 2016). The section describes how the need to focus on long-term
36 transitions rather than incremental changes can be managed through the planning and strategizing of
37 transition pathways; discusses the role of research, development, and innovation policy; highlights the
38 need for enabling low-carbon demand and market creation; reflects on the necessity of establishing and
39 maintaining a level of knowledge and capacity in the policy domain about the industrial transition
40 challenge; and points to the critical importance of coherence across geographical and policy contexts.
41 The section concludes with a reflection on how different groups of actors needs to take up different
42 parts of the responsibility for mitigating climate change in the industrial sector.

1
2 **Figure 11.15 Schematic Figure showing the life cycle of materials (green), mitigation options (light blue)**
3 **and policy approaches (dark blue).**

4 5 **11.6.1 GHG Prices and GHG Markets**

6 Internalizing the cost of GHG emissions in consumer choices and producer investment decisions has
7 been a major strategy promoted by economists and considered by policy makers to mitigate emissions
8 cost-effectively and to incentivize low GHG innovations in a purportedly technology neutral way
9 (Stiglitz et al. 2017; Boyce 2018a). In the absence of a coordinated effort, individual countries, regions
10 and cities have implemented carbon pricing schemes. As of August 23rd, 2021, 64 carbon schemes have
11 been implemented or are scheduled by law for implementation, covering 22.5% of global GHG
12 emissions (World Bank 2020), 35 of which are carbon taxes, primarily implemented on a national level
13 and 29 of which are emissions trading schemes, spread across national and subnational jurisdictions.

14 Assessments of pricing mechanisms show generally that they lead to reduced emissions, even in sectors
15 that receive free allocation such as industry (Bayer and Aklin 2020; Narassimhan et al. 2018; Martin et
16 al. 2016; Haites et al. 2018; Metcalf 2019). However, questions remain as to whether these schemes
17 can bring emissions down fast enough to reach the Paris Agreement goals (World Bank Group 2019;
18 Tvinnereim and Mehling 2018; Boyce 2018b). Most carbon prices are well below the levels needed to
19 motivate investments in high-cost options that are needed to reach net zero emissions (see Section
20 11.4.1.5). Among the 64 carbon price schemes implemented worldwide today, only nine have carbon
21 prices above 40 USD (World Bank 2020). These are all based in Europe and include EU Emissions
22 Trading System (ETS) (above 40 USD since March 2021), Switzerland ETS, and seven countries with
23 carbon taxes. Furthermore, emissions-intensive and trade-exposed (EITE) industries are typically
24 allowed exemptions and receive provisions that shelter them from any significant cost increase in

1 virtually all pricing schemes (Haïtes 2018). These provisions have been allocated due to concerns about
2 loss of competitiveness and carbon leakage which result from relocation and increased imports from
3 jurisdictions with no, or weak, GHG emission regulations (Branger and Quirion 2014a; Jakob 2021a;
4 Branger and Quirion 2014b). Embodied emissions in international trade accounts for one quarter of
5 global CO₂ emissions in 2015 (Moran et al. 2018) and has increased significantly over the past few
6 decades, representing a significant challenge to competitiveness related to climate policy. CBAM, or
7 CBA) are trade-based mechanisms designed to ‘equalise’ the carbon costs for domestic and foreign
8 producers. They are increasingly being considered by policy makers to address carbon leakage and
9 create a level playing field for products produced in jurisdiction with no, or lower, carbon price
10 (Mehling et al. 2019; Markkanen et al. 2021). On 14 July 2021, the European Commission adopted a
11 proposal for a CBAM that requires importers of aluminium, cement, iron and steel, electricity and
12 fertiliser to buy certificates at the ETS price for the emissions embedded in the imported products
13 (European Commission 2021; Mörsdorf 2021). CBAMs should be crafted very carefully, to meet
14 technical and legal challenges (Rocchi et al. 2018; Sakai and Barrett 2016; Jakob et al. 2014; Cosbey et
15 al. 2019; Pyrka et al. 2020; Joltreau and Sommerfeld 2019). Technical challenges arise because
16 estimating the price adjustment requires reliable data on the GHG content of products imported as well
17 as a clear understanding of the climate policies implications from the countries of imports. Application
18 of pricing tools in industry requires standardization (benchmarking) of carbon intensity assessments at
19 products, installations, enterprises, countries, regions, and the global level. The limited number of
20 existing benchmarking systems are not yet harmonized and thus not able fulfill this function
21 effectively. This limits the scope of products that can potentially be covered by CBAM type policies
22 (Bashmakov et al. 2021a).

23 Legal challenges arise because CBAM can be perceived as a protectionist measure violating the
24 principle of non-discrimination under the regulations of World Trade Organization (WTO). However
25 the absence of GHG prices can also be perceived as a subsidy for fossil fuel based production (Al
26 Khourdajie and Finus 2020; Stiglitz 2006; Kuusi et al. 2020). Another argument supporting CBAM
27 implementation is the possibility to induce low GHG investment in nonregulated regions (Cosbey et al.
28 2019).

29 Thus far, California is the only jurisdiction that has implemented CBA tariffs applied on electricity
30 imports from neighbouring states and provides insights on how a CBA can work in practice by using
31 “default” GHG emissions intensity benchmarks (Fowlie et al. 2021). CBAM is an approach likely to be
32 applied first to a few selected energy-intensive industries that are at risk of carbon leakage as the EU is
33 considering. The implementation of CBA needs to balance applicability versus fairness of treatment.
34 An option recently proposed is individual adjustment mechanism to give companies exporting to the
35 EU the option to demonstrate their actual carbon intensity (Mehling and Ritz 2020). Any CBAMs will
36 have to comply with multilaterally agreed rules under the WTO Agreements to be implemented.

37 The adoption of CBAM by different countries may evolve into the formation of climate club where
38 countries would align on specific elements of climate regulation (e.g. primary iron or clinker intensity)
39 to facilitate implementation and incentivize countries to join (Nordhaus 2015; Hagen and Schneider
40 2021; Tagliapietra and Wolff 2021a,b). However, not all the countries have the same abilities to report,
41 adapt and transition to low carbon production. The implications of CBAMs on trade relationships
42 should be considered to avoid country divide and separation from a common goal of global
43 decarbonization (Eicke et al. 2021; Banerjee 2021; Bashmakov 2021; Kuusi et al. 2020; Michaelowa et
44 al. 2019).

45 The globalization of markets and the fragmentation of supply chains complicates the assignment of
46 responsibility for greenhouse gas emissions mitigations related to trade (Jakob et al. 2021). Production-
47 based carbon price schemes minimize the incentives for downstream carbon abatement due to the
48 imperfect pass through of carbon costs and therefore overlook demand-side solutions such as material

1 efficiency (Skelton and Allwood 2017; Baker 2018). An alternative approach is to set the carbon pricing
2 downstream on the consumption of carbon intensive materials, whether they are imported or produced
3 locally (Munnings et al. 2019; Neuhoff et al. 2015, 2019). However, implementation of consumption
4 based GHG pricing is also challenged by the need of product GHG traceability and enforcement
5 transaction costs (Munnings et al. 2019; Jakob et al. 2014). Hybrid approaches are also considered
6 (Neuhoff et al. 2015; Jakob et al. 2021; Bataille et al. 2018a). The efficacy of GHG prices to achieve
7 major industry decarbonization has been challenged by additional real world implementation problems,
8 such as highly regionally fragmented GHG markets (Tvinnereim and Mehling 2018; Boyce 2018b) and
9 the difficult social acceptance of price increases (Raymond 2019; Bailey et al. 2012). The higher GHG
10 prices likely needed to incentivize industry to adopt low GHG solutions pose social equity issues and
11 resistance (Huang et al. 2019b; Wang et al. 2019; Grainger and Kolstad 2010; Bataille et al. 2018b;
12 Hourcade et al. 2018). GHG pricing is also associated with promoting mainly incremental low-cost
13 options and not investments in radical technical change or the transformation of sociotechnical systems
14 (Rosenbloom et al. 2020; Stiglitz 2019; Vogt-Schilb et al. 2018; Grubb 2014). Transparent and strategic
15 management of cap-and-trade proceeds toward inclusive decarbonization transition that support high
16 abatement cost options can contribute toward easing these shortcomings (Raymond 2019; Carl and
17 Fedor 2016). In California, Senate Bill 535 (De León, Statutes of 2012) require that at least a quarter of
18 the proceeds go to projects that provide a benefit to disadvantaged communities (California Climate
19 Investments 2020).

20 Clear and firm emission reduction caps towards 2050 are essential for sending strong signals to
21 businesses. However, many researchers recognize that complementary policies must be developed to
22 set current production and consumption patterns toward a path consistent with achieving the Paris
23 agreement goals as cap and trade or carbon taxes are not enough (Schmalensee and Stavins 2017;
24 Kirchner et al. 2019; Vogt-Schilb and Hallegatte 2017; Bataille et al. 2018b). In this broader policy
25 context, proceeds from pricing schemes can be used to support the deployment of options with near
26 term abatement costs that are too high to be incentivised by the prevailing carbon price, but which show
27 substantial cost reduction potential with scale and learning, and to ensure a just transition (Wang and
28 Lo 2021).

29

30 **11.6.2 Transition pathways planning and strategies**

31 Decarbonising the industry sector requires transitioning how material and products are produced and
32 used today to development pathways that include the strategies outlined in Sections 11.3 and 11.4 and
33 Figure 11.15. Such broad approaches require the development of transition planning that assesses the
34 impacts of the different strategies and consider local conditions and social challenges that may result
35 from conflicts with established practices and interests, with planning and strategies directly linked to
36 these challenges.

37 Governments have traditionally used voluntary agreements or mandatory energy or emission reduction
38 targets to achieve emission reduction for specific emission intensive sectors (e.g., UK Climate Change
39 Agreements; India Performance, Achieve and Trade scheme). Sector visions, roadmaps and pathways
40 combined with a larger context of socio-economic goals, with clear objectives and policy direction are
41 needed for every industrial sectors to achieve decarbonisation and at the time of writing they are
42 emerging for some sectors. Grillitsch et al. (2019b) working from the socio-technical transitions
43 literature, focuses on the need for maintaining “directionality” for innovation (e.g. towards net zero
44 transformation), the capacity for iterative technological and policy “experimentation” and learning,
45 “demand articulation” (e.g. engagement of material efficiency and high value circularity), and “policy
46 coordination” as four main framing challenges. Wesseling et al. (2017b) bridges from the socio-
47 technical transitions literature to a world more recognisable by executives and engineers, composed of
48 structural components that include actors (e.g., firms, trade associations, government, research

1 organisations, consumers, etc.), institutions (e.g., legal structures, norms, values and formal policies or
2 regulations), technologies (e.g. facilities, infrastructure) and system interactions.

3 Several studies (Åhman et al. 2017; Material Economics 2019; Wyns et al. 2019; Bataille et al. 2018a)
4 offer detailed transition plans using roughly the same five overarching strategies: 1) policies to
5 encourage material efficiency and high quality circularity; 2) “supply push” R&D and early
6 commercialisation as well as “demand pull” to develop niche markets and help emerging technologies
7 cross “the valley of death”; 3) GHG pricing or regulations with competitiveness provisions to trigger
8 innovation and systemic GHG reduction; 4) long run, low cost finance mechanisms to enable
9 investment and reduce risk; 5) infrastructure planning and construction (e.g. CO₂ transport and disposal,
10 electricity and hydrogen transmission and storage), and institutional support (e.g. labour market training
11 and transition support; electricity market reform). Wesseling et al. (2017b) and (Bataille et al. 2018a)
12 further add a step to conduct ongoing stakeholder engagements, including stakeholders with effective
13 “veto” power (i.e. firms, unions, government, communities, indigenous groups), to share and gather
14 information, educate, debate, and build consensus for a robust, politically resilient policy package. This
15 engagement of stakeholders can also bring on new supply chain collaborations and bridge the cost pass-
16 through challenge (e.g., the Swedish HYBRIT steel project, or the ELYSIS consortium, with plans to
17 bring fully commercialized inert electrodes for bauxite electrolysis to market by 2024).

18 Detailed sectoral roadmaps that assess the technical, economic, social and political opportunities and
19 provide a clear path to low-GHG development are needed to guide policy designs. For example, the
20 German state of North Rhine Westphalia passed a Climate Process Law that resulted in the adoption of
21 a Climate Protection Plan that set subsector targets through a transparent stakeholder engagement
22 process based on scenario development and identification of low GHG options (Lechtenböhmer et al.
23 2015), see Box 11.3. Another example is the UK set of Industrial Decarbonisation and Energy
24 Efficiency Roadmaps to 2050 as well as the UK Strategic Growth Plan, which are accompanied by
25 Action Plans for each energy intensive subsector.

26

27 **START BOX 11.3 HERE**

28

29 **Box 11.3 IN4Climate NRW – Initiative for a climate-friendly industry in North Rhine-** 30 **Westphalia (NRW)**

31 IN4Climate NRW (www.in4climate.nrw) was launched in September 2019 by the state government of
32 North Rhine-Westphalia (IN4climate.NRW 2019) as a platform for collaboration between
33 representatives from industry, science and politics. IN4climate.NRW offers a common space to develop
34 innovative strategies for a carbon-neutral industrial sector, bringing together different perspectives and
35 competencies.

36 North Rhine-Westphalia is Germany’s industrial heartland. Around 19% of North Rhine-Westphalia’s
37 GHGs have their origin in the industry sector. Consequently, the sector bears a particular responsibility
38 when it comes to climate protection, but the state is also a source of high-quality jobs and export value.
39 The NRW government understands that the state’s current competitive advantage can only be
40 maintained if the regional industry positions itself as a frontrunner for becoming GHG-neutral.

41 In working together across different branches (more than 30 companies representing mainly steel,
42 cement, chemical, aluminium industry, refineries and energy utilities) and enabling a direct interaction
43 between industry and government officials, IN4Climate provides a benefit to the participating
44 companies. People from the different areas are working together in so-called innovation teams and
45 underlying working groups with a self-organized process of setting their milestones and working

1 schedule while reflecting long-term needs as well as short-term requirements based on political or
2 societal discussions.

3 The innovation teams aim to identify and set concrete impulses for development and implementation
4 of breakthrough technologies, specify necessary infrastructures (e.g., for hydrogen production, storage
5 and transport) and appropriate policy settings (i.e., integrated state, national, European policy mix).
6 They also include an attempt to create a discourse between the public and the industry sectors as a kind
7 of sounding board for the early detection of barriers and obstacles.

8 The initiative has been successful so far, for example having developed a clear vision for a hydrogen
9 strategy and an associated policy framework as well as a broader decarbonisation strategy for the whole
10 sector. It is present at the national level as well as at the European level. Being successful and unique
11 IN4Climate is useful as a blueprint for other regions and is often visited by companies and
12 administration staff from other German states.

13 It is particularly the so far missing intensive and dedicated cooperation across industrial sub-sectors that
14 can be seen as success factor. Facing substantial transformation needs associated with structural changes
15 and infrastructure challenges, very often solutions can't be provided and realised by single sector but
16 need cooperation and coordination. Even more, chicken and egg problems like the construction of new
17 infrastructures (e.g., for hydrogen and CO₂ disposal) require cooperation and new modes of
18 collaboration. IN4Climate provides the necessary link for this.

19

20 **END BOX 11.3 HERE**

21

22 **11.6.3 Technological research, development, and innovation**

23 Policies for research, development, and innovation (RDI) for industry are present in most countries but
24 it is only recently, and mainly in developed countries, that decarbonisation of emissions intensive
25 industries has been prioritised (Nilsson et al. 2021; Åhman et al. 2017). Emission intensive industries
26 are characterised by large dominant actors and mature process technologies with high fixed cost, long
27 payback times and low profit margins on the primary production side of the value chain. Investments
28 in RDI are commonly low and aimed at incremental improvements to processes and products
29 (Wesseling et al. 2017).

30

31 **11.6.3.1 Applied research**

32 Investing in RDI for low-GHG process emissions is risky and uncompetitive in the absence of
33 convincing climate policy. Research investment should be guided by assessing options, technology
34 readiness levels, and roadmaps towards technology demonstration and commercialization. The
35 potential GHG and environmental implications need to be assessed early on to assess the sustainability
36 implications and to direct research needs (Zimmerman et al. 2020; Yao and Masanet 2018). Strategic
37 areas for RDI can be focussed on a set of possible process options for producing basic materials using
38 fossil-free energy and feedstock, or CCU and CCS (11.3.5 and 11.3.6). Policies to enhance RDI include
39 public funding for applied research, technological and business model experimentation, pilot and
40 demonstration projects, as well as support for education and training – which further have the positive
41 side-effect of leading to spill-overs and network effects through labour market mobility and
42 collaboration (Nemet et al. 2018). Innovative business models will not emerge if the transition is not
43 considered along the full value chain with a focus on materials efficiency, circularity, and new roles for
44 industry in a transitioning energy system, including possibly providing demand response for electricity

1 through designed-in flexibility, for example, by combining electrolysis hydrogen production with
2 substantial storage (Vogl et al. 2018).

3 Fostering collaborative innovation across sectors through the support of knowledge sharing and
4 capabilities building is important as mitigation options involve new or stronger sectoral couplings
5 (Tönjes et al. 2020). One example is linking chemicals to forestry in the upscaling of forest bio-
6 refineries, although it has proven to be difficult to engage a diverse group of actors in such
7 collaborations (Karlton and Sandén 2012; Bauer et al. 2018). Heterogeneous collaboration and
8 knowledge exchange can be encouraged through conscious design of RDI programs and by supporting
9 network initiatives involving diverse actor groups (Van Rijnsoever et al. 2015; Söderholm et al. 2019).

10

11 *11.6.3.2 Policy support from demonstration to market*

12 Applied research is relatively inexpensive compared to piloting, demonstrations, and early
13 commercialisation, and arguably a lot of it has already been done for the key technologies that need to
14 climb the technology readiness ladder (see **Table 11.3**). This includes electricity and hydrogen-based
15 processes, electro-thermal technologies, high temperature heat pumps, catalysis, lightweight building
16 construction, low embodied carbon construction materials, etc. Demonstration to market strategies can
17 be particularly successful when the complete supply chain is considered. A prominent example of such
18 an integrated supply chain approach is the UK Offshore Wind Accelerator Project. Coordinated by the
19 UK Carbon Trust and working with wind turbine manufacturers, the project looked across the potential
20 supply chain for floating offshore wind and identified what components manufacturers could innovate
21 and produce by themselves, and where there were gaps beyond the capability of any one firm. This
22 process led to several key areas of work where the government and firms could work together; once the
23 concepts were piloted and proven, the firms went back into a competitive mode. The project illustrates
24 the potential importance of third parties, including government, in creating platforms and opportunities
25 for cross-industry exchange and collaboration (Tönjes et al. 2020).

26 Pilot and demonstration projects funded through public - private partnerships contributes to risk
27 mitigation for industries and helps inform on the feasibility, performance, costs and environmental
28 impacts of decarbonization technologies. Most countries already maintain government research and
29 deployment programs. For example, the Horizon Europe has a total budget of 95.5 billion EUR (117
30 billion USD) for 2021-2027, of which 30% will be directed to green technology research. The EU has
31 conducted several demonstration projects for emission intensive industries, such as the Ultra-Low
32 Carbon Steel (ULCOS) project (Abdul Quader et al. 2016), which lead to several small scale pilot that
33 are now going to larger scale firm pilots (e.g., HISARNA, HYBRIT and SIDERWIN). Supported by
34 the EU, several cement firms are working together on the cement LEILAC project, where a new form
35 of limestone calciner is being developed to concentrate the process CO₂ emerging from quicklime
36 production (about 60% of cement emissions) for eventual utilisation or geological storage (as one of
37 many options for cement, see for example, Plaza et al. (2020)). If LEILAC works, it is conceivable that
38 existing cement plants globally that are located near CCS opportunities could have their emissions
39 reduced by 60% with one major retrofit of the kiln.

40 Once a technology has been demonstrated with scale up potential, the next stage is commercialization.
41 This is a very expensive stage, where costs are not yet compensated by revenue (see, e.g., Åhman et al.
42 (2018) and Nemet et al. (2018)). The H-DRI, SIDERWIN and LEILAC examples are all at the stage of
43 scaling up. Given the resource requirement, a diversified portfolio of investors and support is required
44 to share the risk. LEILAC includes several firms, as did the UK Offshore Wind Accelerator.
45 Government funds are also required and could be refunded in the future through an equity position,
46 royalty or tax. Fast growing economies, which are adding new industrial capacity, can provide
47 opportunities to pilot, demonstrate and scale-up new technologies, as shown by the rapid expansion of

1 electric vehicle and solar panel production in China, which contributed to driving down costs (Nemet
2 2019; Jackson et al. 2021; Hsieh et al. 2020).

3 Finally, large capital flows towards deployment of low GHG solutions will not materialise without a
4 growing demand for low carbon materials and products that allows business opportunities. Policy will
5 thus be needed to support the first niche markets which are essential for refining new decarbonized
6 technologies, trouble shooting, and for building manufacturing economies of scale. Market creation
7 does however go beyond the nurturing, shielding, and empowerment of early niches (Smith and Raven
8 2012; Raven et al. 2016) and must also consider how to significantly re-shape existing markets to create
9 space for decarbonized solutions and crowd out fossil-based ones (Mazzucato 2016).

10

11 **11.6.4 Market Pull**

12 The perception of an increasing durable demand for low GHG products induces manufacturers to invest
13 in decarbonisation strategies (Olatunji et al. 2019). Policies can support and accelerate this process by
14 creating niche market, stimulating demand for low carbon products through procurement and financing
15 and by addressing informational and other market barriers.

16

17 ***11.6.4.1 Public Procurement***

18 Governments spend a large portion of their budget on the provision of products and material through
19 infrastructure development, general equipment, and miscellaneous goods. The OECD estimates that an
20 average of 30% of general government expenditure goes to public procurements in OECD countries,
21 representing 12.6% of GDP, which makes government a powerful market actor (OECD 2021). Public
22 procurement can therefore create a significant market pull and be used to pursue strategic environmental
23 goals (Ghisetti 2017). Local, regional and national authorities can use their purchasing power to create
24 niche markets and to guarantee demand for low GHG products and material (Wesseling and Edquist
25 2018; Muslemani et al. 2021). In some cases, governments will have to adapt government procurement
26 policies that are not well suited for the procurement of products and services that focus on the
27 decarbonisation benefits and longer-term procurement commitments of emissions reducing
28 technologies and projects (Ghisetti 2017). Implementation can be challenged by the complexity of
29 criteria, the lack of credible information to check GHG intensities and the added time needed for
30 selection (Testa et al. 2012; Cheng et al. 2018; Geng and Doberstein 2008; Zhu et al. 2013; Liu et al.
31 2019b; Bratt et al. 2013; Lundberg et al. 2015). To ease these hurdles, the EU commission has developed
32 environmental criteria that can be directly inserted in tender documents (Igarashi et al. 2015; European
33 Commission 2016). These criteria are voluntary, and the extent of their application varies across public
34 authorities (Bratt et al. 2013; Testa et al. 2016; Michelsen and de Boer 2009). In the Netherlands,
35 companies achieving a desirable certification level under the national CO₂ Performance Ladder obtain
36 a competitive advantage in public procurement (Rietbergen and Blok 2013; Rietbergen et al. 2015).
37 Globally, many countries have implemented green product procurement or sustainable procurement
38 following Sustainable Development Goal (SDG) 12 – Responsible consumption and production (UNEP
39 2017). Public procurement is also developing at subnational levels. For example, the state of California
40 in the United States passed the Buy Clean California Act (AB 262) that establishes maximum acceptable
41 global warming potentials for eligible steel and glass construction materials for public procurement
42 (USGBC-LA 2018). See Box 11.4.

43

44 **START BOX 11.4 HERE**

45

1

Box 11.4 Buy Clean California Act

2 In October 2017, California passed Assembly Bill (AB) 262, the Buy Clean California Act, a new law
3 requiring state-funded building projects to consider the global warming potential (GWP) of certain
4 construction materials during procurement. The goal of AB 262 is to use California's substantial
5 purchasing power to buy low-carbon products. Such low-carbon public procurement will directly
6 reduce emissions by using lower-carbon products, and indirectly by sending a market signal to
7 manufacturers to reduce their emissions in order to stay competitive in California.

8 The bill requirements are two-pronged: as of January 2020, manufacturers of eligible materials must
9 submit a facility-specific environmental product declaration (EPD), and the eligible materials must
10 demonstrate (through submitted EPDs) GWP below the product-specific compliance limits defined by
11 the state Department of General Services (DGS), which will regulate policy implementation. The
12 eligible materials include structural steel, carbon steel rebar, flat glass, and mineral wool insulation. In
13 January 2021, the DGS published maximum acceptable GWP limits for each product category set at
14 the industry average of facility specific GWP for each material. Beginning July 1, 2021, awarding
15 authorities were required to verify GWP compliance for all eligible materials (DGS 2020; USGBC-LA
16 2018).

17 Prior to adoption of the Buy Clean California Act, the California Department of Transportation
18 (Caltrans) had been evaluating the use of life-cycle assessment and EPDs in evaluating materials. In
19 addition to the materials specified in Buy Clean California Act (noted above), the Caltrans project
20 includes materials used extensively in transportation (concrete, asphalt, and aggregate). Also, the
21 California High-Speed Rail project had begun using EPDs as part of its procurement process. The High-
22 Speed Rail Sustainability Report states that the construction projects will: 1) require EPDs for
23 construction materials including steel products and concrete mix designs, and 2) require "optimized
24 life-cycle scores for major materials" and include additional strategies to reduce impacts across the life
25 cycle of the project (Simonen et al. 2019).

26 Several other states such as Washington, Minnesota, Oregon, Colorado, New York and New Jersey are
27 developing similar types of Buy Clean regulations (BGA 2020; Simonen et al. 2019).

28

29 **END BOX 11.4 HERE**

30

31 ***11.6.4.2 Private Procurement***

32 The number of companies producing sustainability reports has increased rapidly over the last decade
33 (Jackson and Belkhir 2018) and so has the number of pledges to carbon neutrality announced. This
34 trend has mainly been driven by consumer concerns, investor requests, and as a business strategy to
35 gain a competitive advantage (Koberg and Longoni 2019; Higgins and Coffey 2016; Ibáñez-Forés et
36 al. 2016). For example, Apple and the governments of Québec and Canada are the financier and lead
37 market maker in the Elysis consortium to bring inert electrodes to market for bauxite smelting to make
38 zero GHG aluminium. Aluminium is a very small fraction of the cost of a laptop or smartphone, so even
39 expensive low emissions aluminium adds to Apple's brand at very little cost per unit sold. Some
40 countries are also requiring corporate to report their emissions. For example, the French government
41 requires companies with 500 or more employees and financial institutions to report Corporate Social
42 Responsibility (CSR) and disclose publically Scope 1 (direct emissions), Scope 2 (indirect emissions
43 from purchased electricity) and Scope 3 (emissions from supply chain's 2 impacts and consumer's
44 usage and end-of-life recycling practices) emissions (Mason et al. 2016).

1 The most common climate mitigation strategies used by corporates are to set emissions reduction targets
2 in line with the Paris Agreement goals through science-based target (SBT) and to develop internal
3 carbon pricing (Kuo and Chang 2021). The SBT initiative records that 338 SBT companies reduced
4 their emissions by 302 MtCO₂ e between 2015 and 2019 (SBTI 2021). As of August 2021, 858
5 companies had set SBT and over 2,000 companies across the world currently use internal carbon pricing
6 with a median internal carbon price of 25 USD per metric ton of CO₂-eq (Bartlett et al. 2021). The most
7 determined companies have developed internal GHG abatement strategies that incorporate their supply
8 chains' emissions (Martí et al. 2015; Tost et al. 2020; Gillingham et al. 2017) and design procurement
9 contracts that encourage or require their suppliers to also improve their product GHG footprint (Liu et
10 al. 2019a). For many corporations, the emissions impact within their supply chain far exceeds their
11 operations direct emissions (CDP 2019). Therefore, the opportunities to reduce emissions through
12 purchasing goods and services from the supply chain (scope 3) have much greater potentials than from
13 direct emissions.

14 However, these trends have to be approached with caution as some of the emissions reductions are not
15 direct emissions reductions from companies' operations, instead often from offset projects of varying
16 quality (Chrobak 2021). There is a lack of consistency and comparability in the way firms are reporting
17 emissions, which limits the possibilities to assess companies' actual ambition and progress (Blanco et
18 al. 2016; Liu et al. 2015; Burritt and Schaltegger 2014; Sullivan and Gouldson 2012; Rietbergen et al.
19 2015). More research is needed to assess the current impacts of corporate voluntary climate actions and
20 if these efforts meet the Paris agreement's goals (Rietbergen et al. 2015; Wang and Sueyoshi 2018). It
21 will be critically important that the international corporate accounting frameworks, standards, and
22 related guidance (e.g., GHG Protocol) be maintained and improved to reflect evolving needs in the
23 global market and to allow for comparison of objectives and progress.

24

25 *11.6.4.3 GHG content certifications*

26 The development of GHG labels corresponds to a growing demand from consumers desiring
27 information about the climate impacts of their consumption (Darnall et al. 2012; Feucht and Zander
28 2018; Tan et al. 2014). GHG labels fill this information gap by empowering consumers' purchasing
29 decisions and creating higher value for low GHG products and materials (Cohen and Vandenberg
30 2012; Vanclay et al. 2011). The willingness to pay for lower GHG products has been found to be
31 positive but to depend on socioeconomic consumer characteristics, cultural preferences and the product
32 considered (Li et al. 2017; Shuai et al. 2014; Tait et al. 2016; de-Magistris and Gracia 2016; Feucht and
33 Zander 2018). Companies and governments that favour low GHG products and who are seeking to
34 achieve environmental, social, and governance (ESG) goals also need readily available and reliable
35 information about the GHG content of products and materials they purchase and produce (Munasinghe
36 et al. 2016; Long and Young 2016).

37 Numerous methodologies have been developed by public and private organizations to meet the needs
38 for credible and comparable environmental metrics at the product and organization levels. Most follow
39 life cycle assessment standards as described in ISO 14040 and ISO 14044, ISO 14067 for climate
40 change footprint only and ISO 14025 (2006) for environmental product declarations (EPD) but the way
41 system boundaries are applied in practice varies (Liu et al. 2016; Wu et al. 2014). Adoption has been
42 challenged by the complexity and the profusion of applications which contribute to confuse
43 stakeholders (Guenther et al. 2012; Gadema and Oglethorpe 2011; Brécard 2014). The options of
44 applying different system boundaries and allocation principles involve value judgements that in turn
45 influence the results (McManus et al. 2015; Tanaka 2008; Overland 2019; Finnveden et al. 2009). A
46 more systematic and coordinated international approach based on transparent and reliable data and
47 methodologies is needed to induce global low GHG market development (Pandey et al. 2011; Tan et al.
48 2014; Darnall et al. 2012).

1 Within the context of GHG content certifications and EPD development, more transparency is needed
2 to increase international comparability and to validate claims to meet consumers demand for low GHG
3 material and products (Rangelov et al. 2021). Greater automation, publicly available reference
4 databases, benchmarking systems and increased stakeholder collaboration can also support the
5 important role of conveying credible emissions information between producers, traders and consumers.

7 *11.6.4.4 Performance Standards and Codes*

8 Policy makers can set minimum performance standards or maximum emission content specifications
9 through legislation to increase the use of low GHG materials and products by mandating the adoption
10 of low GHG production and construction processes while requiring material and resource efficiency
11 aspects.

12 Construction of buildings represented 11% of energy and process-related carbon dioxide (CO₂)
13 emissions globally in 2018 (IEA and UNEP 2019). The share of embodied emissions in construction is
14 increasing as building energy efficiency is improving and energy supply is decarbonized (Chastas et al.
15 2016). As a result, jurisdictions are increasingly considering new requirements in building codes to
16 reduce embodied emissions. This is the case of France's new building code which is shifting from a
17 thermal regulation (RT 2012) to an environmental regulation (RE 2020) to include embodied GHG
18 LCA metrics for encouraging use of low-GHG building materials (Schwarz et al. 2020; Ministère de la
19 Transition écologique et solidaire 2018). The 2018 International Green Construction Code (IGCC)
20 provides technical requirements that can be adopted by jurisdictions for encouraging low GHG building
21 construction, which also covers minimum longevity and durability of structural, building envelope, and
22 hardscape materials (Art. 1001.3.2.3) (Celadyn 2014). Low GHG Building Rating Systems, such as
23 LEEDs, are voluntary standards which include specific requirements on material resources in their
24 rating scale. Trade-offs between energy performance achievement and material used in building
25 construction needs to be further assessed and considered as low GHG building code requirements
26 develop. Local governments can also lead the way by adopting standards for construction. This is the
27 case of the county of Marin in California which specifies maximum embodied carbon in kgCO_{2-eq} m⁻³
28 and maximum ordinary Portland cement content in lbs/yd³ for different levels of concrete compressive
29 strength (Marin County 2021).

30 Governments are also turning their attention to developing standards to increase the durability of
31 products and materials by requiring options for maintenance, reparability, reusability, upgradability,
32 recyclability and waste handling. For example, the EU Eco-design directive includes new requirements
33 for manufacturers to make available for a minimum of 7 to 10 years spare parts to repair household
34 equipment (Talens Peiró et al. 2020; Nikolaou and Tsagarakis 2021; Calisto Friant et al. 2021). The
35 European Commission plans to widen the resource efficiency requirements beyond energy-related
36 products to cover products such as textiles, furniture as well as high impact intermediary products such
37 as steel, cement and chemicals in a new sustainable product policy legislative initiative. (Polverini 2021;
38 Domenech and Bahn-Walkowiak 2019; Llorente-González and Vence 2019; European Commission
39 2020).

40 Further research is needed to understand how different international and national frameworks, codes,
41 and standards that focus on emissions can work in unison to amplify their mutually desired outcomes.
42 Building performance and market instrument trading frameworks recognized globally do not always
43 incentivize the same outcomes due to the differences in market approach. LCA metrics are a useful tool
44 to help assess optimal options for ultimate emission reduction objectives (Röck et al. 2020; Shadram et
45 al. 2020).

1 **11.6.4.5 Financial Incentives**

2 Fossil-free basic materials production will often lead to higher costs of production, for example, 20–
3 40% more for steel, 70–115% more for cement, and potentially 15–60% for chemicals (Material
4 Economics 2019). There is a nascent literature on what are effectively material “feed-in-tariffs” to
5 bridge the commercialization “valley of death” (Wilson and Grubler 2011) of early development of low
6 GHG materials (Neuhoff et al. 2018; Sartor and Bataille 2019; Wyns et al. 2019; Bataille et al. 2018a).
7 Renewable electricity support schemes have typically been price-based (e.g., production subsidies and
8 feed-in-tariffs) or volume-based (e.g., quota obligations and certificate schemes) and both principles
9 can be applied when thinking about low GHG materials. Auction schemes are typically used for larger
10 scale projects, for example, offshore wind parks.

11 Based on how feed-in-tariffs worked, a contract for difference (CfD) could guarantee a minimum and
12 higher-than-market price for a given volume of early low GHG materials. CfDs could be based on a
13 minimum effective GHG price reflecting parity with the costs of current higher emitting technologies,
14 or directly on the higher base capital and operating costs for a lower GHG material (Richstein 2017;
15 Chiappinelli et al. 2019; Sartor and Bataille 2019; Vogl et al. 2021a). CfDs can also be offered through
16 low GHG material procurement where an agreed price offsets the incremental cost of buying low GHG
17 content product or material. Private firms, by themselves or collectively, can also guarantee a higher
18 than market price for low GHG materials from their supplier for marketing purposes (Bataille 2020a;
19 Bataille et al. 2018a). Reverse auctions (by which the lowest bidder gets the production subsidy) for
20 low GHG materials is also an option but it remains to be analyzed and explored. While these financial
21 incentive schemes have been implemented for renewable energy, their application to incentivize and
22 support low GHG material production have yet to be developed and implemented. The German
23 government is currently developing a draft law which will allow companies that commit to cut GHG
24 emissions by more than half using innovative technologies to bid for 10-year CfDs with a guaranteed
25 price for low-carbon steel, chemical and cement products (Agora Energiewende and Wuppertal Institut
26 2019; BMU 2021).

27 New and innovative financial market contracts for basic materials that represent low-carbon varieties
28 of conventional materials are emerging. This is the case of aluminium for which quantity of low GHG
29 production already exist in countries where hydroelectric power is a common power source. Market
30 developments will allow for low GHG aluminium to trade at a premium rate as demand develops. For
31 example, Harbor Aluminium has launched a green aluminium spot premium at the end of October 2019
32 and the London Metal Exchange has introduced a "green aluminium" spot exchange contract. (LME
33 2020; Das 2021).

34

35 **11.6.4.6 Extended producer responsibility**

36 EPR systems are increasingly used by policy maker to require producers to take responsibility for the
37 end life of their outputs and to cover the cost of recycling of materials or otherwise responsibly
38 managing problematic wastes (Kaza et al. 2018). According to the OECD, there are about 400 EPR
39 systems in operation worldwide, three-quarters of which have been established over the last two
40 decades. One-third of EPR systems cover small consumer electronic equipment, followed by packaging
41 and tyres (each 17%), vehicles, lead-acid batteries and a range of other products (OECD 2016).

42 While the economic value of some discarded materials such as steel, paper and aluminium is generally
43 high enough to justify the cost and efforts of recycling, at current rates of 85% above 60% and 43%
44 respectively (Cullen and Allwood 2013; Graedel et al. 2011), others like plastic or concrete have a much
45 lower re-circularity value (Graedel et al. 2011). Most plastic waste ends up in landfills or dumped in
46 the environment, with 9% recycled and 12% incinerated globally (UNEP 2018; Geyer et al. 2017)).
47 Collected waste plastics from OECD countries were largely exported to China until a ban in 2018

1 required OECD countries to review their practices (Qu et al. 2019). EPR schemes may thus need to be
2 strengthened to actually achieve a reduced use of virgin, GHG intensive materials. The potential for re-
3 circularity of unreacted cement and aggregates in concrete is increasing as new standards and
4 requirement develops. For example, concrete fines are now standardized as a new cement constituent
5 in the European standardization CEN/TC 51 "cements and construction limes".

6
7 **START BOX 11.5 HERE**

8
9 **Box 11.5 Circular economy policy**

10 The implementation of a circular economy relies on the operationalization of the R-imperatives or
11 strategies which extend from the original 3Rs: Reduce, Reuse and Recycle, with the addition of Refuse,
12 Reduce, Re-sell/Re-use, Repair, Re-furbish, Re-manufacture, Re-purpose, Re-cycle, Recover (energy),
13 Re-mine and more (Reike et al. 2018). The R implementation strategies are diverse across countries
14 (Kalmykova et al. 2018; Ghisellini et al. 2016) but, in practice, the lower forms of retention of materials,
15 such as recycling and recover (energy), often dominate. The lack of policies for higher retention of
16 material use such as Reduce, Reuse, repair, remanufacture is due to institutional failures, lack of
17 coordination and lack of strong advocates (Gonzalez Hernandez et al. 2018a).

18 Policies addressing market barriers to circular business development need to demonstrate that circular
19 products meet quality performance standards, ensure that the full environmental costs are reflected in
20 market prices and foster market opportunities for circular products exchange, notably through industrial
21 symbiosis clusters and trading platforms (Hartley et al. 2020; Hertwich 2020; Kirchherr et al. 2018;
22 OECD 2019a). Policy levels span from micro (such as consumer or company) to meso (eco-industrial
23 parks) and macro (provinces, regions and cities) (Geng et al. 2019). The creation of eco-industry parks
24 ("industrial clusters") has been encouraged by governments to facilitate waste exchanges between
25 facilities, where by-products from one industry is used as a feedstock to another (Tian et al. 2014;
26 Winans et al. 2017; Jiao and Boons 2014; Shi and Yu 2014; Ding and Hua 2012). Systematic assessment
27 of wastes and resources is carried out to assess possible exchange between different supply chains and
28 identify synergies of waste streams that include metal scraps, waste plastics, water heat, bagasse, paper,
29 wood scraps, ash, sludge and others (Ding and Hua 2012; Shi and Yu 2014).

30 The development of data collection and indicators is nascent and need to ramp up to quantify the impacts
31 and provide evidence to improve circular economy and materials efficiency policies. Policy makers
32 needs to leverage the potential socio-economic opportunities of transitioning to circular economies
33 (Llorente-González and Vence 2020) which shows positive GDP growth and job creation by shifting to
34 more labor-intensive recycling plants and repair services than resource extraction activities (Cambridge
35 Econometrics et al. 2018; WRAP and Alliance Green 2015). The International Labor Organization
36 estimates that worldwide employment would grow by 0.1 per cent by 2030 under a circular economy
37 scenario (ILO 2018). However questions remain if the type of jobs created are concentrated in low-
38 wage labor-intensive circular activities which may need targeted policy instruments to improve working
39 conditions (Llorente-González and Vence 2020).

40
41 **END BOX 11.5 HERE**

1 **11.6.5 Knowledge and capacity**

2 It is important that government bodies, academia and other actors strengthen their knowledge and
3 capacities for the broad transformational changes envisioned for industry. In Japan, the industry has
4 been voluntarily working on GHG reduction, under the Framework of Keidanren's Commitment to a
5 Low-carbon Society since 2009. Government and scientific experts regularly review their commitments
6 and discuss results, monitoring methods, and reconsidering goals. Industry federations/associations can
7 obtain advice in the follow-up meetings from other industries and academics. The energy and transport
8 sectors have decades of building institutions and expertise, whereas industrial decarbonisation is largely
9 a new policy domain. Most countries have experience in energy efficiency policies, some areas of
10 research and innovation, waste management, regulations for operational permits and pollution control,
11 worker safety and perhaps fuel switching. There is less experience with market demand pull policies
12 although low GHG public procurement is increasingly being tested. Circular economy policies are
13 evolving but potential policies for managing material demand growth are less understood. Material
14 efficiency policies through, for example, product standards or regulation against planned obsolescence
15 are nascent but relatively unexplored (Gonzalez Hernandez et al. 2018a).

16 All this argues for active co-oversight, management and assessment by government, firms, sector
17 associations and other actors, in effect the formation of an active industrial policy that includes
18 decarbonisation in its broader mandate of economic and social development (OECD 2019b; Bataille
19 2020a). This could draw from the quadruple helix innovation model, which considers the role of
20 government, universities, the private sector, the natural environment and social systems to foster
21 collaboration in innovation (Durán-Romero et al. 2020; Carayannis and Campbell 2019). Important
22 aspects of governance include mechanisms for monitoring, transparency, and accountability. It may
23 involve the development of new evaluation approaches, including a greater focus on ex-ante evaluations
24 and assessment of, for example, readiness and capacities, rather than ex-post evaluations of outcomes.
25 Such organisational routines for learning have been identified as a key aspect of policy capacity to
26 govern evolutionary processes (Karo and Kattel 2018; Kattel and Mazzucato 2018). Although many
27 governments have adopted ideas of focusing resources on the mission or challenge of climate change
28 mitigation, comparisons between Western and East-Asian contexts show significant differences in the
29 implementation of governance structures (Wanzenböck et al. 2020; Mazzucato et al. 2020; Karo 2018).
30 Overall, improved knowledge and stronger expertise is important also to handle information
31 asymmetries and the risk of regulatory capture.

32

33 **11.6.6 Policy coherence and integration**

34 Industrial net zero transitions, while technically feasible, involves not just a shift in production
35 technology but major shifts in demand, material efficiency, circularity, supply chain structure and
36 geographic location, labour training and adaptation, finance, and industrial policy. This transition must
37 also link decarbonisation to larger environmental and social goals (e.g. air and water quality, low GHG
38 growth, poverty alleviation, sustainable development goals) (OECD 2019b).

39 Although there is little evidence of carbon leakage so far it will be ever more important to strive for
40 coherence in climate and trade policies as some countries take the lead in decarbonising internationally
41 traded basic materials (Jakob 2021b). At the time of writing the previously academic debate on this
42 issue is shifting to real policy making through debates and negotiations around carbon border
43 adjustment (see 11.6.1) and sectoral agreements or climate clubs (Nordhaus 2015; Nilsson et al. 2021;
44 Åhman et al. 2017; Jakob 2021a). The climate and trade policy integration should also consider what is
45 sometimes called positive leakage, i.e., that heavy industry production moves to where it is easier to
46 reach zero emissions. As a result, policy should go beyond border measures to include, for example,
47 international technology cooperation and transfer and development of shared lead markets.

1 Energy intensive production steps may move where clean resources are most abundant and relatively
2 inexpensive (Bataille et al. 2021a; Gielen et al. 2020). For example, steel making has historically located
3 itself near iron ore and coal resources whereas in the future it may be located near iron ore and zero
4 GHG electricity or close to carbon storage sites (Fischedick et al. 2014b; Vogl et al. 2018; Bataille
5 2020a). This indicates large changes in industrial and supply chain structure, with directly associated
6 needs for employment and skills. Some sectors will grow, and some will shrink, with differing skill
7 needs. Each new workforce cohort needs the general specific skill to provide the employment that is
8 needed at each stage in the transition, implicating a need for co-ordination with policies for education
9 and retraining.

10 Depending on what mixes of deep decarbonisation strategies are followed in a given region (e.g.
11 material efficiency, electrification, hydrogen, biomass, CCU, CCS), infrastructure will need to be
12 planned, financed and constructed The UKCCC Net-zero Technical Report describes the infrastructure
13 needs for achieving net zero GHG in the UK by 2050 for every sector of the economy (UKCCC 2019b).
14 Transportation would be facilitated with pipelines or ships to allow transfer of captured CO₂ for
15 utilisation and disposal, and associated institutional frameworks (IEAGHG 2021). Electrification will
16 require market design and transmission to support increased generation, transmission, and flexible
17 demand. Hydrogen, CCU, and CCS will require significant new or adapted infrastructure. Hydrogen
18 and CO₂ pipelines, and expanded electricity transmission, have natural monopoly characteristics which
19 are normally governed and planned by national and regional grid operators and their regulators.
20 Industrial clustering (a.k.a. eco-parks), such as those planned in Rotterdam and Teeside, UK, would
21 allow more physical and cost-effective sharing of electricity, CCU, CCS, and hydrogen infrastructure
22 but is dependent on physical planning, permitting, and infrastructure policies.

23 Costing analysis (see Chapter 15) indicates an increased upfront need for financial capital which require
24 policies to encourage long term, patient capital that reflects society's preferences for investment in
25 industrial decarbonisation and the minimum 10 or more years horizon before there are significant new
26 commercially available processes.

27 All the above indicate the need for general industrial policy as part of a coherent general economic,
28 taxation, investment, employment and social policy for climate change mitigation (Wyns et al. 2019;
29 Wesseling et al. 2017; Bataille et al. 2018a; Nilsson et al. 2021).

30

31 **11.6.7 Roles and responsibilities**

32 While all climate policy requires topic specific adaptive governance for long term effectiveness (Mathy
33 et al. 2016), deep decarbonisation of heavy industry has special governance challenges, different from
34 those for the electricity, transport or buildings sectors (Åhman et al. 2017; Wesseling et al. 2017;
35 Bataille et al. 2018a). Competition is strong, investments are rare, capital intensive and very "lumpy".
36 In an atmosphere where transformative innovation is required the process is very capital focussed with
37 non-diversifiable risks unless several companies are involved. There are significant infrastructure needs
38 for electricity, hydrogen, and CCS and CCU. Given there is no "natural" market for low emissions
39 materials, there is a need to manage both the supply and demand sides of the market, especially in early
40 phase through lead supplier and markets. Finally, there is a very high probability of surprises and
41 substantial learning, which could affect policy choice, direction, and stringency.

42 Different types of actors thus have to play different, but coordinated roles and responsibilities in
43 developing, supporting, and implementing policies for an industrial transition. Table 11.6 below shows
44 how the different core parts of integrated policy making for an industrial transition may depend on
45 efforts from different actors groups and highlights the responsibility of these actor groups in developing
46 a progressive and enabling policy context for the transition. This includes policy makers at local,

- 1 national, and international arenas as well as civil society organisations, industry firms, and interest
- 2 organisations.

1 **Table 11.6 Examples of the potential roles of different actors in key policy and governance areas for a low GHG transition to indicate the importance of**
 2 **agency and wide stakeholder engagement in the governance of industrial decarbonisation**

Actors	Direction: Planning and strategising pathways to net zero	Innovation: RD&D for new technologies and other solutions	Market creation: Create and shape demand-pull for various solutions	Knowledge and capacity: Build institutional capacity across various actors	Coherence: Establish international and national policy coherence
International bodies and multilateral collaboration	More attention to industry in NDCs. Monitor progress and identify gaps. Develop international roadmaps.	Include heavy industry decarbonisation in technology cooperation (e.g., Mission Innovation).	International standards, benchmarking systems, and GHG labels. Allow for creation and protection of lead markets.	Support knowledge building and sharing on industrial decarbonisation.	Align other Conventions and arenas (e.g., WTO) with climate targets and include heavy industry transitions in negotiations.
Regional and national government, and cities	Require net zero strategies in permitting. Set targets and facilitate roadmaps at various levels. Sunset clauses and phase-out agreements for polluting plants.	Experimentation for recycling, materials efficiency, and demand management. Hydrogen, electrification, and other infrastructure.	Public procurement for innovation and lead markets. Green infrastructure investments.	Develop policy expertise for industrial transformation. Support and facilitate materials efficient and circular solutions through design standards, building codes, recycling, and waste policy.	Support vertical policy coherence (i.e., international, national, city level).
Civil society	Monitor and evaluate leaders and laggards. Support transparency.	Engage in responsible innovation programs, experimentation, and social innovation.	Progressive labelling, standards and criteria for low emissions materials and products (e.g., LCA-based), including updating.	Engage in policy processes and build capacity on industrial decarbonisation. Support consumer information and knowledge.	Monitor and support policy coherence and coordination across policy domains (trade, climate, waste, etc.).
Industrial sectors and associations	Adopt net zero emissions targets, roadmaps, and policy strategies for reaching them. Assess whole value chains, scope 3 emissions and new business models.	Share best practice. Coordination and collaboration. Efficient markets for new technology (e.g., licensing).	Work across (new) value chains to establish lead markets for low emissions materials as well as for materials efficiency and circularity.	Education and retraining for designers, engineers, architects, etc. Information sharing and transparency to reduce information asymmetry.	Coordination across policy domains (trade, climate, waste, etc.). Explore sectoral couplings, new value chains and location of heavy industry.

Corporations and companies	Set zero emissions targets and develop corporate and plant level roadmaps for reaching targets.	Lead and participate in R&D, pilots, and demonstrations. Increase and direct R&D efforts at reaching net zero.	Marketing and procurement of low emissions materials and products. Include scope 3 emissions to assess impact and mitigation strategies.	Engage in value chains for increased recycling and materials efficiency. Build knowledge and capacity for reorientation and transformation.	MNCs avoid race to the bottom, and strategically account for high carbon price as part of transition strategy.

1 **11.7 Knowledge gaps**

2 An increasing body of research proposes deep decarbonisation pathways for energy intensive industries
3 including mitigation options such as materials efficiency, circular economy and new primary processes.
4 These options are underrepresented in climate change scenario modelling and integrated assessment
5 models, some of which do not even reflect evolution of demand for basic materials, which is a key
6 driver behind energy consumption and GHGs emissions in the industrial sector. As a result, no
7 agreement is reached so far between bottom-up and top-down studies on the effectiveness and costs for
8 many promising mitigation options, their respective roles, sequencing and packaging within various
9 mitigation pathways.

10 A significant shift is needed from the transition process of the past mainly based on marginal and
11 incremental changes, with a strong focus on energy efficiency efforts, to one grounded in
12 transformational change where there is limited knowledge of how to implement such change effectively.

13 There is a knowledge gap on comparable, comprehensive, and detailed quantitative information on costs
14 and potentials associated with the mitigation options for deep decarbonisation in industry, as cost
15 estimates are not often comparable due to the regional or country focus, differences in costs metrics,
16 currencies, discount rates, and energy prices across studies and regions.

17 A very large and important uncertainty is the availability of biomass for deep decarbonisation pathways
18 due to competition for biomass feedstock with other priorities and the extent to which electrification
19 can reduce the demand for bioenergy in the industry, transport and energy sectors.

20 CCS and CCU are important mitigation options in industry, for which the potentials and costs vary
21 considerably depending on the diversity of industrial processes, the volume and purity of carbon dioxide
22 flows, the energy requirements, the lifetime of utilisation products and the production route.

23 The effectiveness of mitigation policies in industry is poorly known as so far the sector has largely been
24 sheltered from the impacts of climate policy due to the concerns of competitiveness and carbon leakage.
25 There is a lack of integration of material efficiency and circularity with energy and climate policies
26 which partly results from the inadequacy of monitored indicators to inform policy debates and set
27 targets, a lack of high-level political focus, a history of strong industrial lobbying, uncoordinated policy
28 across subsectors and institutions, and the sequential nature of decision-making along supply chains.

29 Industry as a whole is a very complex web of sectors, sub-sectors and inter-sectoral interactions and
30 dependence, with diverse associated mitigation opportunities and co-benefits and costs. Additional
31 knowledge is needed to understand sectoral interactions in the transformation processes.

32 Industrial climate mitigation policy is supplemental to many other policy instruments developed to
33 reach multiple industrial goals, for the range of stakeholders with their interest and priorities reflecting
34 the assessment of co-benefits and risk and affecting decision-making processes and behaviour of
35 stakeholders. Better knowledge is needed to identify the co-benefits for the adoption of climate change
36 mitigation strategies.

37

38 **Frequently Asked Questions**

39 **FAQ 11.1 What are the key options to reduce industrial emissions?**

40 Industry has a diverse set of GHG emission sources across sub-sectors. To decarbonise industry requires
41 that we pursue several options simultaneously. These include energy efficiency, materials demand
42 management, improving materials efficiency, more circular material flows, electrification, as well as
43 CCU and CCS. Improved materials efficiency and recycling reduces the need for primary resource

1 extraction and the energy intensive primary processing steps. Future recycling may include chemical
2 recycling of plastics if quality requirements make mechanical recycling difficult. One approach, albeit
3 energy intensive, is to break down waste plastics to produce new monomer building blocks, potentially
4 based on biogenic carbon and hydrogen instead of fossil feedstock. Hydrogen can also be used as a
5 reduction agent instead of coke and coal in ironmaking. Process emissions from cement production can
6 be captured and stored or used as feedstock for chemicals and materials. Electricity and hydrogen needs
7 can be very large but the potential for renewable electricity, possibly in combination with other low
8 carbon options, is not a limiting factor.

9

10 **FAQ 11.2 How costly is industrial decarbonisation and will there be synergies or conflicts**
11 **with sustainable development?**

12 In most cases and in early stages of deployment, decarbonisation through electrification or CCS will
13 make the primary production of basic materials such as cement, steel, or polyethylene more expensive.
14 However, demand management, energy and materials efficiency, and more circular material flows can
15 dampen the effect of such cost increases. In addition, the cost of energy intensive materials is typically
16 a very small part of the total price of products, such as an appliance, a bottle of soda or a building, so
17 the effect on consumers is very small. Getting actors to pay more for zero emission materials is a
18 challenge in supply chains with a strong focus on competitiveness and cutting costs, but it is not a
19 significant problem for the broader economy. Reduced demand for services such as square meters of
20 living space or kilometres of car travel is an option where material living standards are already high. If
21 material living standards are very low, increased material use is often needed for more sustainable
22 development. The options of materials and energy efficiency, and more circular material flows,
23 generally have synergies with sustainable development. Increased use of electricity, hydrogen, CCU
24 and CCS may have both positive and negative implications for sustainable development and thus require
25 careful assessment and implementation for different contexts.

26

27 **FAQ 11.3 What needs to happen for a low carbon industry transition?**

28 Broad and sequential policy strategies for industrial development and decarbonisation that pursue
29 several mitigation options at the same time are more likely to result in resource-efficient and cost-
30 effective emission reductions. Industrial decarbonisation is a relatively new field and thus building
31 capacity for industrial transition governance is motivated. For example, policy to support materials
32 efficiency or fundamental technology shifts in primary processes is less developed than energy
33 efficiency policy and carbon pricing. Based on shared visions or pathways for a zero-emission industry,
34 industrial policy needs to support development of new technologies and solutions as well as market
35 creation for low and zero emission materials and products. This implies coordination across several
36 policy domains including research and innovation, waste and recycling, product standards,
37 digitalisation, taxes, regional development, infrastructure, public procurement, permit procedures and
38 more to make the transition to a carbon neutral industry. International competition means that trade
39 rules must be evolved to not conflict with industrial decarbonisation. Some local and regional
40 economies may be disadvantaged from the transition which can motivate re-education and other
41 support.

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1 **Executive summary**

2 **The total emission mitigation potential achievable by the year 2030, calculated based on sectoral**
3 **assessments, is sufficient to reduce global greenhouse gas emissions to half of the current (2019)**
4 **level or less** (*robust evidence, high agreement*). This potential (32 to 44 GtCO₂-eq) requires
5 implementation of a wide range of mitigation options. Options with mitigation costs lower than 20 USD
6 tCO₂⁻¹ make up more than half of this potential and are available for all sectors {12.2, Table 12.3}

7 **Carbon Dioxide Removal (CDR) is a necessary element to achieve net zero CO₂ and GHG**
8 **emissions both globally and nationally, counterbalancing residual emissions from hard-to-**
9 **transition sectors. It is a key element in scenarios likely to limit warming to 2°C or lower by 2100**
10 (*robust evidence, high agreement*). Implementation strategies need to reflect that CDR methods differ
11 in terms of removal process, timescale of carbon storage, technological maturity, mitigation potential,
12 cost, co-benefits, adverse side-effects, and governance requirements. All Illustrative Mitigation
13 Pathways (IMPs) use land-based biological CDR (primarily Afforestation/Reforestation, A/R) and/or
14 bioenergy with carbon capture and storage (BECCS) and some include direct air carbon capture and
15 storage (DACCS). As a median value (5–95% range) across the scenarios likely limiting warming to
16 2°C or lower, cumulative volumes of BECCS, net CO₂ removal on managed land (including A/R), and
17 DACCS reach 328 (168–763) GtCO₂, 252 (20–418) GtCO₂, and 29 (0–339) GtCO₂ for the 2020–2100
18 period, with annual volumes at 2.75 (0.52–9.45) GtCO₂ yr⁻¹ for BECCS and 2.98 (0.23–6.38) GtCO₂
19 yr⁻¹ for the net CO₂ removal on managed land (including A/R), and 0.02 (0–1.74) GtCO₂ yr⁻¹ for
20 DACCS, in 2050. {12.3, Cross-Chapter Box 8 in this chapter}

21 **Despite limited current deployment, moderate to large future mitigation potentials are estimated**
22 **for Direct Air Carbon Capture and Sequestration (DACCS), enhanced weathering (EW) and**
23 **ocean-based CDR methods (including ocean alkalinity enhancement and ocean fertilisation)**
24 (*medium evidence, medium agreement*). The potential for DACCS (5–40 GtCO₂ yr⁻¹) is limited mainly
25 by requirements for low-carbon energy and by cost (100–300 (full range: 84–386) USD tCO₂⁻¹). DACCS
26 is currently at a medium technology readiness level. EW has the potential to remove 2–4 (full range:
27 <1 to ~100) GtCO₂ yr⁻¹, at costs ranging from 50 to 200 (full range: 24–578) USD tCO₂⁻¹. Ocean-based
28 methods have a combined potential to remove 1–100 GtCO₂ yr⁻¹ at costs of 40–500 USD tCO₂⁻¹, but
29 their feasibility is uncertain due to possible side-effects on the marine environment. EW and ocean-
30 based methods are currently at a low technology readiness level. {12.3}

31 **Realising the full mitigation potential from the food system requires change at all stages from**
32 **producer to consumer and waste management, which can be facilitated through integrated policy**
33 **packages** (*robust evidence, high agreement*). Some 23–42% of global GHG emissions are associated
34 with food systems, while there is still wide-spread food insecurity and malnutrition. Absolute GHG
35 emissions from food systems increased from 14 to 17 GtCO₂-eq yr⁻¹ in the period 1990–2018. Both
36 supply and demand side measures are important to reduce the GHG intensity of food systems. Integrated
37 food policy packages based on a combination of market-based, administrative, informative, and
38 behavioural policies can reduce cost compared to uncoordinated interventions, address multiple
39 sustainability goals, and increase acceptance across stakeholders and civil society (*limited evidence,*
40 *medium agreement*). {7.2, 7.4, 12.4}

41 **Diets high in plant protein and low in meat and dairy are associated with lower GHG emissions**
42 (*robust evidence, high agreement*). Ruminant meat shows the highest GHG intensity. Beef from dairy
43 systems has lower emissions intensity than beef from beef herds (8–23 and 17–94 kgCO₂-eq (100g
44 protein)⁻¹, respectively) when a share of emissions is allocated to dairy products. The wide variation in
45 emissions reflects differences in production systems, which range from intensive feedlots with stock

1 raised largely on grains through to rangeland and transhumance production systems. Where appropriate,
2 a shift to diets with a higher share of plant protein, moderate intake of animal-source foods and reduced
3 intake of added sugars, salt and saturated fats could lead to substantial decreases in GHG emissions.
4 Benefits would also include reduced land occupation and nutrient losses to the surrounding
5 environment, while at the same time providing health benefits and reducing mortality from diet-related
6 non-communicable diseases. {7.4.5, 12.4}

7 **Emerging food technologies such as cellular fermentation, cultured meat, plant-based**
8 **alternatives to animal-based food products, and controlled environment agriculture, can bring**
9 **substantial reduction in direct GHG emissions from food production** (*limited evidence, high*
10 *agreement*). These technologies have lower land, water, and nutrient footprints, and address concerns
11 over animal welfare. Access to low-carbon energy is needed to realize the full mitigation potential, as
12 some emerging technologies are relatively more energy intensive. This also holds for deployment of
13 cold chain and packaging technologies, which can help reduce food loss and waste, but increase energy
14 and materials use in the food system. (*limited evidence, high agreement*). {11.4.1.3, 12.4}

15 **Scenarios that likely to limit warming to 2°C or lower by 2100 commonly involve extensive**
16 **mitigation in the AFOLU sector that at the same time provides biomass for mitigation in other**
17 **sectors. Bioenergy is the most land intensive renewable energy option, but the total land**
18 **occupation of other renewable energy options can become significant in high deployment**
19 **scenarios** (*robust evidence, high agreement*). Growing demands for food, feed, biomaterials, and non-
20 fossil fuels increase the competition for land and biomass while climate change creates additional
21 stresses on land, exacerbating existing risks to livelihoods, biodiversity, human and ecosystem health,
22 infrastructure, and food systems. Appropriate integration of bioenergy and other biobased systems, and
23 of other mitigation options, with existing land and biomass uses can improve resource use efficiency,
24 mitigate pressures on natural ecosystems and support adaptation through measures to combat land
25 degradation, enhance food security, and improve resilience through maintenance of the productivity of
26 the land resource base (*medium evidence, high agreement*). {3.2.5, 3.4.6, 12.5}

27 **Bio-based products as part of a circular bioeconomy have potential to support adaptation and**
28 **mitigation. Key to maximizing benefits and managing trade-offs are sectoral integration,**
29 **transparent governance, and stakeholder involvement** (*high confidence*). A sustainable bioeconomy
30 relying on biomass resources will need to be supported by technology innovation and international
31 cooperation and governance of global trade to disincentivize environmental and social externalities
32 (medium confidence). {12.5, Cross-Working Group Box 3}

33 **Coordinated, cross-sectoral approaches to climate change mitigation should be adopted to target**
34 **synergies and minimize trade-offs between sectors and with respect to sustainable development**
35 (*robust evidence, high agreement*). This requires integrated planning using multiple-objective-multiple-
36 impact policy frameworks. Strong inter-dependencies and cross-sectoral linkages create both
37 opportunities for synergies and the need to address trade-offs related to mitigation options and
38 technologies. This can only be done if coordinated sectoral approaches to climate change mitigations
39 policies that mainstream these interactions are adopted. Integrated planning and cross-sectoral
40 alignment of climate change policies are particularly evident in developing countries' NDCs pledged
41 under the Paris Agreement, where key priority sectors such as agriculture and energy are closely aligned
42 between the proposed mitigation and adaptation actions in the context of sustainable development and
43 the SDGs. {12.6.2}

44 **Carbon leakage is a critical cross-sectoral and cross-country consequence of differentiated**
45 **climate policy** (*robust evidence, medium agreement*). Carbon leakage occurs when mitigation measures

1 implemented in one country/sector lead to increased emissions in other countries/sectors. Global
2 commodity value chains and associated international transport are important mechanisms of carbon
3 leakage. Reducing emissions from the value chain and transportation can offer opportunities to mitigate
4 three elements of cross-sectoral spill-overs and related leakage: 1) domestic cross-sectoral spill-overs
5 within the same country; 2) international spill-overs within a single sector resulting from substitution
6 of domestic production of carbon-intensive goods with their imports from abroad; and 3) international
7 cross-sectoral spill-overs among sectors in different countries. {12.6.3}

8 **Cross-sectoral considerations in mitigation finance are critical for the effectiveness of mitigation**
9 **action as well as for balancing the often conflicting social, developmental, and environmental**
10 **policy goals at the sectoral level** (*medium evidence, medium agreement*). True resource mobilisation
11 plans that properly address mitigation costs and benefits at sectoral level cannot be developed in
12 isolation of their cross-sectoral implications. There is an urgent need for multilateral financing
13 institutions to align their frameworks and delivery mechanisms including the use of blended financing
14 to facilitate cross-sectoral solutions as opposed to causing competition for resources among sectors.
15 {12.6.4}

16 **Understanding the co-benefits and trade-offs associated with mitigation is key to supporting**
17 **societies to prioritize among the various sectoral policy options** (*medium evidence, medium*
18 *agreement*). For example, CDR options can have positive impacts on ecosystem services and the SDGs,
19 but also potential adverse side-effects; transforming food systems has potential co-benefits for several
20 SDGs, but also trade-offs; and land-based mitigation measures may have multiple co-benefits but may
21 also be associated with trade-offs among environmental, social, and economic objectives. Therefore,
22 the possible implementation of the different sectoral mitigation options would depend on how societies
23 prioritise mitigation versus other products and services including food, material wellbeing, nature
24 conservation and biodiversity protection, as well as on other considerations such as society's future
25 dependence on CDR and on carbon-based energy and materials. {12.3, 12.4, 12.5, 12.6.1}

26 **Governance of CDR, food systems and land-based mitigation can support effective and equitable**
27 **policy implementation** (*medium evidence, high agreement*). Effectively responding to climate change
28 while advancing sustainable development will require coordinated efforts among a diverse set of state-
29 and non-state-actors on global, multi-national, national, and sub-national levels. Governance
30 arrangements in public policy domains that cut through traditional sectors are confronted with specific
31 challenges, such as establishing reliable systems for monitoring, reporting and verification (MRV) that
32 allow evaluation of mitigation outcomes and co-benefits. Effectively integrating CDR into mitigation
33 portfolios can build on already existing rules, procedures and instruments for emissions abatement.
34 Additionally, to accelerate research, development, and demonstration, and to incentivise CDR
35 deployment, a political commitment to formal integration into existing climate policy frameworks is
36 required, including reliable MRV of carbon flows. Food systems governance may be pioneered through
37 local food policy initiatives complemented by national and international initiatives, but governance on
38 the national level tends to be fragmented, and thus have limited capacity to address structural issues like
39 inequities in access. The governance of land-based mitigation, including land-based CDR, can draw on
40 lessons from previous experience with regulating biofuels and forest carbon; however, integrating these
41 insights requires governance that goes beyond project-level approaches and emphasizes integrated land
42 use planning and management within the frame of the SDGs. {7.4 Box 7.2, 7.6, 12.3.3, 12.4, 12.5}

43

44

1 **12.1 Introduction**

2 **12.1.1 Chapter overview**

3 The scope of this chapter was motivated by the need for a succinct bottom-up cross-sectoral view of
4 greenhouse gas (GHG) emissions mitigation coupled with the desire to provide systemic perspectives
5 of critical mitigation potentials and options that go beyond individual sectors and cover cross-sectoral
6 topics such as food systems, land systems, and carbon dioxide removal (CDR) methods. Driven by this
7 motivation, Chapter 12 provides a focused thematic assessment of CDR methods and food systems,
8 followed by consideration of land-related impacts of mitigation options (land-based CDR and other
9 mitigation options that occupy land) and other cross-sectoral impacts of mitigation, with emphasis on
10 synergies and trade-offs between mitigation options, and between mitigation and other environmental
11 and socio-economic objectives. The systems focus is unique to AR6 and is of critical policy relevance
12 as it informs coordinated approaches to planning interventions that deliver multiple benefits and
13 minimise trade-offs, and coordinated policy approaches to support such planning, to tap relatively
14 under-explored areas for the strengthening and acceleration of mitigation efforts in the short to medium
15 term, and for dealing with residual emissions in hard-to-transition sectors in the medium to long term.

16 Table 12.1 presents an overview of the cross-sectoral perspectives addressed in Chapter 12, mapping
17 the chapter main themes to the sectoral and global chapters in this report. These mappings reflect the
18 cross-sectoral aspects of mitigation options in the context of sustainable development, sectoral policy
19 interactions, governance, implications in terms of international trade, spill-over effects, and
20 competitiveness, and cross-sectoral financing options for mitigation. While some cross-sector
21 technologies are covered in more detail in sectoral chapters, this chapter covers important cross-sectoral
22 linkages and provides synthesis concerning costs and potentials of mitigation options, and co-benefits
23 and trade-offs that can be associated with deployment of mitigation options. Additionally, Chapter 12
24 covers CDR methods and specific considerations related to land use and food systems, complementing
25 Chapter 7. The literature assessed in the chapter includes both peer-reviewed and grey literature post
26 IPCC AR5 including IPCC SR1.5, IPCC SRCCL and IPCC SROCC. Knowledge gaps are identified
27 and reflected where encountered, as well as in a separate section. Finally, a strong link is maintained
28 with sectoral chapters and the relevant global chapters of this report to ensure consistency.

29

30 **12.1.2 Chapter content**

31 Chapters 5 to 11 assess outcomes from mitigation measures that are applicable in individual sectors,
32 and potential co-benefits and adverse side effects of these individual measures. Chapter 12 brings
33 together the cross-sectoral aspects of these assessments including synergies and trade-offs as well as
34 the implications of measures that have application in more than one sector and measures whose
35 implementation in one sector impacts implementation in other sectors.

36 Taking stock of the sectoral mitigation assessments, Chapter 12 provides a summary synthesis of
37 sectoral mitigation costs and potentials in the short and long term along with comparison to the top-
38 down IAM assessment literature of Chapter 3 and the national/regional assessment literature of Chapter
39 4.

40 In the context of cross-sectoral synergies and trade-offs, the chapter identifies a number of mitigation
41 measures that have application in more than one sector. Examples include measures involving product
42 and material circularity, which contribute to mitigation of GHG emissions in a number of ways, such

1 as treatment of organic waste to reduce methane emissions, avoid emissions through generation of
2 renewable energy, and reduce emissions through substitution of synthetic fertilisers. Low carbon energy
3 technologies such as solar and wind may be used for grid electricity supply, as embedded generation in
4 the buildings sector (e.g., rooftop solar) and for energy supply in the agriculture sector. Nuclear and
5 bio-based thermal electric generation can provide multiple synergies including base load to augment
6 solar and wind, district heating, and seawater desalination. Grid-integrated hydrogen systems can buffer
7 variability of solar and wind power and is being explored as a mitigation option in the transport and
8 industry sectors. Carbon Capture and Storage (CCS) has potential application in a number of industrial
9 processes (cement, iron and steel, petroleum refining and pulp and paper) and the fossil fuel electricity
10 sector. When coupled with energy recovery from biomass (BECCS), CCS can help to provide CO₂
11 removal from the atmosphere. On the demand side, electric vehicles are also considered an option for
12 balancing variable power, energy efficiency options find application across the sectors, as does reducing
13 demand for goods and services, and improving material use efficiency. Focused inquiry into these areas
14 of cross-sectoral perspectives is provided for CDR, food systems, and land-based mitigation options.

15 A range of examples of where mitigation measures result in cross-sectoral interactions and integration
16 is identified. The mitigation potential of electric vehicles, including plug-in hybrids, is linked to the
17 extent of decarbonisation of the electricity grid, as well as to the liquid fuel supply emissions profile.
18 Making buildings energy positive, where excess energy is used to charge vehicles, can increase the
19 potential of electric and hybrid vehicles. Advanced process control and process optimisation in industry
20 can reduce energy demand and material inputs, which in turn can reduce emissions linked to resource
21 extraction and manufacturing. Trees and green roofs planted to counter urban heat islands reduce the
22 demand for energy for air conditioning and simultaneously sequester carbon. Material and product
23 circularity contributes to mitigation, such as treatment of organic waste to reduce methane emissions,
24 generate renewable energy, and to substitute for synthetic fertilisers.

25 The chapter also discusses cross-sectoral mitigation potential related to diffusion of General-Purpose
26 Technologies (GPT), such as electrification, digitalisation, and hydrogen. Examples include the use of
27 hydrogen as an energy carrier, which, when coupled with low carbon energy, has potential for driving
28 mitigation in energy, industry, transport, and buildings (Box 12.5), and digitalisation has the potential
29 for reducing GHG emissions through energy savings across multiple sectors.

30 The efficient realisation of the above examples of cross-sectoral mitigation would require careful design
31 of government interventions across planning, policy, finance, governance, and capacity building fronts.
32 In this respect, Chapter 12 assesses literature on cross-sectoral integrated policies, cross-sectoral
33 financing solutions, cross-sectoral spill-overs and competitiveness effects, and on cross-sectoral
34 governance for climate change mitigation.

35 Finally, in the context of cross-sectoral synergies and trade-offs, the chapter assesses the non-climate
36 mitigation co-benefits and adverse effects in relation to SDGs, building on the fast-growing literature
37 on the non-climate impacts of mitigation.

38

39 **12.1.3 Chapter layout**

40 The chapter is mapped into seven sections. Cost and potentials of mitigation technologies are discussed
41 in Section 12.2, where a comparative assessment and a summary of sectoral mitigation cost and
42 potentials is provided in coordination with the sectoral Chapters 5 to 11, along with a comparison to
43 aggregate cost and potentials based on IAM outputs presented in Chapter 3.

1 Section 12.3 provides a synthesis of the state and potential contribution of CDR methods for addressing
2 climate change. CDR options associated with the AFOLU and Energy sectors are dealt with in Chapters
3 6 and 7 and synthesised in Section 12.3. Other methods, not dealt with elsewhere, are covered in more
4 detail. A comparative assessment is provided for the different CDR options in terms of costs, potentials,
5 governance, impacts and risks, and synergies and trade-offs.

6 Section 12.4 assesses the literature on food systems and GHG emissions. The term ‘food system’ refers
7 to a composite of elements (environment, people, inputs, processes, infrastructures, institutions, etc.)
8 and activities that relate to the production, processing, distribution, preparation and consumption of
9 food, and the outputs of these activities, including socio-economic and environmental outcomes.
10 Climate change mitigation opportunities and related implications for sustainable development and
11 adaptation are assessed, including those arising from food production, landscape impacts, supply chain
12 and distribution, and diet shifts.

13 Section 12.5 provides a cross-sectoral perspective on land occupation and related impacts, risks and
14 opportunities associated with land-based mitigation options as well as mitigation options that are not
15 designated land-based, yet occupy land. It builds on SRCCCL and Chapter 7 in this report, which covers
16 mitigation in agriculture, forestry and other land use (AFOLU), including biomass production for
17 mitigation in other sectors. In addition to an assessment of biophysical and socioeconomic risks, impacts
18 and opportunities, this section includes a cross-chapter box (WGII and WGIII) on Mitigation and
19 Adaptation via the Bioeconomy, and a box on Land Degradation Neutrality as a framework to manage
20 trade-offs in land-based mitigation.

21 Section 12.6 provides a cross-sectoral perspective on mitigation, co-benefits, and trade-offs, including
22 those related to sustainable development and adaptation. The synthesised sectoral mitigation synergies
23 and trade-offs are mapped into options/technologies, policies, international trade, and finance domains.
24 Cross-sectoral mitigation technologies fall into three categories in which the implementation of the
25 technology: (i) occurs in parallel in more than one sector; (ii) could involve interaction between sectors,
26 and/or (iii) could create resource competition among sectors. Policies that have direct sectoral effects
27 include specific policies for reducing GHG emissions and non-climate policies that yield GHG
28 emissions reductions as co-benefits. Policies may also have indirect cross-sectoral effects, including
29 synergies and trade-offs that may, in addition, spill over to other countries.

30 Section 12.7 provides an overview of knowledge gaps, which could be used to inform further research.

1

Table 12.1 An overview of cross-sector perspectives addressed in Chapter 12

	<i>Sectoral chapters</i>							<i>Global chapters</i>

1

1 **12.2 Aggregation of sectoral costs and potentials**

2 The aim of this section is to provide a consolidated overview of the net emissions reduction potentials
3 and costs for mitigation options available in the various sectors dealt with in the sectoral chapters 6, 7,
4 9, 10 and 11 of this assessment report. This overview provides policy-makers with an understanding of
5 which options are more or less important in terms of mitigating emissions in the short term (here
6 interpreted as 2030), and which ones are more or less costly. The intention is not to provide a high level
7 of accuracy for each technology cost or potential, but rather to indicate relative importance on a global
8 scale and whether costs are low, intermediate or high. The section starts with an introduction (Section
9 12.2.1), providing definitions and the background. Next, ranges of net emission reduction potentials
10 and the associated costs for the year 2030 are presented (Section 12.2.2) and compared to earlier
11 estimates and with the outputs of integrated assessment models (IAMs) (Section 12.2.3). Finally, an
12 outlook to the year 2050 is provided (Section 12.2.4).

13 **12.2.1 Introduction**

14 The term ‘mitigation potential’ is used here to report the quantity of net greenhouse gas emissions
15 reductions that can be achieved by a given mitigation option relative to specified reference scenario.
16 The net greenhouse gas emission reduction is the sum of reduced emissions and enhanced sinks. Several
17 types of potential can be distinguished. The technical potential is the mitigation potential constrained
18 by theoretical limits in addition to the availability of technology and practices. Quantification of
19 technical potentials primarily takes into account technical considerations, but social, economic and/or
20 environmental considerations are sometimes also considered, if these represent strong barriers for the
21 deployment of an option. The economic potential, being the potential reported in this section, is the
22 proportion of the technical potential for which the social benefits exceed the social costs, taking into
23 account a social discount rate and the value of externalities (see glossary). In this section, only
24 externalities related to greenhouse gas emissions are taken into account. They are represented by using
25 different cost cut-off levels of options in terms of USD per tonne of avoided CO₂-eq emissions. Other
26 potentials, such as market potentials, could also be considered, but they are not included in this section.

27 The analysis presented here is based, as far as possible, on information contained in Chapters 6, 7, 9,
28 10 and 11, where costs and potentials, referred to here as ‘sectoral mitigation potentials’ have been
29 discussed for each individual sector. In the past, these were designated as bottom-up potentials, in
30 contrast to the top-down potentials that are obtained from integrated energy-economic models and
31 IAMs. However, IAMs increasingly include ‘bottom-up’ elements, which makes the distinction less
32 clear. Still, sectoral studies often have more technical and economic detail than IAMs. They may also
33 provide more up-to-date information on technology options and associated costs. However, aggregation
34 of results from sectoral studies is more complex, and although interactions and overlap are corrected
35 for as far as possible in this analysis, it is recognised that such systemic effects are much more rigorously
36 taken into account in IAMs. A comparison is made between the sectoral results and the outcomes of the
37 IAMs in Section 12.2.3.

38 Costs of mitigation options will change over time. For many technologies, costs will reduce as a result
39 of technological learning. An attempt has been made to take into account the average, implementation-
40 weighted costs until 2030. However, the underlying literature did not always allow such costs to be
41 presented. For the year 2030, the results are presented similarly to AR4, with a breakdown of the
42 potential in “cost bins”. For the year 2050, a more qualitative approach is provided. The origins of the
43 cost data in this section mostly are based on studies carried out in the period 2015-2020. Given the wide
44 range of the cost bins that are used in this section it is not meaningful (and often not possible) to convert

1 to USD-values for one specific year. This may lead to some extra uncertainty, but this is expected to be
2 relatively small.

3 As indicated previously, net emission reduction potentials are presented based on comparison with a
4 reference scenario. Unfortunately, not all costs and potentials found in the literature are determined
5 against the same reference scenarios. In this assessment reference scenarios are based on what were
6 assumed current-policy scenarios in the period 2015-2019. Typical reference scenarios are the SSP2
7 scenarios (Fricko et al. 2017) and the Current Policies scenario from the World Energy Outlook 2019
8 (IEA 2019). They can both be considered scenarios with middle-of-the-road expectations on population
9 growth and economic development, but there are still some differences between the two (Table 12.2).
10 The net emission reduction potentials reported here were generally based on analyses carried out before
11 2020, so the impact of the COVID-19 pandemic was not taken into account. For comparison, the Stated
12 Policies scenario of the World Energy Outlook 2020 (IEA 2020a) is also shown, one of the scenarios
13 in which the impact of COVID-19 was considered. Variations of up to 10% between the different
14 reference scenarios exist with respect to macro-variables such as total primary energy use and total
15 GHG emissions. The potential estimates presented below should be interpreted against this background.
16 The total emissions under the reference scenarios in 2030 are expected to be in the range of 54 to 68
17 GtCO₂-eq yr⁻¹ with a median of 60 GtCO₂-eq yr⁻¹ (Chapter 4, Table 4.1).

18 For the energy sector the potentials are determined using the World Energy Outlook 2019 Current
19 Policies Scenario as a reference (IEA 2019). However, for the economic assessment more recent LCOEs
20 for different electricity generating technologies were used (IEA 2020a). For the agriculture, forestry
21 and other land use (AFOLU) sector, the potentials were derived from a variety of studies. It may be
22 expected that the best estimates, as averages, match with the reference in a middle-of-the-road scenario.
23 For the buildings sector the Current Policies scenario of World Energy Outlook 2019 (IEA 2019) was
24 used as a reference. For the transport sector, the references of the underlying sources were used. For the
25 industry sector, the scenarios used have emissions that are slightly higher than in the Current Policies
26 scenario from the World Energy Outlook 2019 (IEA 2019).

1 **Table 12.2: Key characteristics of the scenarios that are used as a reference for determining costs and**
 2 **potentials. The values are for the year 2030.**

	SSP2 reference	All reference scenarios	WEO- 2019	WEO- 2020	AR6 Chapter 4
	(MESSAGE - GLOBIOM) (Fricko et al. 2017)	median (25/75 per- centiles in parenthesis) (AR6 scenarios database)	(Current Policies) (IEA 2019)	(Stated Policies) (IEA 2020a)	(Chapter 4, Table 4.1)
Real GDP (PPP) (10 ¹² USD)	158 (USD ₂₀₁₀)	159 (154–171)	3.6% p.a.↑ (2018 to 2030)	2.9% p.a.↑ (2019 to 2030)	
Population (billion)	8.30	8.30 (8.20–8.34)	8.60		
Total primary energy use (EJ)	627	670 (635–718)	710	660	
Total final energy use (EJ)	499	480 (457–508)	502	472	
Energy-related CO ₂ emissions (Gt)	33.0	37.9 (34.7–41.4)	37.4	33.2*	37 (35–45)
CO ₂ emissions energy and industry (Gt)	37.9	42.3 (39.0–45.8)		36.0	
Total CO ₂ (emissions Gt)	40.6	45.7 (41.8–49.4)			43 (38–51)
Total greenhouse gas emissions (GtCO ₂ -eq)	52.7	59.7 (55.0–65.8)			60 (54–68)

3 *The difference between WEO-2020 and WEO-2019 is partly explained by the fact that WEO-2019 had two
 4 different reference scenarios: Current Policies and Stated Policies. WEO-2020 has only one reference: the Stated
 5 Policies Scenario (STEPS), which “is based on today’s policy settings”. The Stated Policy scenario in WEO-
 6 2019 had energy-related emissions of 34.9 GtCO₂.

7

1 **12.2.2 Costs and potentials of options for 2030**

2 In this section, we present an overview of mitigation options per sector. An overview of net emission
3 reduction potentials for different mitigation options is presented in Table 12.3.

4 Firstly, a brief overview of the process of data collection is presented, with a more detailed overview
5 being found in Supplementary Material SM 12.A.2. For the energy sector, the starting point for the
6 determination of the emission reduction potentials was the Emissions Gap Report (UNEP 2017), but
7 new literature was also assessed, and a few studies that provide updated estimates of the mitigation
8 potentials were included. It was found that higher mitigation potentials than in the UNEP report are
9 now reported for solar and wind energy, but at the same time electricity production by solar and wind
10 energy in the reference scenario has increased, compared to earlier versions of the World Energy
11 Outlook. The net effect is a modest increase of the average value of the potential, and a wider uncertainty
12 range. Costs of electricity generating technologies are discussed in Chapter 6, (Section 6.4.7) with a
13 summary of LCOEs from the literature being presented in Section 6.4.7. Mitigation costs of electricity
14 production technology depend on local conditions and on the baseline technology being displaced, and
15 it is difficult to determine the distribution over the cost ranges used in this assessment. However, it is
16 possible to indicate a broad cost range for these technologies. These cost ranges are presented in Table
17 12.3. For onshore wind and utility scale solar energy, there is strong evidence that despite regional
18 difference in resource potential and cost, a large part of the mitigation potential can be found in the
19 negative cost category or at cost parity with fossil fuel based options. This is also the case for nuclear
20 energy in some regions. Other technologies show mostly positive mitigation potentials, the highest
21 mitigation costs are for CCS, bioelectricity with CCS, for details see Supplementary Material SM
22 12.A.2.

23 For the AFOLU sector, assessments of global net emission reduction studies were provided by Chapter
24 7 (Table 7.3). The number of studies depends on the type of mitigation action, but ranges from 5 to 9.
25 Each of these studies relies on a much larger number of underlying data sources. From these studies,
26 emission reduction ranges and best estimates were derived. The studies presented refer to different years
27 in the period 2020 to 2050, and the mitigation potential presented for AFOLU primarily refers to the
28 average over the period 2020 to 2050. However, because most of the activities involve storage of carbon
29 in stocks that accumulate carbon, or conversely decay over time (e.g., forests, mangroves, peatland
30 soils, agricultural soils, wood products), the 2020 to 2050 average provides a good approximation of
31 the amount of permanent atmospheric CO₂ mitigation that could be available at a given price in 2030.
32 The exception is BECCS which is in an early upscaling phase, so the potential estimated by Chapter 7
33 as an average for the 2020 to 2050 period is not included in Table 12.3. Note that for the energy sector
34 a mitigation potential for BECCS is provided in Table 12.3.

35 The emission reduction potentials for the buildings sector were based on the analysis by Chapter 9
36 authors of a large number of sectoral studies for individual countries or regions. In total, the chapter
37 analysed the results of 67 studies that assess the potential of technological energy efficiency and onsite
38 renewable energy production and use, and the results of 11 studies that assess the potential of sufficiency
39 measures helping avoid demand for energy and materials. The sufficiency measures were included in
40 models by reorganization of human activities, efficient design, planning, and use of building space,
41 higher density of building and settlement inhabitancy, redefining and downsizing goods and equipment,
42 limiting their use to health, living, and working standards, and their sharing. Most of these studies
43 targeted 2050 for the decarbonisation of buildings; the potentials in 2030 reported here rely on the
44 estimates for 2030 provided by these studies or on the interpolated estimates targeting these 2050
45 figures. Based on these individual country studies, regional aggregate emission reduction percentages
46 were found. The potential estimates were assembled in the order sufficiency, efficiency, renewable

1 options, correcting the amount of the potential at each step for the interaction with preceding measures.
2 Note that the option ‘Enhanced use of wood products’ was analysed by Chapter 7, but is listed under
3 the buildings sector in Table 12.3, as such enhanced use of wood takes place predominantly in the
4 construction sector.

5 For the transport sector, Chapter 10 provided data on the emission reduction potential for shipping. For
6 the other transportation modes, additional sources were used to achieve a complete overview of
7 emission reduction potentials (for further details, see Supplementary Material 12.A.2). A limited
8 number of estimates for global emission reduction potential is available: the total number of sources is
9 about 10, and some estimates rely on just one source. The data have been coordinated with Chapter 10
10 authors.

11 For the industrial sector, global emission reduction potentials per technology class per sector were
12 derived by Chapter 11 authors, using primarily sectoral or technology-oriented literature. The analysis
13 is based on about 75 studies, including sectoral assessments (Sections 11.4.1, 11.4.2, Figure 11.13).

14 For methane emission reduction from oil and gas operations, coal mining, waste treatment and
15 wastewater, an analysis was done, based on three major data sources in this area (US EPA 2019;
16 Harmsen et al. 2019; Höglund-Isaksson et al. 2020), and for oil and gas operations complemented by
17 (IEA 2021a). A similar analysis for reductions of emissions of fluorinated gases was carried out based
18 on analysis by the same institutes (Purohit and Höglund-Isaksson 2017; US EPA 2019; Harmsen et al.
19 2019). Data for CDR options not discussed previously (such as DACCS and enhanced weathering)
20 were taken from Section 12.3. For more details about data sources and data processing, see
21 Supplementary Material 12.A, Section SM 12.A.2.

22 In Table 12.4 mitigation potentials for all gases are presented in GtCO₂-eq. For most sectors the
23 mitigation potentials (notably for methane emissions reductions from coal, oil and gas, waste and
24 wastewater) have been converted to CO₂-eq using global warming potentials (GWP) values as presented
25 in the 6th Assessment Report (Cross-Chapter Box 2 in Chapter 2). However, the underlying literature
26 did not always accommodate this, in which cases older GWP values apply. Given the uncertainty ranges
27 in the mitigation potentials in Table 12.3, the impact on the results of using different GWP values is
28 considered to be very small.

Table 12.3: Detailed overview of global net GHG emission reduction potentials (GtCO₂-eq) in the various cost categories for the year 2030. Note that potentials within and across sectors cannot be summed, as the adoption of some options may affect the mitigation potentials of other options. Only monetary costs and benefits of options are taken into account. Negative costs occur when the benefits are higher than the costs. For wind energy, for example, this is the case if production costs are lower than those of the fossil alternatives. Ranges are indicated for each option separately, or indicated for the sector as a whole (see column “Notes”); they reflect full ranges. Cost ranges are not cumulative, e.g., to obtain the full potential below 50 USD tCO₂-eq⁻¹, the potentials in the cost bins <0, 0–20 and 20–50 USD tCO₂-eq⁻¹ need to be summed together.

Emission reduction options (including carbon sequestration options)	Cost categories (USD tCO ₂ -eq ⁻¹)					Notes
	<0	0–20	20–50	50–100	100–200	
<i>Energy sector</i>						<i>Cost ranges are derived as ranges of LCOEs for different electricity generating technologies and the potentials are updated from UNEP (2017).</i>
Wind energy		2.1–5.6 (majority in <0 range)				Costs for system integration of intermittent renewables are not included, but these are expected to have limited impact until 2030 and will depend on market design and cross-sectoral integration
Solar energy		2.0–7.0 (majority in <0 range)				Ibid.
Nuclear energy			0.88 ±50%			
Bioelectricity				0.86 ±50%		Biomass use for indoor heating and industrial heat is not included here. Currently, about 90% of renewable industrial heat consumption is biobased, mainly in industries that can use their own biomass waste and residues (IEA, 2020)
Hydropower			0.32 ±50%			Mitigation costs show large variation and may end up beyond these ranges.

Geothermal energy		0.74 ±50%				Mitigation costs show large variation and may end up beyond these ranges.
Carbon capture and storage (CCS)				0.54 ±50%		
Bioelectricity with CCS				0.30 ±50%		
CH ₄ emission reduction from coal mining	0.04 (0.01–0.06)	0.41 (0.15–0.64)	0.03 (0.02–0.05)	0.02 (0.01–0.03)		
CH ₄ emission reduction from oil and gas operations	0.31 (0.12–0.56)	0.61 (0.23–1.30)	0.07 (0.03–0.20)	0.06 (0.00–0.29)	0.10 (0–0.29)	
<i>Land-based mitigation options (including agriculture and forestry)</i>						<p><i>Potentials for AFOLU are averages for the period 2020–2050, and represent a proxy for mitigation in 2030.</i></p> <p><i>Technical potentials listed below include the potentials already listed in the previous columns.</i></p> <p><i>Note that in Table 7.3 the same potentials are listed, but they are cumulative over the cost bins.</i></p>
Carbon sequestration in agriculture (soil carbon sequestration, agroforestry and biochar application)		0.50 (0.38–0.60)	0.73 (0.5–1.0)	2.21 (0.6–3.9)		Technical potential: 9.5 (range 1.1–25.3)
CH ₄ and N ₂ O emission reduction in agriculture (reduced enteric fermentation, improved		0.35	-	0.28		Technical potential: 1.7 (range 0.5–3.2)

manure management, nutrient management, rice cultivation)		(0.11–0.84)		(0.19–0.46)		GWPs used from AR4 and AR5
Protection of natural ecosystems (avoid deforestation, loss and degradation of peatlands, coastal wetlands and grasslands)		2.28 (1.7–2.9)	0.12 (0.06–0.18)	1.63 (1.3–4.2)	0.22 (0.09–0.45)	Technical potential 6.2 (range 2.8–14.4)
Restoration (afforestation, reforestation, peatland restoration, coastal wetland restoration)		0.15	0.57 (0.2–1.5)	1.46 (0.6–2.3)	0.66 (0.4–1.1)	Technical potential 5.0 (range 1.1–12.3)
Improved forest management, fire management		0.38 (0.32–0.44)	-	0.78 (0.32–1.44)		Technical potential 1.8 (range 1.1–2.8)
Reduce food loss and food waste						Feasible potential 0.5 (0.1–0.9) Technical potential 0.7 (0.1–1.6) Estimates reflect direct mitigation from diverted agricultural production only, not including land-use effects
Shift to sustainable healthy diets						Feasible potential 1.7 (1.0–2.7) Technical potential 3.5 (2.1–5.5) Estimates reflect direct mitigation from diverted agricultural production only, not including land-use effects

<i>Buildings</i>						<i>The numbers were corrected for the potential overlap between options in the order “sufficiency, efficiency, renewable measures” and they could be therefore added up. In 2050, much larger and cheaper potential is available (see 9.6 in Chapter 9); the potential in 2030 is lower and more expensive mostly due to various feasibility constrains.</i>
Sufficiency to avoid demand for energy services (e.g., efficient building use and increased inhabitancy and density)	0.56 (0.28–0.84)					
Efficient lighting, appliances and equipment, including ICT, water heating and cooking technologies	0.73 (0.54–0.91)					
New buildings with very high energy performance (change in construction methods, management and operation of buildings, efficient heating, ventilation and air conditioning)			0.35 (0.26–0.53)		0.83 (0.62–1.24)	
Onsite renewable production and use (often backed-up with demand-side flexibility and digitalization measures, typically installed in very new high energy performance buildings)			0.20 (0.15–0.30)		0.27 (0.20–0.40)	

Improvement of existing building stock (thermal efficiency of building envelopes, management and operation of buildings, and efficient heating, ventilation and air conditioning leading to “deep” energy savings)						0.27 (0.20–0.34)	Additionally, there is 0.50 (range 0.37–0.62) GtCO ₂ -eq of potential above a price of 200 USD tCO ₂ -eq ⁻¹
Enhanced use of wood products							Technical potential 1.0 (range 0.04–3.7) Economic potential 0.38 (range 0.3–0.5) (varying carbon prices). Potential is mainly in the construction sector.
<i>Transport</i>							Options for the transportation sector have an uncertainty of ±50%.
Light duty vehicles – fuel efficiency	0.6						
Light duty vehicles – electric vehicles	0.5–0.7						Depending on the carbon intensity of the electricity supplied to the vehicles.
Light duty vehicles – shift to public transport	0.5						
Light duty vehicles – shift to bikes and e-bikes	0.2						
Heavy duty vehicles – fuel efficiency	0.4						
Heavy duty vehicles – electric vehicles	0.2						
Heavy duty vehicles – shift to rail							No data available.
Shipping – efficiency, optimisation, biofuels	0.5 (0.4–0.7)						

Aviation – energy efficiency	0.12–0.32					Limited evidence
Biofuels			0.6–0.8			
<i>Industry</i>						<p><i>The numbers for the industry sector typically have an uncertainty of ±25%.</i></p> <p><i>The numbers are corrected for overlap between the options, except for the 0.15 GtCO₂ potential in the highest cost bin. For the rest they can be aggregated to provide full potentials.</i></p>
Energy efficiency		1.14				This only applies to more efficient use of fuels. More efficient use of electricity is not included.
Material efficiency			0.93			
Circularity (enhanced recycling)			0.48			
Fuel switching			1.28	0.67	0.15	
Feedstock decarbonisation, process change				0.38		
Carbon capture, utilization and storage (CCU and CCS)					0.15	
Cementitious material substitution			0.28			
Reduction of non-CO ₂ emissions		0.2				

<i>Cross-sectorial</i>						
Emission reduction of fluorinated gases	0.26 (0.01–0.50)	0.68 (0.55–0.90)	0.18 (0.01–0.42)	0.09 (0–0.20)	0.03 (0–0.05)	GWPs not updated
Reduction of CH ₄ emissions from solid waste	0.33 (0.24–0.43)	0.11 (0.03–0.15)	0.06 (0.03–0.08)	0.04 (0.01–0.10)	0.08 (0.02–0.12)	
Reduction of CH ₄ emissions from wastewater	0.02 (0–0.05)	0.03 (0.01–0.05)	0.04 (0.01–0.07)	0.03 (0.02–0.04)	0.07 (0.01–0.16)	
Direct air carbon capture and storage					very small	There is potential in these categories, but given the current technology readiness levels, for 2030 the potential is limited. Also, it is not certain whether the costs will already drop below 200 USD tCO ₂ ⁻¹ before 2030. In the longer term, much larger potentials are projected, see Section 12.3.1.
Enhanced weathering					very small	

1 For all options, uncertainty ranges of the mitigation potentials are given in Table 12.3. As far as possible,
2 the ranges represent the variation in assessments found in the literature. This is the case for wind and
3 solar energy, for the AFOLU options, for the methane mitigation options (coal, oil and gas, waste and
4 wastewater) and for fluorinated gas mitigation. For the latter options, some variability exists for each
5 cost bin, but aggregated over cost ranges the variation is much smaller, typically $\pm 50\%$. For the
6 buildings sector and the industrial sector options, the uncertainty in the mitigation potential is estimated
7 by the lead authors of Chapters. For options for which only limited sources were available an uncertainty
8 range of $\pm 50\%$ was used. Overall, the uncertainty range per option is typically in the range of $\pm 20\%$ to
9 $\pm 60\%$.

10 Despite these uncertainties, clearly a number of options with high potentials can be identified, including
11 solar energy, wind energy, reducing conversion of forests and other natural ecosystems, and restoration
12 of forests and other natural ecosystems. As mid-range values, they each represent 4 to 7% of total
13 reference emissions for 2030. Soil carbon sequestration in agriculture and fuel switching in industry
14 can also be considered as options with high potential, although it should be noted that these options
15 consist of a number of discernible sub-options, see Table 12.3. It can be observed that for each sector,
16 a variety of options is available. Many of the smaller options each make up 1 to 2% of the reference
17 emissions for 2030. Within this group of smaller options there are some categories that, summed
18 together, stand out as substantial: the energy efficiency options and the methane mitigations options.

19 Costs are highly variable across the options. All sectors have several options for which at least part of
20 the potential has mitigation costs below 20 USD tCO_2^{-1} . The only exception is the industrial sector, in
21 which only energy efficiency is available below this cost level. At the same time, a substantial part of
22 the emission reduction potential comes at higher cost, much being in the 20 to 100 USD tCO_2^{-1} cost
23 ranges. All sectors have substantial additional potential in these cost ranges; only for transportation is
24 this limited. Aggregation of the potentials per cost bin shows that the potential in these cost bins is
25 marginally smaller than in the two cheapest cost bins. For some options, potential was identified in the
26 100 to 200 tCO_2^{-1} cost bin. The mitigation potentials identified in this cost range make up only a small
27 part of the total mitigation potential. It could be that there is limited potential in this range; however, a
28 more plausible explanation, supported by several authors of sectoral chapters, is that this cost range is
29 relatively unexplored.

30 In this assessment, the emphasis is on the specific mitigation costs of the various options, and these are
31 often considered as an indicator to prioritise options. However, in such a prioritisation, other elements
32 will also play a role, like the development of technology for the longer term (Section 12.2.4) and the
33 need to optimise investments over longer time periods, see for example Vogt-Schilb et al. (2018) who
34 argue that sometimes it makes sense to start with implementing the most expensive option.

35 In this section, an overview of emission mitigation options for the year 2030 was presented. The
36 overview of the mitigation potential is based on a variety of approaches, relying on a large number of
37 sources, and the number of sources varied strongly from sector to sector. The main conclusions from
38 this section are: i) there is a variety of options per sector, ii) per sector the options combined show
39 significant mitigation potential, iii) there are a few major options and a lot of smaller ones, and iv) more
40 than half of the potential comes at costs below 20 USD tCO_2^{-1} (between sectors: *medium to robust*
41 *evidence, high agreement*).

42

12.2.3 Aggregation of sectoral results and comparison with earlier analyses and Integrated Assessment Models

In this section, the mitigation potentials are aggregated per sector, and then to the global economy. These potentials, which are based on sectoral analysis, are then compared to the results from earlier assessments and the results from Integrated Assessment Models (IAMs). Given the incompleteness of data on the mitigation potential at mitigation costs larger than 100 USD tCO₂⁻¹, the focus will be on options with mitigation costs below 100 USD tCO₂⁻¹.

As suggested previously, the overview presented in Table 12.3 should be interpreted with care, as the implementation of one option may affect the mitigation potential of another option. Most sectoral chapters have supplied mitigation potentials that were already adjusted for overlap and mutual influences (industry, buildings, AFOLU). For the energy sector, interactions between the options will occur, but parallel implementation of all the options seems to be possible; if all options at costs levels below 100 USD tCO₂⁻¹ would be implemented, this would lead to an additional power generation with no direct CO₂ emissions of 41% of the total projected generation in 2030. This seems to be possible, but as higher penetrations are relatively unexplored, we apply a smaller uncertainty range at the high end. For the calculation of the aggregate potentials in the energy sector, error propagation rules were applied. For the transport sector, there will be interaction between the technical measures on the one hand and the modal shift measures on the other hand. Given the small mitigation contribution of the modal shift options, these interactions will be negligible. The resulting aggregate mitigation potentials and their uncertainty ranges per (sub)sector are given in Table 12.4 (columns indicated as ‘AR6’). This overview confirms the large potentials per sector, even when taking the uncertainty ranges into account.

Calculating aggregated mitigation potentials for the global economy requires that interactions between sectors also need to be taken into account (Section 12.6). First of all, there may be overlap between the electricity supply sector and the electricity demand sectors: if the electricity sector is extensively decarbonized, the avoided emissions due to electricity efficiency measures and local electricity production will be significantly reduced. Therefore, this demand-side mitigation potential is only taken into account for 25% (reflecting the degree of further decarbonisation of the power sector) in the cross-sectoral aggregation. For the other demand sectors, this problem does not arise. The industry sector did not provide estimates for electricity efficiency improvement and in the transport sector the utilization of electricity to date is very low. Electrification options may occur in all sectors, but this enhances the mitigation potential in combination with a decreased carbon intensity of the power sector. For other energy sector options, methane emission reduction from coal, oil and natural gas operations, the situation is more complex. The total emission reduction potential for fossil fuels in the other sectors is high. Should this potential be realised, this would lead to a reduction of the potential reported here. However, reducing fossil fuel use also leads to a reduction in the upstream CH₄ emissions, so in the case of reducing fossil fuel use, these upstream emissions will also be avoided, so no overestimate of the aggregate emission reduction potential occurs.

The total potential, given these corrections for overlap, leads to a mid-range value for the total mitigation potential at costs below 100 USD tCO₂-eq⁻¹ of 38 GtCO₂-eq. Given the fact that it is not to be expected that mitigation potentials of the various sectors are mutually correlated, i.e. it is not to be expected that mitigation potentials are all on the high side or all on the low side), the ranges are aggregated using error propagation rules, which leads to a range for the mitigation potential of 32 to 44 GtCO₂-eq.

1 **Table 12.4 Overview of aggregate sectoral net GHG emission reduction potentials (GtCO₂-eq)**
 2 **for the year 2030 at costs below 100 USD tCO₂-eq⁻¹. Comparisons with earlier assessments are**
 3 **also provided. Note that sectors are not entirely comparable across the three different estimates.**

Sector	Mitigation potentials at costs less than 100 USD tCO ₂ -eq ⁻¹				
	AR6 best estimate	AR6 range	AR4 (Barker et al. 2007)	UNEP- 2017 best estimate (UNEP 2017)	UNEP- 2017 range (UNEP 2017)
Electricity sector	11.0	7.9–12.5	6.2–9.3	10.3	9.5–11.0
Other energy sector (methane)	1.6	1.1–2.1		2.2	1.7–2.6
Agriculture	4.1	1.7–6.7	2.3–6.4	4.8	3.6–6.0
Forestry and other land- use related options	7.3	3.9–13.1	1.3–4.2	5.3	4.1–6.5
AFOLU demand-side options (estimates reflect direct mitigation from diverted agricultural production only, not including land-use effects)	2.2	1.1–3.6			1.3–3.4
Buildings (potentials up to 200 USD tCO ₂ -eq ⁻¹ in parentheses)	Dir 0.7 (1.1) Ind 1.3 (2.1) Tot 2.0 (3.2)	0.5–1.0 (0.7–1.5) 0.9–1.8 (1.5–3.1) 1.4–2.9 (2.3–4.6)	Dir 2.3–2.9 Ind 3.0–3.8 Tot 5.4–6.7	Dir 1.9 Ind 4.0 Tot 5.9	Dir 1.6–2.1

Transport	3.8	1.9–5.7	1.6–2.5	4.7	4.1–5.3
Industry	Dir 5.4	4.0–6.7	Dir 2.3–4.9 Ind 0.83 Tot 3.1–5.7	Dir 3.9 Ind 1.9 Tot 5.8	Dir 3.0–4.8
Fluorinated gases (all sectors)	1.2	0.7–1.5	NE	1.5	1.2–1.8
Waste and wastewater	0.7	0.6–0.8	0.4–1.0	0.4	0.3–0.5
Enhanced weathering	-	-	-	1.0	0.7–1.2
Total of all sectors	38	32–44	15.8–31.1	38	35–41

1 Dir = reduction of direct emissions, Ind = reduction of indirect emissions (related to electricity production), Tot
2 = reduction of total emissions, NA = not applicable, NE = not estimated, AR4: Table 11.3, UNEP-2017: Chapter
3 4.

4
5 Mitigation costs and potentials for 2030 have been presented previously, notably in the AR4 Chapter
6 11 on Mitigation from a cross-sectoral perspective (Barker et al. 2007) and the Emissions Gap Report
7 (UNEP 2017). Note that AR5 did not provide emission reduction potentials in this form. The aggregated
8 potentials reported here are higher than those estimated in AR4. Note however, that AR4 suggested the
9 potentials were underestimated by 10 to 15%, but a higher potential still remains in the current
10 assessment. In a sector-by-sector comparison, higher potentials than in AR4 can be observed especially
11 for the energy sector and the forestry sector, and to a more limited extent for the industry sector and the
12 transport sector. For the energy sector, the change can largely be explained by the higher estimates for
13 wind and solar energy and the improved understanding of how to integrate high shares of intermittent
14 renewable energy sources into power systems. For industry and transport, the higher potentials can be
15 partly explained by the inclusion of more options, like recycling and material efficiency (for industry)
16 and electric transportation and modal shifts for transport. For buildings a lower potential can be
17 observed compared to AR4, one reason is that the 2030 reference direct and indirect emissions were
18 estimated as 45% and 11% higher in AR4 than they were in AR6 (signalling a much quicker actual
19 switch to electricity than was thought 15 to 20 years ago, among other reasons). The other reason for a
20 difference is that the scenarios considered in AR4 had 25 to 30 years between their start year until the
21 target year of 2030 and the scenarios reviewed in AR6 has only 10 to 15 years before 2030. The current
22 retrofitting rates of existing buildings and penetration rates of nearly zero energy buildings do not allow

1 decarbonizing the sector over 10-15 years, but they do over a longer time period. A much larger
2 potential than reported here for 2030 can still be realized in the timeframe up to 2050 (Section 9.6.2).

3 Another global analysis was done by McKinsey (2009) which presents a marginal abatement cost curve
4 for 2030, suggesting a total potential of 38 GtCO₂-eq (note that the reference for this study is 70 GtCO₂-
5 eq, which is at the high end of the reference range used in this assessment).

6 The potentials reported here are comparable with UNEP (2017). Note that material for the energy sector
7 from the UNEP report was partly reused in this analysis. Furthermore, some options for the transport
8 sector (aviation and biofuels) were identical to the estimates in the UNEP report. The remaining
9 mitigation potentials are all based on new – and much more extended – assessment. There are some
10 notable changes. The AR6 mitigation potential for forestry is substantially larger. For buildings the
11 potential is smaller, mainly related to the smaller mitigation potential for electric appliances than in the
12 UNEP report. But overall, the estimates of the total mitigation potential are well aligned, which
13 confirms there is substantial consistency across various emissions estimates.

14 The results of the sectoral mitigation potentials are also compared with mitigation impacts as calculated
15 by IAMs. To this end, cumulative sectoral potentials over cost ranges were determined, based on the
16 information in Table 12.3. For options that are in various cost ranges, we assumed that they are evenly
17 distributed over these cost ranges. The only exception is wind and solar energy, for which it is indicated
18 that the majority of the mitigation potential is in the negative cost range. It was assumed that the fraction
19 in the negative cost range was 60%; the remainder is evenly distributed over the other cost ranges. These
20 cumulative potentials were compared with emission reductions realized in IAMs at certain price levels
21 for CO₂. Note that these price levels selected in IAMs are average price levels – not all IAMs use
22 globally uniform carbon prices, so underlying these cost levels, there may be regional differentiation.
23 Data were taken from the AR6 scenarios database. Note that, strictly speaking, not all models in the
24 database are IAMs; in this analysis all models in the database were used, but the term IAMs is used as
25 shorthand in the text that follows. All scenarios likely to limit warming to 2°C or lower are included for
26 the comparison (i.e., the categories of scenarios C1-C3 in Chapter 3). A comparison per sector is
27 provided in Figure 12.1. It is important to note that two different things are compared in this figure: on
28 the one hand emission reduction potentials and on the other hand realisations of (part of) the potential
29 within the context of a certain scenario. Having said that, a number of lessons can be learned from the
30 comparison of both.

31

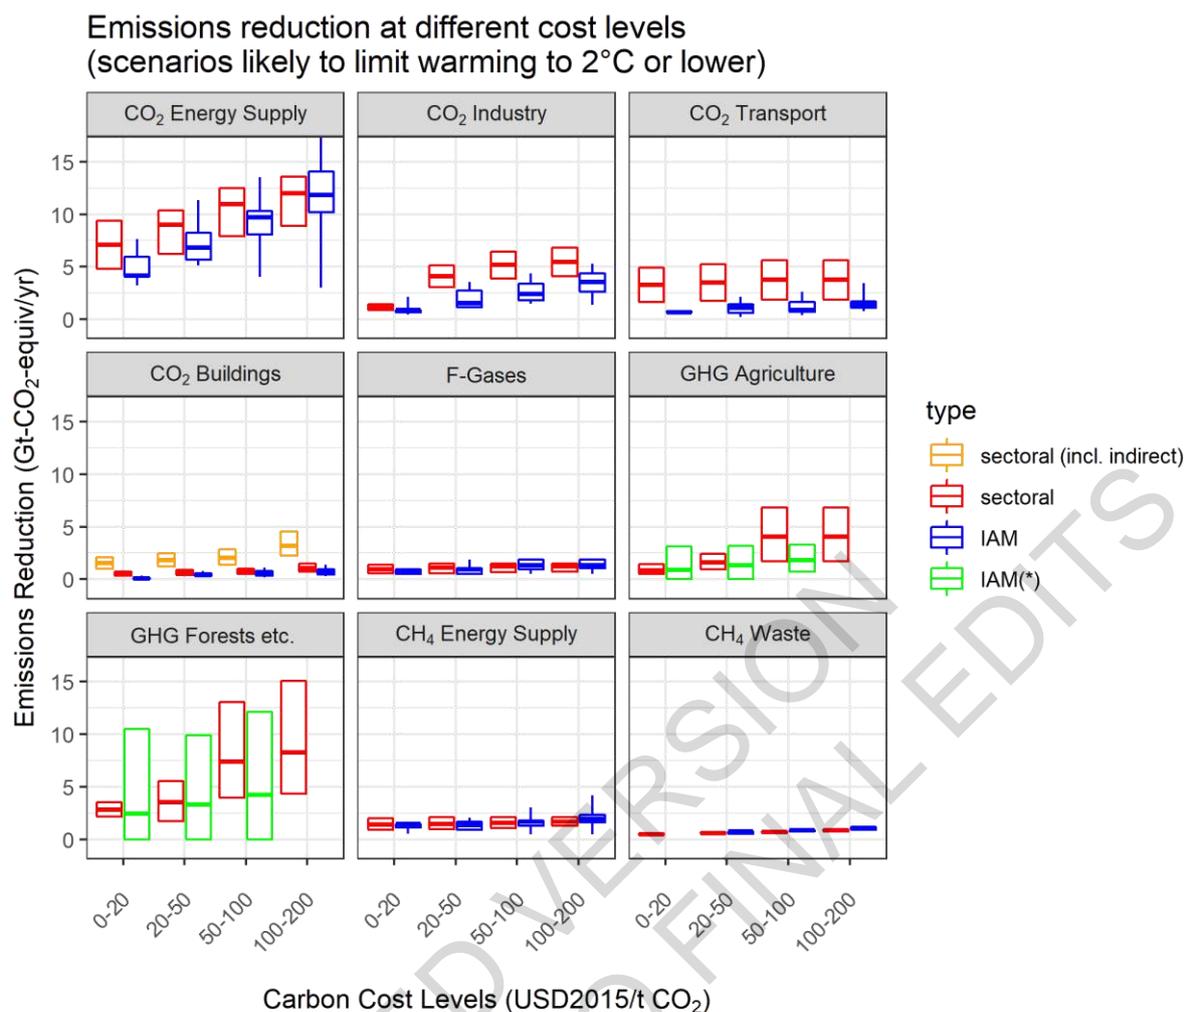

Figure 12.1 Comparison of sectoral estimates for the emission reduction potential with the emission reductions calculated using IAMs.

The latter are given as box plots of global emissions reduction for each sector (blue and green) at different global carbon cost levels (horizontal axis) for 2030, based on all scenarios likely limiting warming to 2°C or lower (see Chapter 3) in the AR6 scenarios database (IPCC 2021). For IAMs, the cost levels correspond to the levels of the carbon price. Hinges in the blue box plots represent the interquartile ranges and whiskers extend to 5th and 95th percentiles while the hinges in the green box plots describe the full range, and the middle point indicates the mean, not the median. In red, the estimates from the sectoral analysis are given. In all cases, only direct emission reductions are presented, except for the orange boxes (for buildings), which include indirect emission reductions. The orange boxes are only given for reasons of completeness, also for buildings the blue boxes should be compared with the red boxes. Orange and red boxes represent the full ranges of estimates. For IAMs, global carbon prices are applied, which are subject to significant uncertainty.

For the energy supply sector, the emission reductions projected by the IAMs are for the higher cost levels comparable with the potentials found in the sectoral analysis. But at lower cost levels, the emission reductions as projected by IAMs are smaller than for the sectoral analysis. This is likely due to the fact that high costs for solar energy and wind energy are assumed in IAM models (Krey et al. 2019; Shiraki and Sugiyama 2020). This is not surprising, as the scenario database comprises studies dating back to 2015. A more detailed comparison for the power

1 sector is given in Figure 12.2. Both the sectoral analysis and the IAMs find that both solar and wind
2 energy in particular show strong growth potential, although there is a continuing role for other low-
3 carbon technologies, like nuclear energy and hydropower.

4 For the AFOLU sector, the sectoral studies provide net emission reduction potentials comparable with
5 projections from the IAMs at costs levels up to 50 USD tCO₂-eq⁻¹. However, beyond that level the
6 mitigation potential found in the sectoral analysis is larger than in the IAMs. For agriculture, it can be
7 explained by the fact that carbon sequestration options, like soil carbon, biochar and agroforestry have
8 little to no representation in IAMs. Similarly, for forestry and other land-use related options, the
9 protection and restoration of other ecosystems than forests (peatland, coastal wetlands and savannas)
10 are not represented in IAMs. Also note that some IAM baselines already have small carbon prices which
11 induce land-based mitigation, while in others, mitigation, particularly from reduced deforestation is part
12 of the storyline even without an implemented carbon price. Both of these effects dampen the mitigation
13 potential available in the USD 100 tCO₂-eq⁻¹ carbon price scenario from IAMs. Furthermore, estimates
14 of mitigation through forestry and other land use related options from the AR6 IAM scenario database
15 represent the net emissions from A/R and deforestation, thus are likely to be lower than the sectoral
16 estimates of A/R potential expressed as gross removals.

17 For the buildings and transport sectors, the sectoral mitigation potentials are higher than those projected
18 by the IAMs. The difference in the transport sector is particularly significant. One possible explanation
19 is that options with negative costs are already included in the reference. In addition, some options, like
20 avoiding demand for energy services in the building sector and modal shift in transportation are less
21 well represented in IAMs.

22 For the industry sector, the sectoral emission reduction potentials are somewhat higher than those
23 reported on average by IAMs. The difference can well be explained by the fact that most IAMs do not
24 include circularity options like material efficiency and recycling; these options together account for 1.5
25 GtCO₂-eq at costs levels from 20 USD tCO₂-eq⁻¹ onwards.

26 For mitigation of emissions of methane and fluorinated gases, the comparability between the sectoral
27 results and IAMs is good.

28 Overall, it is concluded that there are differences between the sectoral analysis and the IAM outcomes,
29 but most of the differences can be explained by the exclusion of specific options in most IAMs. This
30 comparability confirms the reliability of the sectoral analysis of emission reduction potential. It also
31 demonstrates the added value of sectoral analyses of mitigation potentials: they can more rapidly adapt
32 to changes in price levels of technologies and adopt new options for emission mitigation.

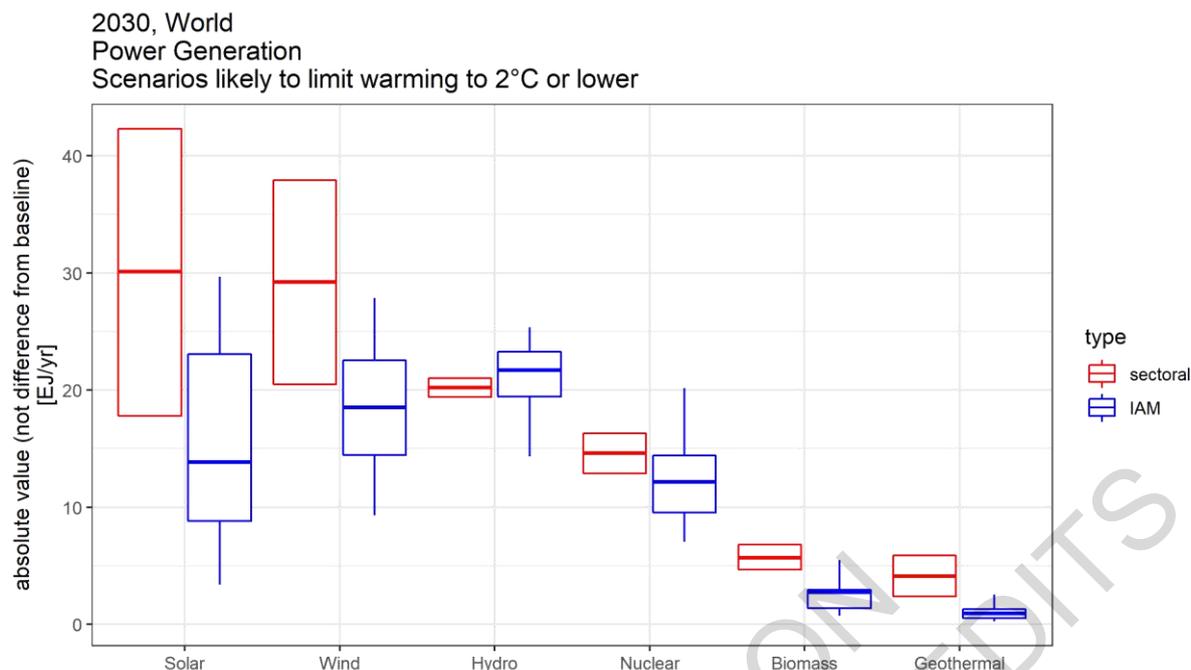

Figure 12.2 Electricity production in 2030 as calculated by Integrated Assessment Models (blue), compared with electricity production potentials found in the sectoral analysis (red).

In both cases cost cut-offs at 100 USD tCO₂⁻¹ are applied. Hinges in the blue box plots represent the interquartile ranges and whiskers extend to 5 and 95 percentiles while the hinges in the red box plots describe the full range.

In this section, the information on individual options reported in Section 12.2.2 to sectoral and economy-wide totals has been aggregated. It is concluded that, based on the sectoral analysis, the global mitigation potential is in the range of 32 to 44 GtCO₂-eq. This mitigation potential is substantially higher than that reported in AR4, but it is comparable to the more recent estimate by UNEP (2017). Differences exist with the results of IAMs, but most of these can be well explained. The conclusion that the global potential is in this range can be drawn with *high agreement and robust evidence*.

Given the median projection of the reference emissions of 60 GtCO₂-eq in 2030, the range of mitigation potentials presented here is sufficient to bring down global emissions in the year 2030 to a level of 16 to 28 GtCO₂-eq. Taking into account that there is a range in reference projections for 2030 of 54 to 68 GtCO₂-eq, the resulting emissions level shows a wider range: 12 to 31 GtCO₂-eq. This is about at or below half of the most recent (2019) emission value of 59±6.6 GtCO₂-eq (*high confidence*).

12.2.4 Sectoral findings on emission pathways until 2050

As noted previously, a more qualitative approach is followed and less quantitative information is presented for 2050. The sectoral results are summarised in Table 12.5. In addition to the many technologies that already play a role by 2030 (Table 12.3) additional technologies may be needed for deep decarbonisation, for example for managing power systems with high shares of intermittent renewable sources and for providing new fuels and associated infrastructure for sectors that are hard to decarbonise. New processes also play an important role, notably for industrial processes. In general,

- 1 stronger sector coupling is needed, particularly increased integration of energy end-use and supply
- 2 sectors.

1 **Table 12.5: Mitigation options and their characteristics for 2050**

Sector	Major options	Degree to which net zero-GHG is possible
Energy sector	<p>Range of supply side options possible (see 2030 overview).</p> <p>Increased share of electricity in final energy use</p> <p>Potentially important role for hydrogen, ammonia, etc.</p>	Zero CO ₂ energy system is possible
Agriculture, forestry and other land use	Options comparable to those in 2030. Permanence is important.	Some hard-to-abate activities will still have positive emissions, but for the sector as a whole, net negative emissions are possible through carbon sequestration in agriculture and forestry
Buildings	Sufficiency, high performance new and existing buildings with efficient HVAC esp. heat pumps, building management and operation, efficient appliances, onsite renewables backed up with demand flexibility and digitalisation measures	At least 8.2 GtCO ₂ or 61% reduction, as compared to the baseline is possible with options on demand-side. This is a low estimate, because in some developing regions literature is not sufficient to derive a comprehensive estimate. Nearly net zero CO ₂ emissions are possible if grid electricity will also be decarbonised. Carbon storage in buildings provides CDR.
Transport	Electrification can become a major option for many transport modes. For long-haul trucking, ships and aviation, in addition biofuels, hydrogen and potentially synthetic fuels can be applied.	To a large extent if the electricity sector is fully decarbonized and the deployment of alternative fuels for long-haul trucking, aviation and shipping is successful.
Industry	<p>Stronger role for material efficiency and recycling.</p> <p>Full decarbonisation through new processes, CCS, CCU and hydrogen can become dominant</p>	Approx. 85% reduction is possible. Net zero CO ₂ emissions are possible with retrofitting and early retirement.

12.3 Carbon dioxide removal (CDR)

CDR refers to a cluster of technologies, practices, and approaches that remove and sequester carbon dioxide from the atmosphere and durably store the carbon in geological, terrestrial, ocean reservoirs, or in products. Despite the common feature of removing carbon dioxide, CDR methods can be very different (Smith et al. 2017). There are proposed methods for removal of non-CO₂ greenhouse gases such as methane (Jackson et al. 2019, 2021) but scarcity of literature on these methods prevents assessment here.

A number of CDR methods (e.g., Afforestation/Reforestation (A/R), Bioenergy with carbon capture and storage (BECCS), soil carbon sequestration (SCS), biochar, wetland/peatland restoration and coastal restoration) are dealt with elsewhere in this report (Chapters 6 and 7). These methods are synthesised in Section 12.3.2. Others, not dealt with elsewhere, i.e., Direct Air Carbon Capture and Storage (DACCS), enhanced weathering of minerals (EW) and ocean-based approaches including ocean fertilisation (OF) and alkalinity (OA) enhancement, are discussed in Sections 12.3.1.1 to 12.3.1.3 below (see also IPCC SROCC and WGI, Section 5.6). Some methods such as BECCS and DACCS involve carbon storage in geological formations, which is discussed in Chapter 6. The climate system and the carbon cycle responses to CDR deployment and each method's physical and biogeochemical characteristics such as storage form and duration are assessed in Chapters 4 and 5 of the WGI report.

START CROSS-CHAPTER BOX 8 HERE

Cross-Chapter Box 8 Carbon Dioxide Removal: Key characteristics and multiple roles in mitigation strategies

Oliver Geden (Germany), Alaa Al Khourdajie (United Kingdom/Syria), Chris Bataille (Canada), Göran Berndes (Sweden), Holly Jean Buck (the United States of America), Katherine Calvin (the United States of America), Annette Cowie (Australia), Kiane de Kleijne (the Netherlands), Jan Minx (Germany), Gert-Jan Nabuurs (the Netherlands), Glen Peters (Australia/Norway), Andy Reisinger (New Zealand), Peter Smith (United Kingdom), Masahiro Sugiyama (Japan)

Carbon Dioxide Removal (CDR) is a necessary element of mitigation portfolios to achieve net zero CO₂ and GHG emissions both globally and nationally, counterbalancing residual emissions from 'hard-to-transition' sectors such as industry, transport and agriculture. CDR is a key element in scenarios likely to limit warming to 2°C or lower, regardless of whether global emissions reach near-zero, net zero or net-negative levels (Sections 3.3, 3.4, 3.5 in Chapter 3 and Section 12.3 in this chapter). While national mitigation portfolios aiming at net zero or net-negative emissions will need to include some level of CDR, the choice of methods and the scale and timing of their deployment will depend on the ambition for gross emission reductions, how sustainability and feasibility constraints are managed, and how political preferences and social acceptability evolve (Section 12.3.3). This box gives an overview of CDR methods, presents a categorisation based on the key characteristics of removal processes and storage timescales, and clarifies the multiple roles of CDR in mitigation strategies. The term *negative emissions* is used in this report only when referring to the net emissions outcome at a systems level (e.g., *net negative emissions* at global, national, sectoral or supply chain levels).

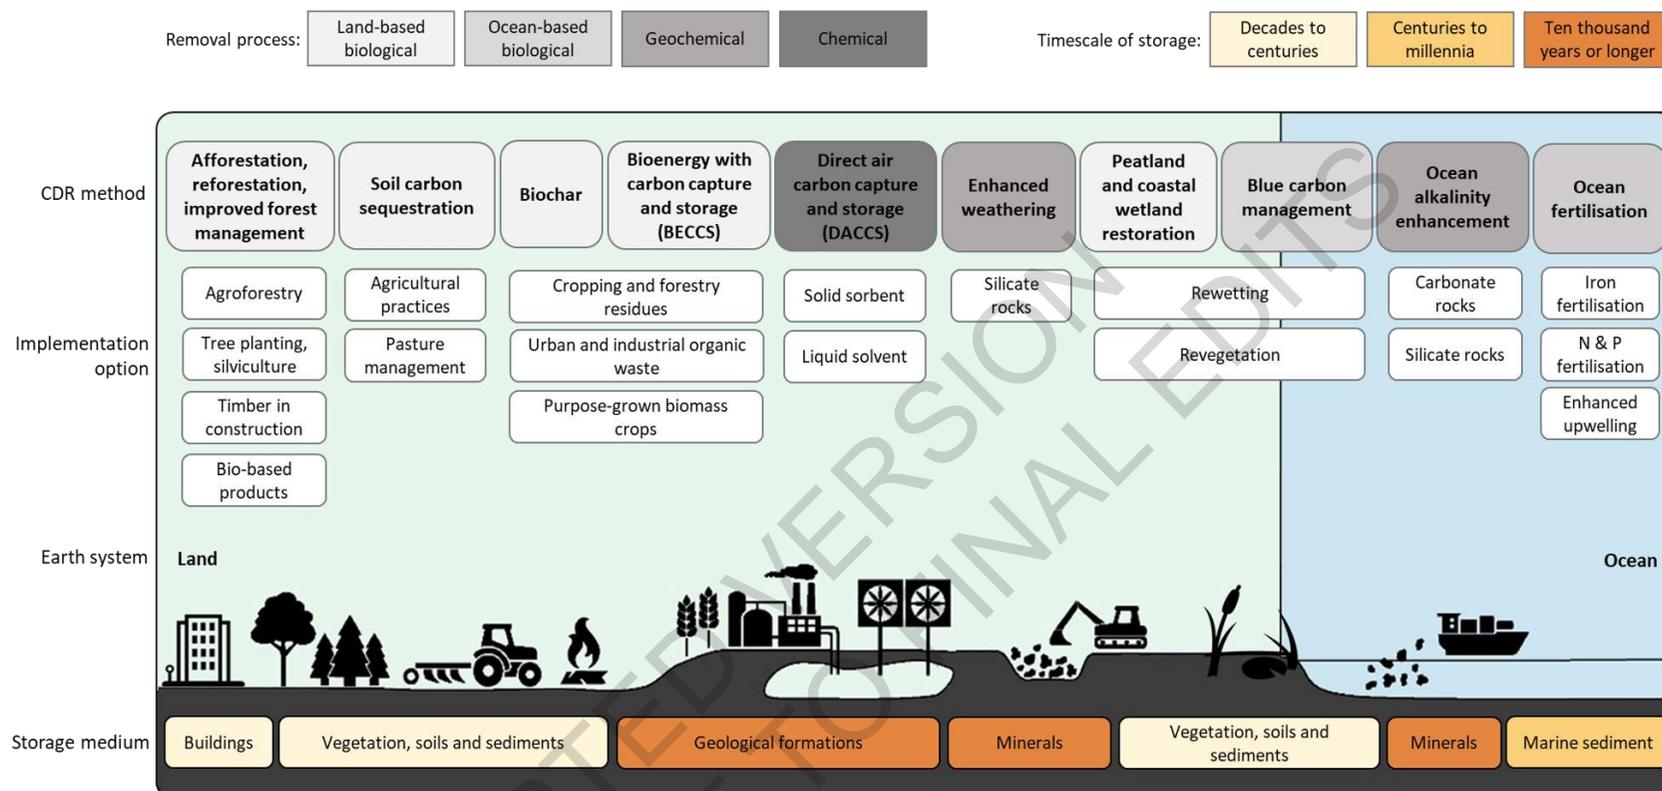

Categorisation of the main CDR methods

CDR refers to anthropogenic activities that remove CO₂ from the atmosphere and store it durably in geological, terrestrial, or ocean reservoirs, or in products. It includes anthropogenic enhancement of biological, geochemical or chemical CO₂ sinks, but excludes natural CO₂ uptake not directly caused by human activities. Increases in land carbon sink strength due to CO₂ fertilisation or other indirect effects

1 of human activities are not considered CDR (see Glossary). Carbon Capture and Storage (CCS) and
2 Carbon Capture and Utilisation (CCU) applied to CO₂ from fossil fuel use are not CDR methods as they
3 do not remove CO₂ from the atmosphere. CCS and CCU can, however, be part of CDR methods if the
4 CO₂ has been captured from the atmosphere, either indirectly in the form of biomass or directly from
5 ambient air, and stored durably in geological reservoirs or products (Sections 11.3.6 in Chapter 11 and
6 Section 12.3 in this chapter).

7 There are many different CDR methods and associated implementation options (Cross-Chapter Box 8,
8 Figure 1). Some of these methods (including afforestation and improved forest management, wetland
9 restoration and SCS) have been practiced for decades to millennia, although not necessarily with the
10 intention of removing carbon from the atmosphere. Conversely, methods such as Direct Air Carbon
11 Capture and Storage (DACCS), Bioenergy with Carbon Capture and Storage (BECCS) and Enhanced
12 Weathering are novel, and while experience is growing, their demonstration and deployment are limited
13 in scale. CDR methods have been categorised in different ways in the literature, highlighting different
14 characteristics. In this report, as in AR6 WGI, the categorisation is based on the role of CDR methods
15 in the carbon cycle, i.e., on the removal process (*land-based biological; ocean-based biological;*
16 *geochemical; chemical*) and on the timescale of storage (*decades to centuries; centuries to millennia;*
17 *ten thousand years or longer*). The timescale of storage is closely linked to the storage medium: carbon
18 stored in ocean reservoirs (through enhanced weathering, ocean alkalinity enhancement or ocean
19 fertilisation) and in geological formations (through BECCS or DACCS) generally has longer storage
20 times and is less vulnerable to reversal through human actions or disturbances such as drought and
21 wildfire than carbon stored in terrestrial reservoirs (vegetation, soil). Furthermore, carbon stored in
22 vegetation or through SCS has shorter storage times and is more vulnerable than carbon stored in
23 buildings as wood products; as biochar in soils, cement and other materials; or in chemical products
24 made from biomass or potentially through direct air capture (WGI, Section 5.6, Figure 5.36; WGIII,
25 Section 11.3.6; Fuss et al. 2018; Minx et al. 2018; NAS 2019). Within the same category (e.g., land-
26 based biological CDR) options often differ with respect to other dynamic or context-specific dimensions
27 such as mitigation potential, cost, potential for co-benefits and adverse side-effects, and technology
28 readiness level (Section 12.3, Table 12.6).

29

Cross-Chapter Box 8, Figure 1: Carbon Dioxide Removal taxonomy.

Methods are categorised based on removal process (grey shades) and storage medium (for which timescales of storage are given, yellow/brown shades). Main implementation options are included for each CDR method. Note that specific land-based implementation options can be associated with several CDR methods, e.g., agroforestry can support soil carbon sequestration and provide biomass for biochar or BECCS.

Source: This figure is an extended version of Figure 2 in (Minx et al. 2018).

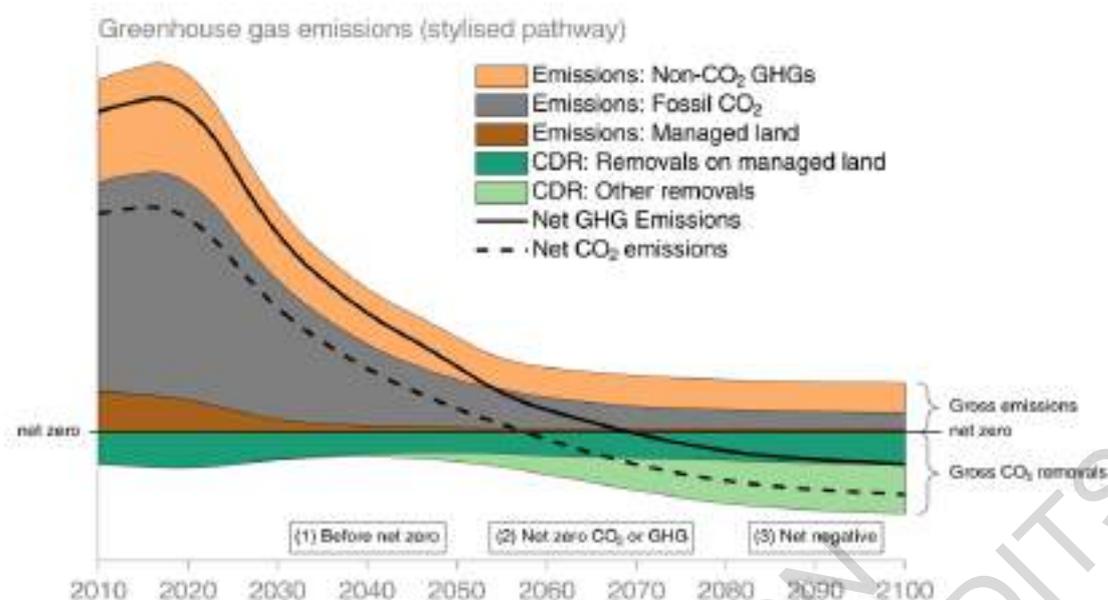

1 Roles of CDR in mitigation strategies

2 Within ambitious mitigation strategies at global or national levels, CDR cannot serve as a substitute for
3 deep emissions reductions but can fulfil multiple complementary roles: (1) further reduce net CO₂ or
4 GHG emission levels in the near-term; (2) counterbalance residual emissions from ‘hard-to-transition’
5 sectors, such as CO₂ from industrial activities and long-distance transport (e.g., aviation, shipping), or
6 methane and nitrous oxide from agriculture, in order to help reach net zero CO₂ or GHG emissions in
7 the mid-term; (3) achieve and sustain net-negative CO₂ or GHG emissions in the long-term, by
8 deploying CDR at levels exceeding annual residual gross CO₂ or GHG emissions (Sections 2.7.3 in
9 Chapter 2, 3.3 and 3.5 in Chapter 3).

10 In general, these roles of CDR are not mutually exclusive and can exist in parallel. For example,
11 achieving net zero CO₂ or GHG emissions globally might involve some countries already reaching net-
12 negative levels at the time of global net zero, allowing other countries more time to achieve this.
13 Equally, achieving net-negative CO₂ emissions globally, which could address a potential temperature
14 overshoot by lowering atmospheric CO₂ concentrations, does not necessarily involve all countries
15 reaching net-negative levels (Cross-Chapter Box 3 in Chapter 3; Rajamani et al. 2021; Rogelj et al.
16 2021).

17 Cross-Chapter Box 8, Figure 2 shows these multiple roles of CDR in a stylised ambitious mitigation
18 pathway that can be applied to global and national levels. While such mitigation pathways will differ
19 in their shape and exact composition, they include the same basic components: CO₂ emissions from
20 fossil sources, CO₂ emissions from managed land, non-CO₂ emissions, and various forms of CDR.
21 Figure 2 also illustrates the importance of distinguishing between gross CO₂ removals from the
22 atmosphere through deployment of CDR methods and the net emissions outcome (i.e., gross emissions
23 minus gross removals).

24 CDR methods currently deployed on managed land, such as afforestation or reforestation and improved
25 forest management, lead to CO₂ removals already today, even when net emissions from land use are
26 still positive, e.g., when gross emissions from deforestation and draining peatlands exceed gross
27 removals from afforestation or reforestation and ecosystem conservation (Sections 2.2 in Chapter 2, 7.2
28 in Chapter 7, Cross-Chapter Box 6 in Chapter 7). As there are currently no removal methods for non-
29 CO₂ gases that have progressed beyond conceptual discussions (Jackson et al. 2021), achieving net zero
30 GHG implies gross CO₂ removals to counterbalance residual emissions of both CO₂ and non-CO₂ gases,
31 applying GWP100 as the metric for reporting CO₂-equivalent emissions, as required for emissions
32 reporting under the Rulebook of the Paris Agreement (Cross-Chapter Box 2 in Chapter 2).

1

2 **Cross-Chapter Box 8, Figure 2: Roles of CDR in global or national mitigation strategies. Stylised pathway**
 3 **showing multiple functions of CDR in different phases of ambitious mitigation: (1) further reducing net**
 4 **CO₂ or GHG emission levels in near-term; (2) counterbalancing residual emissions to help reach net zero**
 5 **CO₂ or GHG emissions in the mid-term; (3) achieve and sustain net-negative CO₂ or GHG emissions in**
 6 **the long-term.**

7 Net zero CO₂ emissions will be achieved earlier than net zero GHG emissions. As volumes of residual
 8 non-CO₂ emissions are expected to be significant, this time-lag could reach one to several decades,
 9 depending on the respective size and composition of residual GHG emissions at the time of net zero.
 10 Furthermore, counterbalancing residual non-CO₂ emissions by CO₂ removals will lead to net-negative
 11 CO₂ emissions at the time of net zero GHG emissions (Cross-Chapter Box 3 in Chapter 3).

12 **END CROSS-CHAPTER BOX 8 HERE**

13 While many governments have included A/R and other forestry measures into their NDCs under the
 14 Paris Agreement (Moe and Røttering 2018; Fyson and Jeffery 2019; Mace et al. 2021), and a few
 15 countries also mention BECCS, DACCS and enhanced weathering in their mid-century low emission
 16 development strategies (Buylova et al. 2021), very few are pursuing the integration of a broad range of
 17 CDR methods into national mitigation portfolios so far (Box 12.1 in Section 12.3.3) (Schenuit et al.
 18 2021). There are concerns that the prospect of large-scale CDR could, depending on the design of
 19 mitigation strategies, obstruct near-term emission reduction efforts (Lenzi et al. 2018; Markusson et al.
 20 2018), mask insufficient policy interventions (Geden 2016; Carton 2019), might lead to an overreliance
 21 on technologies that are still in their infancy (Anderson and Peters 2016; Larkin et al. 2018; Grant et al.
 22 2021), could overburden future generations (Lenzi 2018; Shue 2018; Bednar et al. 2019) might evoke
 23 new conflicts over equitable burden-sharing (Pozo et al. 2020; Lee et al. 2021; Mohan et al. 2021),
 24 could impact food security, biodiversity or land rights (Buck 2016; Boysen et al. 2017; Dooley and
 25 Kartha 2018; Hurlbert et al. 2019; Dooley et al. 2021), or might be perceived negatively by stakeholders
 26 and broader public audiences (Royal Society and Royal Academy of Engineering 2018; Colvin et al.
 27 2020). Conversely, without considering different timescales of carbon storage (Fuss et al. 2018;
 28 Hepburn et al. 2019) and implementation of reliable measurement, reporting and verification of carbon
 29 flows (Mace et al. 2021), CDR deployment might not deliver the intended benefit of removing CO₂
 30 durably from the atmosphere. Furthermore, without appropriate incentive schemes and market designs

1 (Honegger et al. 2021b), CDR implementation options could see under-investment. The many
2 challenges in research, development and demonstration of novel approaches, to advance innovation
3 according to broader societal objectives and to bring down costs, could delay their scaling up and
4 deployment (Nemet et al. 2018). Depending on the scale and deployment scenario, CDR methods could
5 bring about various co-benefits and adverse side effects (see below). All this highlights the need for
6 appropriate CDR governance and policies (Section 12.3.3).

7 The volumes of future global CDR deployment assumed in IAM-based mitigation scenarios are large
8 compared to current volumes of deployment, which presents a challenge since rapid and sustained
9 upscaling from a small base is particularly difficult (de Coninck et al. 2018; Nemet et al. 2018; Hanna
10 et al. 2021). All Illustrative Mitigation Pathways (IMPs) likely to limit warming to 2°C or lower use
11 some form of CDR. Across the full range of similarly ambitious IAM scenarios (scenario categories
12 C1-C3; see Section 3.3.), the annual net CO₂ removal (i.e., gross removals, including A/R, minus gross
13 emissions) on managed land reaches 0.86 [0.01–4.11] GtCO₂ yr⁻¹ by 2030, 2.98 [0.23–6.38] GtCO₂ yr⁻¹
14 by 2050, and 4.19 [0.1–6.91] GtCO₂ yr⁻¹ by 2100 (values are the medians and bracketed values denote
15 the 5-95 percentile range). The annual BECCS deployment is 0.08 [0–1.09] GtCO₂ yr⁻¹, 2.75 [0.52–
16 9.45] GtCO₂ yr⁻¹, and 8.96 [2.63–16.15] GtCO₂ yr⁻¹ for these years, respectively. The annual DACCS
17 deployment reaches 0 [0–0.02] GtCO₂ yr⁻¹ by 2030, 0.02 [0–1.74] GtCO₂ yr⁻¹ by 2050, and 1.02 [0–
18 12.6] GtCO₂ yr⁻¹ by 2100 (Figure 12.3)¹. Cumulative volumes of BECCS, net CO₂ removal on managed
19 land, and DACCS reach 328 [168–763] GtCO₂, 252 [20–418] GtCO₂, and 29 [0–339] GtCO₂ for the
20 2020–2100 period, respectively. Reaching the higher end of CDR volumes is subject to issues regarding
21 their feasibility (see below), especially if achieved with only a limited number of CDR methods. Recent
22 studies have identified some drivers for large-scale CDR deployment in IAM scenarios, including
23 insufficient representation of variable renewables, a high discount rate that tends to increase initial
24 carbon budget overshoot and therefore inflates usage of CDR to achieve net-negative emissions at later
25 times, omission of CDR methods aside from BECCS and A/R (Köberle 2019; Emmerling et al. 2019;
26 Hilaire et al. 2019), and limited deployment of demand-side options (Grubler et al. 2018; Daioglou et
27 al. 2019; van Vuuren et al. 2018). The levels of CDR in IAMs in modelled pathways would change
28 depending on the allowable overshoot of policy targets such as temperature or radiative forcing and the
29 costs of non-CDR mitigation options (Johansson et al. 2020; van der Wijst et al. 2021). (see also Section
30 3.2.2)

FOOTNOTE¹ We use representative options for labels of each variable reported in the AR6 scenarios database.

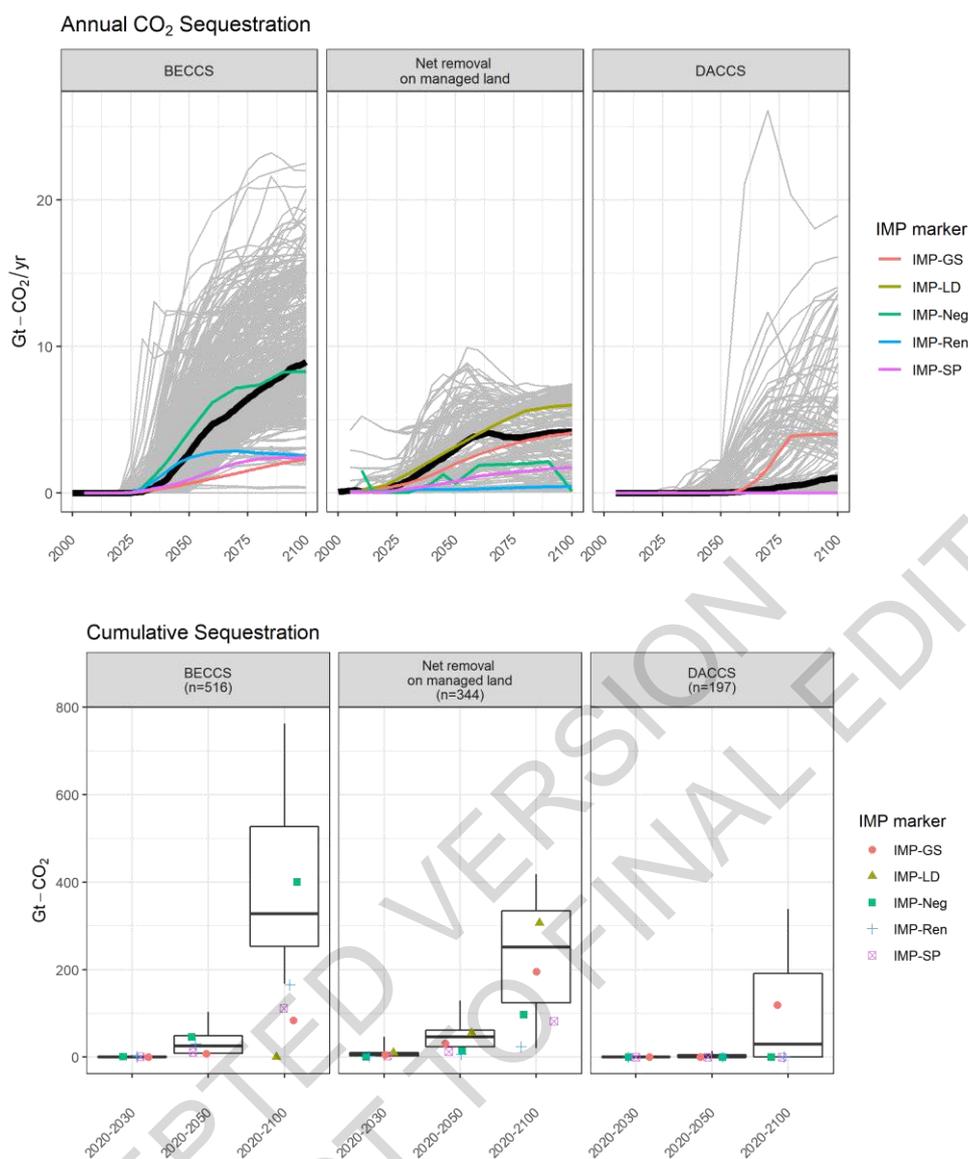

Figure 12.3 Sequestration of three predominant CDR methods: BECCS, net CO₂ removal on managed land (that is, gross removal through A/R minus emissions from deforestation), and DACCS (upper panels) annual sequestration and (lower panels) cumulative sequestration.

The IAM scenarios correspond to those likely limiting warming to 2°C or lower. The black line in each of the upper panels indicates the median of all the scenarios in categories C1-C3. Hinges in the lower panels represent the interquartile ranges while whiskers extend to 5th and 95th percentiles. The IMPs are highlighted with colours, as shown in the key. The number of scenarios is indicated in the header of each panel. The number of scenarios with a non-zero DACCS value is 146.

While many CDR methods are gradually being explored, IAM scenarios have focused mostly on BECCS and A/R (Tavoni and Socolow 2013; Fuhrman et al. 2019; Rickels et al. 2019; Calvin et al. 2021; Diniz Oliveira et al. 2021). Although some IAM studies have also included other methods such as DACCS (Chen and Tavoni 2013; Marcucci et al. 2017; Realmonte et al. 2019; Akimoto et al. 2021; Fuhrman et al. 2020, 2021a), enhanced weathering (Strefler et al. 2021), SCS and biochar (Holz et al. 2018) there is much less literature compared to studies on BECCS (Hilaire et al. 2019). A large scale, coordinated IAM study on BECCS (“EMF-33”) has been conducted (Muratori et al. 2020; Rose et al. 2020a) but none exists for other CDR methods. A recent review proposes a combination of various CDR methods (Fuss et al. 2018) but more in-depth literature on such a portfolio approach is limited

1 (Strefler et al. 2021). A multi-criteria analysis has identified pathways with CDR portfolios different
2 from least-cost pathways often dominated by BECCS and A/R (Rueda et al. 2021).

3 At the national and regional level, the role of land-based biological CDR methods has long been
4 analysed, but there is little detailed technoeconomic assessment of the role of other CDR. There is a
5 small but emerging literature providing such assessments for developed countries (Baik et al. 2018;
6 Sanchez et al. 2018; Patrizio et al. 2018; Larsen et al. 2019; Daggash et al. 2018; Kato and Kurosawa
7 2019; Kraxner et al. 2014; Breyer et al. 2019; McQueen et al. 2020; Bistline and Blanford 2021; Jackson
8 et al. 2021; Kato and Kurosawa 2021; García-Freites et al. 2021; Negri et al. 2021) while the literature
9 outside of developed countries is limited (Alatiq et al. 2021; Fuhrman et al. 2021b; Weng et al. 2021).

10 In IAMs, CDR is contributed mainly by the energy sector (through BECCS) and AFOLU sector
11 (through A/R) (See Figure 12.3). IAMs are starting to include other CDR methods, such as DACCS
12 and enhanced weathering (Section 12.3.1), which are yet to be attributed to specific sectors in IAMs.
13 Following IPCC guidance for UNFCCC inventories, A/R and SCS are reported in LULUCF, while
14 BECCS would be reported in the sector where the carbon capture occurs, that is, the energy sector in
15 the case of electricity and heat production, and the industry sector for BECCS linked to manufacturing
16 (e.g., steel or hydrogen) (Tanzer et al. 2020; Bui et al. 2021; Tanzer et al. 2021).

17 **12.3.1 CDR methods not assessed elsewhere in this report: DACCS, enhanced** 18 **weathering and ocean-based approaches**

19 This section assesses the CDR methods that are not carried out solely within conventional sectors and
20 so are not covered in other parts of the report: direct air carbon capture and storage, enhanced
21 weathering, and ocean-based approaches. It provides an overview of each CDR method, costs,
22 potentials, risks and impacts, co-benefits, and their role in mitigation pathways. Since these processes,
23 approaches and technologies have medium to low technology readiness levels, they are subject to
24 significant uncertainty.

25 **12.3.1.1 Direct Air Carbon Capture and Storage (DACCS)**

26 Direct air capture (DAC) is a chemical process to capture ambient CO₂ from the atmosphere. Captured
27 CO₂ can be stored underground (direct air capture carbon and storage, DACCS) or utilised in products
28 (direct air capture carbon and utilisation, DACCU). DACCS shares with conventional CCS the transport
29 and storage components but is distinct in its capture part. Because CO₂ is a well-mixed GHG, DACCS
30 can be sited relatively flexibly, though its locational flexibility is constrained by the availability of low-
31 carbon energy and storage sites. Capturing the CO₂ involves three basic steps: a) contacting the air, b)
32 capturing on a liquid or solid sorbent or a liquid solvent, c) regeneration of the solvent or the sorbent
33 (with heat, moisture and/or pressure). After capture, the CO₂ stream can be stored underground or
34 utilised. The duration of storage is an important consideration; geological reservoirs or mineralisation
35 result in removal for > 1000 years. The duration of the removal through DACCU (Breyer et al. 2019)
36 varies with the lifetime of respective products (Wilcox et al. 2017; Gunnarsson et al. 2018; Bui et al.
37 2018; Creutzig et al. 2019; Royal Society and Royal Academy of Engineering 2018; Fuss et al. 2018),
38 ranging from weeks to months for synthetic fuels to centuries or more for building materials (e.g.,
39 concrete cured using mineral carbonation) (Hepburn et al. 2019). The efficiency and environmental
40 impacts of DACCS and DACCU options depend on the carbon intensity of the energy input (electricity
41 and heat) and other life-cycle assessment (LCA) considerations (Jacobson 2019; Global CO₂ Initiative
42 2018). See Chapters 6 and 11 for further details regarding carbon capture and utilisation. Another key
43 consideration is the net carbon CO₂ removal of DACCS over its life cycle (Madhu et al. 2021). Deutz
44 and Bardow (2021) and Terlouw et al. (2021) demonstrated that the life-cycle net emissions of DACCS

1 systems can be negative, even for existing supply chains and some current energy mixes. They found
2 that the GHG-intensity of energy sources is a key factor.

3 DAC options can be differentiated by the specific chemical processes used to capture ambient CO₂ from
4 the air and recover it from the sorbent (Fasihi et al. 2019). The main categories are a) liquid solvents
5 with high-temperature regeneration, b) solid sorbents with low temperature regeneration and c)
6 regenerating by moisturising of solid sorbents. Other approaches such as electro-swing (Voskian and
7 Hatton 2019) have been proposed but are less developed. Compared to other CDR methods, the primary
8 barrier to upscaling DAC is its high cost and large energy requirement (*high confidence*) (Nemet et al.
9 2018), which can be reduced through innovation. It has therefore attracted entrepreneurs and private
10 investments (IEA 2020b).

11 *Status:* There are some demonstration projects by start-up companies and academic researchers, who
12 are developing various types of DAC, including aqueous potassium solvent with calcium carbonation
13 and solid sorbents with heat regeneration (NASEM 2019). These projects are supported mostly by
14 private investments and grants or sometimes serve utilisation niche markets (e.g., CO₂ for beverages,
15 greenhouses, enhanced oil recovery). As of 2021, there are more than ten plants worldwide, with a scale
16 of ktCO₂ yr⁻¹ or smaller (IEA 2020b; NASEM 2019; Larsen et al. 2019). Because of the fundamental
17 difference in the CO₂ concentration in the capture stage, DACCS does not benefit directly from RD&D
18 of conventional CCS. Public RD&D programs dedicated to DAC have therefore been proposed
19 (NASEM 2019; Larsen et al. 2019). Possible research topics include development of new liquid solvents,
20 novel solid sorbents, and novel equipment or system designs, and the need for third-party evaluation of
21 techno-economic aspects has also been emphasized (NASEM 2019). However, since basic research
22 does not appear to be a primary barrier, both NASEM (2019) and Larsen et al. (2019) argue for a
23 stronger focus on demonstration in the US context. Though the US and UK governments have begun
24 funding DACCS research (IEA 2020b), the scale of R&D activities is limited.

25 *Costs:* As the process captures dilute CO₂ (~0.04%) from the ambient air, it is less efficient and more
26 costly than conventional carbon capture applied to power plants and industrial installations (*high*
27 *confidence*) (with a CO₂ concentration of ~10%). The cost of a liquid solvent system is dominated by
28 the energy cost (because of the much higher energy demand for CO₂ regeneration, which reduces the
29 efficiency) while capital costs account for a significant share of the cost of solid sorbent systems (Fasihi
30 et al. 2019). The range of the DAC cost estimates found in the literature is wide (60–1000 USD tCO₂⁻¹
31) (Fuss et al. 2018) partly because different studies assume different use cases, differing phases (first
32 plant vs. *n*th plant) (Lackner et al. 2012), different configurations, and disparate system boundaries.
33 Estimates of industrial origin are often on the lower side (Ishimoto et al. 2017). Fuss et al. (2018) suggest
34 a cost range of 600–1000 USD tCO₂⁻¹ for first-of-a-kind plants, and 100–300 USD tCO₂⁻¹ as experience
35 accumulates. An expert elicitation study found a similar cost level for 2050 with a median of around
36 200 USD tCO₂⁻¹ (Shayegh et al. 2021) (*medium evidence, medium agreement*). NASEM (2019)
37 systematically evaluated the costs of different designs and found a range of 84–386 USD₂₀₁₅ tCO₂⁻¹ for
38 the designs currently considered by active technology developers. This cost range excludes the site-
39 specific costs of transportation or storage.

40 *Potentials:* There is no specific study on the potential of DACCS but the literature has assumed that the
41 technical potential of DACCS is virtually unlimited provided that high energy requirements could be
42 met (*medium evidence, high agreement*) (Lawrence et al. 2018; Marcucci et al. 2017; Fuss et al. 2018)
43 since DACCS encounters less non-cost constraints than any other CDR method. Focusing only on the
44 Maghreb region, Breyer et al. (2020) reported an optimistic potential 150 GtCO₂ at less than 61 USD
45 tCO₂⁻¹ for 2050. Fuss et al. (2018) suggest a potential of 0.5–5 GtCO₂ yr⁻¹ by 2050 because of
46 environmental side effects and limits to underground storage. In addition to the ultimate potentials,

1 Realmonte et al. (2019) noted the rate of scale-up as a strong constraint on deployment. Meckling and
2 Biber (2021) discuss a policy roadmap to address the political economy for upscaling. More systematic
3 analysis on potentials is necessary; first and foremost on national and regional levels, including the
4 requirements for low-carbon heat and power, water and material demand, availability of geological
5 storage and the need for land in case of low-density energy sources such as solar or wind power.

6 *Risks and impacts:* DACCS requires a considerable amount of energy (*high confidence*), and depending
7 on the type of technology, water, and make-up sorbents, while its land footprint is small compared to
8 other CDR methods (Smith et al. 2016), but depending on the source of energy for DACCS (e.g.,
9 renewables vs. nuclear), it could require a significant land footprint (NASEM 2019; Sekera and
10 Lichtenberger 2020). The theoretical minimum energy requirement for separating CO₂ gas from the air
11 is ~0.5 GJ tCO₂⁻¹ (Socolow et al. 2011). Fasihi et al. (2019) reviewed the published estimates of energy
12 requirements and found that for the current technologies, the total energy requirement is ~4–10 GJ tCO₂⁻¹,
13 with heat accounting for about 80% and electricity about 20% (McQueen et al. 2021). At a 10 GtCO₂
14 yr⁻¹ sequestration scale, this would translate into 40–100 EJ yr⁻¹ of energy consumption (32–80 EJ yr⁻¹
15 for heat and 8–20 EJ yr⁻¹ electricity), which can be contrasted with the current primary energy supply
16 of ~600 EJ yr⁻¹ and electricity generation of ~100 EJ yr⁻¹. For the solid sorbent technology, low-
17 temperature heat could be sourced from heat pumps powered by low-carbon sources such as renewables
18 (Breyer et al. 2020), waste heat (Beuttler et al. 2019), and nuclear energy (Sandalow et al. 2018). Unless
19 sourced from a clean source, this amount of energy could cause environmental damage (Jacobson 2019).
20 Because DACCS is an open system, water lost from evaporation must be replenished. Water loss varies,
21 depending on technology (including adjustable factors such as the concentration of the liquid solvent)
22 as well as environmental conditions (e.g., temperate vs. tropical climates). For a liquid solvent system,
23 it can be 0–50 tH₂O tCO₂⁻¹ (Fasihi et al. 2019). A water loss rate of ~1–10 tH₂O tCO₂⁻¹ (Socolow et al.
24 2011) would translate into ~10–100 GtH₂O = 10–100 km³ to capture 1ma0 GtCO₂ from the atmosphere.
25 Some solid sorbent technologies actually produce water as a by-product, for example 0.8–2 tH₂O tCO₂⁻¹
26 for a solid-sorbent technology with heat regeneration (Beuttler et al. 2019; Fasihi et al. 2019). Large-
27 scale deployment of DACCS would also require a significant quantity of materials, and energy to
28 produce them (Chatterjee and Huang 2020). Hydroxide solutions are currently being produced as a by-
29 product of chlorine but replacement (make-up) requirement of such materials at scale exceeds the
30 current market supply (Realmonte et al. 2019). The land requirements for DAC units are not large
31 enough to be of concern (Madhu et al. 2021). Furthermore, these can be placed on unproductive lands,
32 in contrast to biological CDR. Nevertheless, to ensure that CO₂-depleted air does not enter the air
33 contactor of an adjacent DAC system, there must be enough space between DAC units, similar to wind
34 power turbines. Considering this, Socolow et al. (2011) estimated a land footprint of 1.5 km² MtCO₂⁻¹.
35 In contrast, large energy requirements can lead to significant footprints if low-density energy sources
36 (e.g., solar PV) are used (Smith et al. 2016). For the issues associated with CO₂ utilisation and storage,
37 see Chapter 6.

38 *Co-benefits:* While Wohland et al. (2018) proposed solid sorbent-based DAC plants as a Power-to-X
39 technology that could use excess renewable power (at the time of low or even negative prices), such
40 operation would add additional costs. Installations would need to be designed for intermittent operations
41 (i.e., at low load factors) which would negatively affect capital and operation costs (Sandalow et al.
42 2018; Daggash et al. 2018) as a high time-resolution model suggests a high utilisation rate (Breyer et
43 al. 2020). Solid sorbent DAC designs can potentially remove more water from the ambient air than
44 needed for regeneration, thereby delivering surplus water that would contribute to Sustainable
45 Development Goal (SDG) 6 (*Clean Water and Sanitation*) in arid regions (Sandalow et al. 2018; Fasihi
46 et al. 2019).

1 *Trade-offs and spill over effects:* Liquid solvent DACCS systems need substantial amounts of water
2 (Fasihi et al. 2019), although much less than BECCS systems (Smith et al. 2016), which could
3 negatively affect SDG 6 (*Clean Water and Sanitation*). Although the high energy demand of DACCS
4 could affect SDG 7 (*Affordable and Clean Energy*) negatively through potential competition or
5 positively through learning effects (Beuttler et al. 2019), its impact has not been thoroughly assessed
6 yet.

7 *Role in mitigation pathways:* There are a few IAM studies that have explicitly incorporated DACCS.
8 Stringent emissions constraints in these studies lead to high carbon prices, allowing DACCS to play an
9 important role in mitigation. Chen and Tavoni (2013) examined the role of DACCS in an IAM
10 (WITCH) and found that incorporating DACCS in their IAM reduces the overall cost of mitigation and
11 tends to postpone the timing of mitigation. The scale of capture goes up to 37 GtCO₂ yr⁻¹ in 2100.
12 (Akimoto et al. 2021) introduced DACCS in the integrated assessment model DNE21+, and also found
13 the long-term marginal cost of abatement is significantly reduced by DACCS. Marcucci et al. (2017)
14 ran MERGE-ETL, an integrated model with endogenous learning, and showed that DACCS allows for
15 a model solution for the 1.5°C target, and that DACCS substitutes for BECCS under stringent targets.
16 In their analysis, DACCS captures up to 38.3 GtCO₂ yr⁻¹ in 2100. Realmonte et al. (2019) modelled two
17 types of DACCS (based on liquid and solid sorbents) with two IAMs (TIAM-Grantham and WITCH),
18 and showed that in deep mitigation scenarios, DACCS complements, rather than substitutes, other CDR
19 methods such as BECCS, and that DACCS is effective at containing mitigation costs. At the national
20 scale, Larsen et al. (2019) utilised the Regional Investment and Operations (RIO) Platform coupled with
21 the Energy PATHWAYS model, and explicitly represented DAC in US energy systems scenarios. They
22 found that in a scenario that reaches net zero emissions by 2045, about 0.6 GtCO₂ or 1.8 GtCO₂ of
23 DACCS would be deployed, depending on the availability of biological carbon sinks and bioenergy.
24 The modelling supporting the European Commission’s initial proposal for net zero GHG emissions by
25 2050 incorporated DAC, whose captured CO₂ is used for both synthetic fuel production (DACCU) and
26 storage (DACCS) (Capros et al. 2019). Fuhrman et al. (2021a) evaluated the role of DACCS across 5
27 shared socioeconomic pathways with the GCAM modelling framework and identified a substantial role
28 of DACCS in mitigation and a decreased pressure on land and water resources from BECCS, even under
29 the assumption of limited energy efficiency improvement and conservative cost declines of DACCS
30 technologies. The newest iteration of the World Economic Outlook by IEA (2021b) deploys CDR on
31 a limited scale, and DACCS removes 0.6 GtCO₂ in 2050 for its Net Zero CO₂ Emissions scenario.

32 Status, costs, potentials, risk and impacts, co-benefits, trade-offs and spillover effects and the role in
33 mitigation pathways of DACCS are summarised in Table 12.6.

34 **12.3.1.2 Enhanced weathering**

35 Enhanced weathering involves a) the mining of rocks containing minerals that naturally absorb CO₂
36 from the atmosphere over geological timescales (as they become exposed to the atmosphere through
37 geological weathering), b) the comminution of these rocks to increase the surface area, and c) the
38 spreading of these crushed rocks on soils (or in the ocean/coastal environments; Section 12.3.1.3) so
39 that they react with atmospheric CO₂ (Schuiling and Krijgsman 2006; Hartmann et al. 2013; Beerling
40 et al. 2018; Goll et al. 2021). Construction waste, and waste materials from mining can also be used as
41 a source material for enhanced weathering. Silicate rocks such as basalt, containing minerals rich in
42 calcium and magnesium and lacking metal ions such as nickel and chromium, are most suitable for
43 enhanced weathering (Beerling et al. 2018); they reduce soil solution acidity during dissolution, and
44 promote the chemical transformation of CO₂ to bicarbonate ions. The bicarbonate ions can precipitate
45 in soils and drainage waters as a solid carbonate mineral (Manning 2008), or remain dissolved and
46 increase alkalinity levels in the ocean when the water reaches the sea (Renforth and Henderson 2017).

1 The modelling study by Cipolla et al. (2021) found that rate of weathering is greater in high rainfall
2 environments, and was increased by organic matter amendment.

3 *Status:* Enhanced weathering has been demonstrated in the laboratory and in small scale field trials
4 (TRL 3–4) but has yet to be demonstrated at scale (Beerling et al. 2018; Amann et al. 2020). The
5 chemical reactions are well understood (Gillman 1980; Gillman et al. 2001; Manning 2008), but the
6 behaviour of the crushed rocks in the field and potential co-benefits and adverse-side effects of
7 enhanced weathering require further research (Beerling et al. 2018). Small scale laboratory experiments
8 have calculated weathering rates that are orders of magnitude slower than the theoretical limit for mass
9 transfer-controlled forsterite (Renforth et al. 2015; Amann et al. 2020) and basalt dissolution (Kelland
10 et al. 2020). Uncertainty surrounding silicate mineral dissolution rates in soils, the fate of the released
11 products, the extent of legacy reserves of mining by-products that might be exploited, location and
12 availability of rock extraction sites, and the impact on ecosystems remain poorly quantified and require
13 further research to better understand feasibility (Renforth 2012; Moosdorf et al. 2014; Beerling et al.
14 2018). Closely monitored, large-scale demonstration projects would allow these aspects to be studied
15 (Smith et al. 2019a; Beerling et al. 2020).

16 *Costs:* Fuss et al. (2018), in a systematic review of the costs and potentials of CDR methods including
17 enhanced weathering, note that costs are closely related to the source of the rock, the technology used
18 for rock grinding and material transport (Hartmann et al. 2013; Renforth 2012; Strefler et al. 2018). Due
19 to differences in the methods and assumptions between studies, literature ranges are highly uncertain
20 and range from 15–40 USD tCO₂⁻¹ to 3460 USD tCO₂⁻¹ (Köhler et al. 2010; Taylor et al. 2016). Renforth
21 (2012) reported operational costs in the UK of applying mafic rocks (rocks with high magnesium and
22 iron silicate mineral concentrations) of 70–578 USD tCO₂⁻¹, and for ultramafic rocks (rocks rich in
23 magnesium and iron silicate minerals but with very low silica content - the low silica content enhances
24 weathering rates) of 24–123 USD tCO₂⁻¹. Beerling et al. (2020) combined a spatially resolved
25 weathering model with a technoeconomic assessment to suggest costs of between 54–220 USD tCO₂⁻¹
26 (with a weighted mean of 118–128 USD tCO₂⁻¹). Fuss et al. (2018) suggested an author judgement cost
27 range of 50–200 USD tCO₂⁻¹ for a potential of 2–4 GtCO₂ yr⁻¹ from 2050, excluding biological storage.

28 *Potentials:* In a systematic review of the costs and potentials of enhanced weathering, Fuss et al. (2018)
29 report a wide range of potentials (*limited evidence, low agreement*). The highest reported regional
30 sequestration potential, 88.1 GtCO₂ yr⁻¹, is reported for the spreading of pulverised rock over a very
31 large land area in the tropics, a region considered promising given the higher temperatures and greater
32 rainfall (Taylor et al. 2016). Considering cropland areas only, the potential carbon removal was
33 estimated by Strefler et al. (2018) to be 95 GtCO₂ yr⁻¹ for dunite and 4.9 GtCO₂ yr⁻¹ for basalt. Slightly
34 lower potentials were estimated by Lenton (2014) where the potential of carbon removal by enhanced
35 weathering (including adding carbonate and olivine to both oceans and soils) was estimated to be 3.7
36 GtCO₂ yr⁻¹ by 2100, but with mean annual removal an order of magnitude less at 0.2 GtC-eq yr⁻¹
37 (Lenton 2014). The estimates reported in Smith et al. (2016) are based on the potential estimates of
38 Lenton (2014). Beerling et al. (2020) estimate that up to 2 GtCO₂ yr⁻¹ could be removed by 2050 by
39 spreading basalt onto 35–59% (weighted mean 53%) of agricultural land of 12 countries. Fuss et al.
40 (2018) provide an author judgement range for potential of 2–4 GtCO₂ yr⁻¹ for 2050.

41 *Risks and impacts:* Mining of rocks for enhanced weathering will have local impacts and carries risks
42 similar to that associated with the mining of mineral construction aggregates, with the possible
43 additional risk of greater dust generation from fine comminution and land application. In addition to
44 direct habitat destruction and increased traffic to access mining sites, there could be adverse impacts on
45 local water quality (Younger and Wolkersdorfer 2004).

1 *Co-benefits*: Enhanced weathering can improve plant growth by pH modification and increased mineral
2 supply (Kantola et al. 2017; Beerling et al. 2018), can enhance SCS in some soils (Beerling et al. 2018)
3 thereby protecting against soil erosion (Wright and Upadhyaya 1998), and increasing the cation
4 exchange capacity, resulting in increased nutrient retention and availability (Baldock and Skjemstad
5 2000; Yu et al. 2017; Guntzer et al. 2012; Tubana et al. 2016; Manning 2010; Haque et al. 2019; Smith
6 et al. 2019a; Gillman 1980; Gillman et al. 2001). Through these actions, it can contribute to the UN
7 SDGs 2 *Zero Hunger*, 15 *Life of Land* (by reducing land demand for croplands), 13 *Climate Action*
8 (through CDR), 14 *Life Below Water* (by ameliorating ocean acidification) and 6 *Clean Water and*
9 *Sanitation* (Smith et al. 2019a). To more directly ameliorate ocean acidification while increasing CDR
10 and reducing impacts on land ecosystems, alkaline minerals could instead be directly added to the ocean
11 (Section 12.3.1.3). There are potential benefits in poverty reduction through employment of local
12 workers in mining (Pegg 2006).

13 *Trade-offs and spill over effects*: Air quality could be adversely affected by the spreading of rock dust
14 (Edwards et al. 2017), though this can partly be ameliorated by water-spraying (Grundnig et al. 2006).
15 As noted above, any significant expansion of the mining industry would require careful assessment to
16 avoid possible detrimental effects on biodiversity (Amundson et al. 2015). The processing of an
17 additional 10 billion tonnes of rock would require up to 3000 TWh, which could represent
18 approximately 0.1-6 % of global electricity in 2100. The emissions associated with this additional
19 energy generation may reduce the net carbon dioxide removal by up to 30% with present day grid
20 average emissions, but this efficiency loss would decrease with low-carbon power (Beerling et al.
21 2020).

22 *Role in mitigation pathways*: Only one study to date has included enhanced weathering in an integrated
23 assessment model to explore mitigation pathways (Strefler et al. 2021).

24 Status, costs, potentials, risk and impacts, co-benefits, trade-offs and spill over effects and the role in
25 mitigation pathways of enhanced weathering are summarised in Table 12.6.

26 **12.3.1.3 Ocean-based methods**

27 The ocean, which covers over 70% of the Earth's surface, contains ~38,000 GtC, some 45 times more
28 than the present atmosphere, and oceanic uptake has already consumed close to 30-40% of
29 anthropogenic C emissions (Gruber et al. 2019, Sabine et al. 2004). The ocean is characterised by
30 diverse biogeochemical cycles involving carbon, and ocean circulation has much longer timescales than
31 the atmosphere, meaning that additional anthropogenic carbon could potentially be stored in the ocean
32 for centuries to millennia for methods that increase deep ocean dissolved carbon concentrations or
33 temporarily bury the carbon; or essentially permanently (over ten thousand years) for methods that store
34 the carbon in mineral forms or as ions by increasing alkalinity (Siegel et al., 2021) (Cross-Chapter Box
35 8 Figure 1). A wide range of methods and implementation options for marine CDR have been proposed
36 (Gattuso et al. 2018; Hoegh-Guldberg et al. 2018; GESAMP 2019). The most studied ocean-based CDR
37 methods are ocean fertilisation, alkalinity enhancement (including electrochemical methods) and
38 intensification of biologically driven carbon fluxes and storage in marine ecosystems, referred to as
39 "blue carbon". The mitigation potentials, costs, co-benefits and trade-offs of these three options are
40 discussed below. Less well studied are methods including artificial upwelling, terrestrial biomass
41 dumping into oceans, direct CO₂ removal from seawater (with CCS), and sinking marine biomass into
42 the deep ocean or harvesting it for bioenergy (with CCS) or biochar (GESAMP 2019). These methods
43 are summarized briefly below. Potential climate response and influence on the carbon budget of ocean-
44 based CDR methods are discussed in Chapter 5 in WGI AR6.

1 **Ocean fertilisation (OF)**. One natural mechanism of carbon transfer from the atmosphere to the deep
2 ocean is the ocean biological pump, which is driven by the sinking of organic particles from the upper
3 ocean. These particles derive ultimately from primary production by phytoplankton and most of them
4 are remineralised within the upper ocean with only a small fraction reaching the deep ocean where the
5 carbon can be sequestered on centennial and longer timescales. Increasing nutrient availability would
6 stimulate uptake of CO₂ through phytoplankton photosynthesis producing organic matter, some of
7 which would be exported into the deep ocean, sequestering carbon. In areas of the ocean where
8 macronutrients (nitrogen, phosphorus) are available in sufficient quantities (about 25% of the total
9 area), the growth of phytoplankton is limited by the lack of trace elements such as iron. Thus, OF CDR
10 can be based on two implementation options to increase the productivity of phytoplankton (Minx et al.
11 2018): macronutrient enrichment and micronutrient enrichment. A third option highlighted in
12 GESAMP (2019) is based on fertilisation for fish stock enhancement, for instance, as naturally occurs
13 in eastern boundary current systems. Iron fertilisation is the best studied OF option to date, but
14 knowledge so far is still inadequate to predict global ecological and biogeochemical consequences.

15 *Status:* OF has a natural analogue: periods of glaciation in the geological past are associated with
16 changes in deposition of dust containing iron into the ocean. Increased formation of phytoplankton has
17 also been observed during seasonal deposition of dust from the Arabian Peninsula and ash deposition
18 on the ocean surface after volcanic eruptions (Jaccard et al., 2013; Achterberg et al. 2013; Olgun et al.
19 2013; Martínez-García et al. 2014). OF options may appear technologically feasible, and enhancement
20 of photosynthesis and CO₂ uptake from surface waters is confirmed by a number of field experiments
21 conducted in different areas of the ocean, but there is scientific uncertainty about the proportion of
22 newly formed organic carbon that is transferred to deep ocean, and the longevity of storage (Blain et al.
23 2008; Williamson et al. 2012; Trull et al. 2015). The efficiency of OF also depends on the region and
24 experimental conditions, especially in relation to the availability of other nutrients, light and
25 temperature (Aumont and Bopp 2006). In the case of macronutrients, very large quantities are needed
26 and the proposed scaling of this technique has been viewed as unrealistic (Williamson and Bodle 2016).

27 *Costs:* Ocean fertilisation costs depend on nutrient production and its delivery to the application area
28 (Jones 2014). The costs range from 2 USD tCO₂⁻¹ for fertilisation with iron (Boyd 2008) to 457 USD
29 tCO₂⁻¹ for nitrate (Harrison 2013). Reported costs for macronutrient application at 20 USD tCO₂⁻¹ (Jones
30 2014), contrast with higher estimates by (Harrison 2013) reporting that low costs are due to
31 overestimation of sequestration capacity and underestimation of logistical costs. The median of OF
32 cost estimates, 230 USD tCO₂⁻¹ (Gattuso et al., 2021) indicates low cost-effectiveness, albeit
33 uncertainties are large.

34 *Potentials:* Theoretical calculations indicate that organic carbon export increases 2–20 kg per gram of
35 iron added, but experiments indicate much lower efficiency: a significant part of the CO₂ can be emitted
36 back the atmosphere because much of the organic carbon produced is remineralised in the upper ocean.
37 Efficiency also varies with location (Bopp et al. 2013). Between studies, there are substantial
38 differences in the ratio of iron added to carbon fixed photosynthetically, and in the ratio of iron added
39 to carbon eventually sequestered (Trull et al. 2015), which has implications both for the success of this
40 strategy, and its cost. Estimates indicate potentially achievable net sequestration rates of 1–3 GtCO₂ yr⁻¹
41 for iron fertilisation, translating into cumulative CDR of 100–300 GtCO₂ by 2100 (Ryaboshapko and
42 Revokatova 2015; Minx et al. 2018), whereas OF with macronutrients has a higher theoretical potential
43 of 5.5 GtCO₂ yr⁻¹ (Harrison 2017; Gattuso et al. 2021). Modelling studies show a maximum effect on
44 atmospheric CO₂ of 15–45 ppmv in 2100 (Zeebe and Archer 2005; Aumont and Bopp 2006; Keller et
45 al. 2014; Gattuso et al. 2021).

1 *Risks and impacts:* Several of the mesoscale iron enrichment experiments have seen the emergence of
2 potentially toxic species of diatoms (Silver et al. 2010; Trick et al. 2010). There is also (limited)
3 evidence of increased concentrations of other GHGs such as methane and nitrous oxide during the
4 subsurface decomposition of the sinking particles from iron-stimulated blooms (Law 2008). Impacts on
5 marine biology and food web structure are not well known, however OF at large scale could cause
6 changes in nutrient distributions or anoxia in subsurface water (Fuhrman and Capone 1991; DFO 2010).
7 Other potential risks are perturbation to marine ecosystems via reorganisation of community structure,
8 enhanced deep ocean acidification (Oschlies et al. 2010) and effects on human food supply.

9 *Co-benefits:* Co-benefits of OF include a potential increase in fish biomass through enhanced biological
10 production (Minx et al. 2018) and reduced ocean acidification in the short term in the upper ocean (by
11 CO₂ removal), though it could be enhanced in the long term in the ocean interior (by CO₂ release)
12 (Oschlies et al., 2010; Gattuso et al. 2018).

13 *Trade-offs and spill-over effects:* Potential drawbacks include subsurface ocean acidification and
14 deoxygenation (Oschlies et al., 2010; Cao and Caldeira 2010; Williamson et al. 2012); altered regional
15 meridional nutrient supply and fundamental alteration of food webs (GESAMP 2019); and increased
16 production of N₂O and CH₄ (Jin and Gruber 2003; Lampitt et al. 2008). Ocean fertilisation is considered
17 to have negative consequences for eight SDGs, and a combination of both positive and negative
18 consequences for seven SDGs (Honegger et al. 2020).

19 **Ocean Alkalinity enhancement (OAE).** CDR through ‘ocean alkalinity enhancement’ or ‘artificial
20 ocean alkalisation’ (Renforth and Henderson 2017) can be based on: 1) the dissolution of natural
21 alkaline minerals that are added directly to the ocean or coastal environments; 2) the dissolution of such
22 minerals upstream from the ocean (e.g., ‘enhanced weathering’, Section 12.3.1.2); 3) the addition of
23 synthetic alkaline materials directly to the ocean or upstream; and 4) electrochemical processing of
24 seawater. In the case of 2), minerals are dissolved on land and the dissolution products are conveyed to
25 the ocean through runoff and river flow. These processes result in chemical transformation of CO₂ and
26 sequestration as bicarbonate and carbonate ions (HCO₃⁻, CO₃²⁻) in the ocean. Imbalances between the
27 input and removal fluxes of alkalinity can result in changes in global oceanic alkalinity and therefore
28 the capacity of the ocean to store C. Such alkalinity-induced changes in partitioning of C between
29 atmosphere and ocean are thought to play an important role in controlling climate change on timescales
30 of 1000 years and longer (e.g., Zeebe 2012). The residence time of dissolved inorganic carbon in the
31 deep ocean is around 100,000 years. However, residence time may decrease if alkalinity is reduced by
32 a net increase in carbonate minerals by either increased formation (precipitation) or reduced dissolution
33 of carbonate (Renforth and Henderson 2017). The alkalinity of seawater could potentially also be
34 increased by electrochemical methods, either directly by reactions at the cathode that increase the
35 alkalinity of the surrounding solution that can be discharged into the ocean, or by forcing the
36 precipitation of solid alkaline materials (e.g., hydroxide minerals) that can then be added to the ocean
37 (e.g., Rau et al. 2013; La Plante et al. 2021).

38 *Status:* OAE has been demonstrated by a small number of laboratory experiments (in addition to
39 enhanced weathering, Section 12.3.1.2). The use of enhanced ocean alkalinity for C storage was first
40 proposed by Kheshgi (1995) who considered the creation of highly reactive lime that would readily
41 dissolve in the surface ocean and sequester CO₂. An alternative method proposed the dissolution of
42 carbonate minerals (e.g., CaCO₃) in the presence of waste flue gas CO₂ and seawater as a means
43 capturing CO₂ and converting it to bicarbonate ions (Rau and Caldeira 1999; Rau 2011). House et al.
44 (2007) proposed the creation of alkalinity in the ocean through electrolysis. The fate of the stored carbon
45 is the same for these proposals (i.e., HCO₃⁻ and CO₃²⁻ ions), but the reaction pathway is different.
46 Enhanced weathering of silicate minerals such as olivine could add alkalinity to the ocean, for example,

1 by placing olivine sand in coastal areas (Montserrat et al. 2017; Meysman and Montserrat 2017). Some
2 authors suggest use of maritime transport to discharge calcium hydroxide (slaked lime, SL) (Caserini
3 et al. 2021).

4 *Costs:* Techno-economic assessments of OAE largely focus on quantifying overall energy and carbon
5 balances. Cost ranges are 40–260 USD tCO₂⁻¹ (Fuss et al. 2018). Considering life cycle carbon and
6 energy balances for various OA options, adding lime (or other reactive calcium or magnesium
7 oxide/hydroxides) to the ocean would cost 64–260 USD tCO₂⁻¹ (Renforth et al. 2013; Renforth &
8 Kruger 2013; Caserini et al. 2019). Rau (2008) and Rau et al. (2018) estimate that electrochemical
9 processes for increasing ocean alkalinity may have a net cost of 3–160 USD tCO₂⁻¹, largely depending
10 on energy cost and co-product (H₂) market value. In the case of direct addition of alkaline minerals to
11 the ocean (i.e., without calcination), the cost is estimated to be 20–50 USD tCO₂⁻¹ (Harvey 2008; Köhler
12 et al. 2013; Renforth and Henderson 2017).

13 *Potentials:* For OAE, the ocean theoretically has the capacity to store thousands of GtCO₂
14 (cumulatively) without exceeding pre-industrial levels of carbonate saturation (Renforth and Henderson
15 2017) if the impacts were distributed evenly across the surface ocean. The potential of increasing ocean
16 alkalinity may be constrained by the capability to extract, process, and react minerals (Section 12.3.1.2);
17 the demand for co-benefits (see below), or to minimise impacts around points of addition. Important
18 challenges with respect to the detailed quantification of the CO₂ sequestration efficiency include
19 nonstoichiometric dissolution, reversed weathering and potential pore water saturation in the case of
20 adding minerals to shallow coastal environments (Meysman and Montserrat 2017). Fuss et al. (2018)
21 suggest storage potentials of 1–100 GtCO₂ yr⁻¹. (González and Ilyina 2016) suggested that addition of
22 114 Pmol of alkalinity to the surface ocean could remove 3400 GtCO₂ from the atmosphere.

23 *Risks and impacts:* For OAE, the local impact of increasing alkalinity on ocean chemistry can depend
24 on the speed at which the impacted seawater is diluted/circulated and the exchange of CO₂ from the
25 atmosphere (Bach et al. 2019). Also, more extreme carbonate chemistry perturbations due to non-
26 equilibrated alkalinity could affect local marine biota (Bach et al. 2019), although biological impacts
27 are largely unknown. Air-equilibrated seawater has a much lower potential to perturb seawater
28 carbonate chemistry. However, seawater with slow air-sea gas exchange, in which alkalinity increases,
29 consumes CO₂ from the surrounding water without immediate replenishment from the atmosphere,
30 which would increase seawater pH and saturation states and may impact marine biota (Meysman and
31 Montserrat 2017; Montserrat et al. 2017). It may be possible to use this effect to ameliorate ocean
32 acidification. Like enhanced weathering, some proposals may result in the dissolution products of
33 silicate minerals (e.g., Si, Fe, K, Ni) being supplied to ocean ecosystems (Meysman and Montserrat
34 2017; Montserrat et al. 2017). Ecological and biogeochemical consequences of OA largely depend on
35 the minerals used. When natural minerals such as olivine are used, the release of additional Si and Fe
36 could have fertilising effects (Bach et al. 2019). In addition to perturbations to marine ecosystems via
37 reorganisation of community structure, potentially adverse effects of OA that should be studied include
38 the release of toxic trace metals from some deposited minerals (Hartmann et al. 2013).

39 *Co-benefits:* Intentional addition of alkalinity to the oceans through OAE would decrease the risk to
40 ocean ecosystems caused by the CO₂-induced impact of ocean acidification on marine biota and the
41 global carbon cycle (Doney et al. 2009; Köhler et al. 2010; Rau et al. 2012; Williamson and Turley
42 2012; Albright et al. 2016; Bach et al. 2019). OA could be jointly implemented with enhanced
43 weathering (see section 12.3.1.2), spreading the finely crushed rock in the ocean rather than land.
44 Regional alkalisation could be effective in protecting coral reefs against acidification (Feng et al.
45 2016) (Mongin et al., 2021) and coastal OA could be part of a broader strategy for geochemical

1 management of the coastal zone, safeguarding specific coastal ecosystems from the adverse impact of
2 ocean acidification, such as important shellfisheries (Meysman and Montserrat 2017).

3 *Trade-offs and spill-over effects:* There is a paucity of research on biological effects of alkalinity
4 addition. The very few studies that have explored the impact of elevated alkalinity on ocean ecosystems
5 have largely been limited to single species experiments (Cripps et al. 2013; Gore et al. 2019) and a
6 constrained field study quantifying the net calcification response of a coral reef flat to alkalinity
7 enhancement (Albright et al. 2016). The addition rate would have to be great enough to overcome
8 mixing of the local seawater with the ambient environment, but not sufficient to detrimentally impact
9 ecosystems. More research is required to assess locations in which this may be feasible, and how such
10 a scheme may operate (Renforth and Henderson 2017). The environmental impact of large-scale release
11 of natural dissolution products into the coastal environment will strongly depend on the scale of olivine
12 application, the characteristics of the coastal water body (e.g., residence time) and the particular biota
13 present (e.g., coral reefs will react differently compared with seagrasses) (Meysman and Montserrat
14 2017). Model simulations (González et al. 2018) suggest that termination of OA implemented on a
15 massive scale under a high CO₂ emission scenario (RCP8.5) might pose high risks to biological systems
16 sensitive to rapid environmental changes because it would cause a sharp increase in ocean acidification.
17 For example, OA termination would lead to a decrease in surface pH in warm shallow regions where
18 vulnerable coral reefs are located, and a drop in the carbonate saturation state. However, other studies
19 with lower levels of OA have shown no termination effect (Keller et al., 2014).

20 **Blue carbon management.** The term “blue carbon” was used originally to refer to biological carbon
21 sequestration in all marine ecosystems, but it is increasingly applied to CDR associated with rooted
22 vegetation in the coastal zone, such as tidal marshes, mangroves and seagrasses. Potential for carbon
23 sequestration in other coastal and non-coastal ecosystems, such as macroalgae (e.g., kelp), is debated
24 (Krause-Jensen et al., 2018; Krause-Jensen and Duarte, 2016). In this report, blue carbon refers to CDR
25 through coastal blue carbon management.

26 *Status:* In recent years, there has been increasing research on the potential, effectiveness, risks, and
27 possibility of enhancing CO₂ sequestration in shallow coastal ecosystems (Duarte, 2017). About 20%
28 of the countries that are signatories to the Paris Agreement refer to blue carbon approaches for climate
29 change mitigation in their NDCs and are moving toward measuring blue carbon in inventories. About
30 40% of those same countries have pledged to manage shallow coastal ecosystems for climate change
31 adaptation (Kuwae and Hori 2019).

32 *Costs:* There are large differences in cost of CDR applying blue carbon management methods between
33 different ecosystems (and at the local level). Median values are estimated as 240, 30,000, and 7,800
34 USD tCO₂⁻¹, respectively for mangroves, salt marsh and seagrass habitats (Gattuso et al. 2021).
35 Currently estimated cost effectiveness (for climate change mitigation) is very low (Siikamäki et al.
36 2012; Bayraktarov et al. 2016; Narayan et al. 2016).

37 *Potentials:* Globally, the total potential carbon sequestration rate through blue carbon CDR is estimated
38 in the range 0.02–0.08 GtCO₂ yr⁻¹ (Wilcox et al. 2017; National Academies of Sciences 2019). Gattuso
39 et al. (2021) estimate the theoretical cumulative potential of coastal blue carbon management by 2100
40 to be 95 GtCO₂, taking into account the maximum area that can be occupied by these habitats and
41 historic losses of mangroves, seagrass and salt marsh ecosystems.

42 *Risks and impacts:* For blue carbon management, potential risks relate to the high sensitivity of coastal
43 ecosystems to external impacts associated with both degradation and attempts to increase carbon
44 sequestration. Under expected future warming, sea-level rise and changes in coastal management, blue
45 carbon ecosystems are at risk, and their stored carbon is at risk of being lost (Bindoff et al. 2019).

1 *Co-benefits:* Blue carbon management provides many non-climatic benefits and can contribute to
2 ecosystem-based adaptation, also reducing emissions associated with habitat degradation and loss
3 (Howard et al. 2017; Hamilton and Friess 2018). Shallow coastal ecosystems have been severely
4 affected by human activity; significant areas have already been deforested or degraded and continue to
5 be denuded. These processes are accompanied by carbon emissions. The conservation and restoration
6 of coastal ecosystems, which will lead to increased carbon sequestration, is also essential for the
7 preservation of basic ecosystem services, and healthy ecosystems tend to be more resilient to the effects
8 of climate change.

9 *Trade-offs and spill-over effects:* Blue carbon management schemes should consist of a mix of
10 restoration, conservation and areal increase, including complex engineering interventions that enhance
11 natural capital, safeguard their resilience and the ecosystem services they provide, and decrease the
12 sensitivity of such ecosystems to further disturbances.

13 **Overview of other ocean-based CDR approaches**

14 **Artificial Upwelling** This concept uses pipes or other methods to pump nutrient-rich deep ocean water
15 to the surface where it has a fertilizing effect (see OF section). To achieve CO₂ removal at a Gt
16 magnitude, modelling studies have shown that artificial upwelling would have to be implemented on a
17 massive scale (over 50% of the ocean to deliver maximum rate of 10GtCO₂ yr⁻¹ under RCP 8.5)
18 (Oschlies et al., 2010, Keller et al. 2014). Because the deep water is much colder than surface water, at
19 massive scale this could cool the Earth's surface by several degrees, but the cooling effect would cease
20 as the deeper ocean warms, and would reverse, leading to rapid warming, if the pumping ceased
21 (Oschlies et al., 2010, Keller et al. 2014).

22 Furthermore, the cooling would also severely alter atmospheric circulation and precipitation patterns
23 (Kwiatkowski et al. 2015). Several upwelling approaches have been developed and tested (Pan et al.,
24 2016) and more R&D is underway.

25 **Terrestrial biomass dumping** There are proposals to sink terrestrial biomass (crop residues or logs)
26 into the deep ocean as a means of sequestering carbon (Strand and Benford 2009). Sinking biochar has
27 also been proposed (Miller and Orton, 2021). Decomposition would be inhibited by the cold and
28 sometimes hypoxic/anoxic environment on the ocean floor, and absence of bacteria that decompose
29 terrestrial lignocellulosic biomass, so storage timescale is estimated at hundreds to thousands of years
30 (Strand and Benford 2009)(Burdige 2005). Potential side-effects on marine ecosystems, chemistry, or
31 circulation have not been thoroughly assessed. Neither have these concepts been evaluated with respect
32 to the impacts on land from enhanced transfer of nutrients and organic matter to the ocean, nor the
33 relative merits of alternative applications of residues and biochar as an energy source or soil amendment
34 (Chapter 7).

35 **Marine biomass CDR options** Proposals have been made to grow macroalgae (Duarte et al., 2017) for
36 BECCS (N'Yeurt et al. 2012; Duarte et al. 2013; Chen et al., 2015), to sink cultured macroalgae into
37 the deep sea, or to use marine algae for biochar (Roberts et al., 2015). Naturally growing sargassum
38 has also been considered for these purposes (Bach et al., 2021). Froehlich et al. (2019) found a
39 substantial area of the ocean (ca. 48 million km²) suitable for farming seaweed. N'Yeurt et al. (2012)
40 suggested that converting 9% of the oceans to macroalgal aquaculture could take up 19 GtCO₂ in
41 biomass, generate 12 Gt per annum of biogas, and the CO₂ produced by burning the biogas could be
42 captured and sequestered. Productivity of farmed macroalgae in the open ocean could potentially be
43 enhanced through fertilizing via artificial upwelling (Fan et al., 2020) or through cultivation platforms
44 that dive at night to access nutrient-rich waters below the, often nutrient-limited, surface ocean. If the

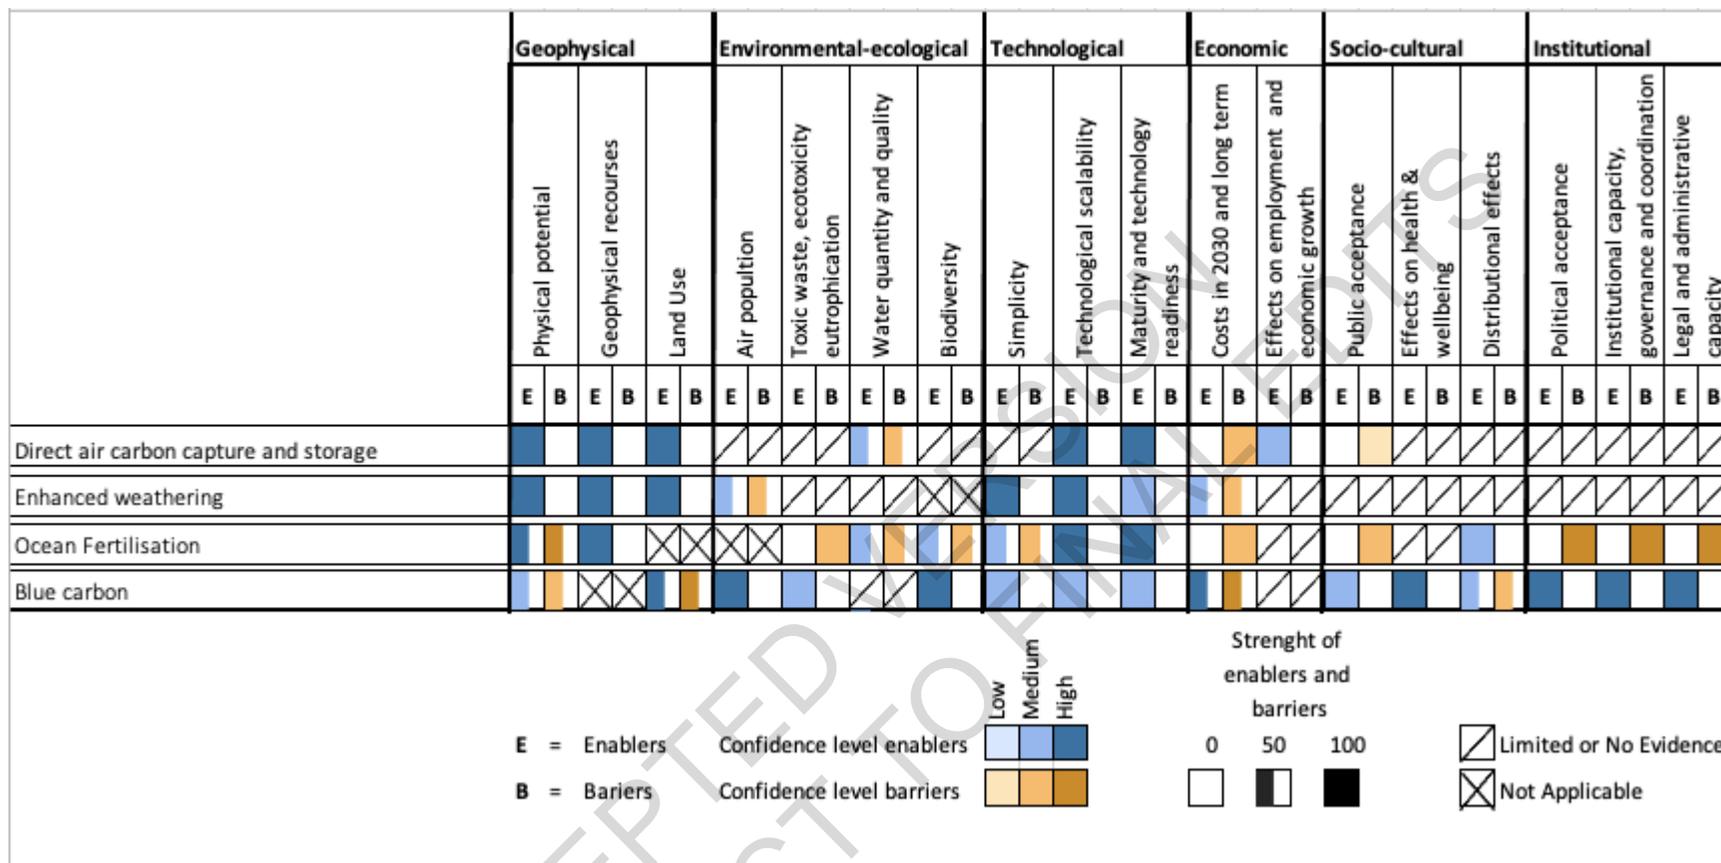

1 biomass were sunk, it is unknown how long the carbon would remain in the deep ocean and what the
2 additional impacts would be. Research and development on macroalgae cultivation and use is currently
3 underway in multiple parts of the world, though not necessarily directly focused on CDR.

4 **Extraction of CO₂ from seawater (with storage)** CO₂ can be extracted by applying a vacuum, or by
5 purging with a gas low in CO₂ (Koweek et al., 2016). CO₂ stripping can also be accomplished by
6 acidifying seawater with a mineral acid, or through electrodialysis and electrolysis, to convert
7 bicarbonate ions (HCO₃⁻) to CO₂ (Eisaman et al., 2018; Eisaman 2020; Willauer et al., 2017, Digdaya
8 et al., 2020) Sharifian et al., 2021). The removal of CO₂ from the ocean surface leads to undersaturation
9 in the water, thus forcing CO₂ to move from the atmosphere into the ocean to restore equilibrium.
10 Electrochemical seawater CO₂ extraction has been modeled, prototyped, and analyzed from a techno-
11 economic perspective (Eisaman et al., 2012; Willauer et al., 2017; de Lannoy et al., 2018; Eisaman et
12 al., 2018a; Eisaman et al., 2018b).

13 Status, costs, potentials, risk and impacts, co-benefits, trade-offs and spill-over effects and the role in
14 mitigation pathways of ocean-based approaches are summarised in Table 12.6.

15 *12.3.1.4 Feasibility assessment*

16 Following the framework presented in Section 6.4 and Annex II.11, a multi-dimensional feasibility
17 assessment on the CDR methods covered here is provided in Figure 12.4, taking into account the
18 assessment presented in this section. Both DACCS and EW perform positively on the geophysical and
19 technological dimensions while for ocean-based approaches performance is mixed. There is limited
20 evidence to assess social-cultural, environmental/ecological, and institutional dimensions as the
21 literature is still nascent for DACCS and EW, while these aspects are positive for blue carbon and mixed
22 or negative for ocean fertilization. On the economic dimension, the cost is assessed negatively for all
23 CDR methods.

3

Figure 12.4 Summary of the extent to which different factors would enable or inhibit the deployment of the carbon dioxide methods DACCS, EW, ocean fertilisation and blue carbon management.

4

5

6

7

8

9

Blue bars indicate the extent to which the indicator enables the implementation of the CDR method (E) and orange bars indicate the extent to which an indicator is a barrier (B) to the deployment of the method, relative to the maximum possible barriers and enablers assessed. An ‘X’ signifies the indicator is not applicable or does not affect the feasibility of the method, while a forward slash indicates that there is no or limited evidence whether the indicator affects the feasibility of the method. The shading indicates the level of confidence, with darker shading signifying higher levels of confidence. Supplementary Material 12.B provides an overview of the factors affecting the feasibility of CDR methods and how they differ across context (e.g., region), time (e.g., 2030 versus 2050), and scale (e.g., small versus large), and includes a line of sight on which the assessment is based. The assessment methodology is explained in Annex II, Part II, Section 11.

1

2 **12.3.2 Consideration of methods assessed in sectoral chapters; A/R, biochar, BECCS,** 3 **soil carbon sequestration**

4 *Status:* BECCS, A/R, soil carbon sequestration (SCS) and biochar are land-based biological CDR
5 methods (Smith et al. 2016). BECCS combines biomass use for energy with CCS to capture and store
6 the biogenic carbon geologically (Section 6.4.2.6); A/R and SCS involve fixing atmospheric carbon in
7 biomass and soils, and biochar involves converting biomass to biochar and using it as a soil amendment.
8 These CDR methods can be associated with both co-benefits and adverse side-effects, see Section 7.4,
9 12.5 and (Schleicher et al. 2019; Smith et al. 2019b; Hurlbert et al. 2019; Mbow et al. 2019; Olsson et
10 al. 2019; Smith et al. 2016; Babin et al. 2021; Dooley et al. 2021).

11 Among CDR methods, BECCS and A/R are most commonly selected by IAMs to meet the requirements
12 of likely limiting warming to 2°C or lower. This is partially because of the long lead time required to
13 refine IAMs to include additional methods and update technoeconomic parameters. Currently, few
14 IAMs represent SCS or biochar (Frank et al. 2017). Given the removal potential of SCS and biochar
15 and some potential co-benefits, more efforts should be made to include these methods within IAMs, so
16 that their mitigation potential can be compared to other CDR methods, along with possible co-benefits
17 and adverse side effects (Smith et al. 2016; Rogelj et al. 2018) (Section 12.5).

18 *Potential:* The technical potential for BECCS by 2050 is estimated at 0.5–11.3 GtCO₂-eq yr⁻¹ (Chapter
19 7, Table 7.3). These potentials do not include avoided emissions resulting from the use of heat,
20 electricity and/or fuels provided by the BECCS system, which depends on substitution patterns,
21 conversion efficiencies, and supply chain emissions for the BECCS and substituted energy systems (see
22 Box 7.7 in Chapter 7). The mitigation effect of BECCS also depends on how deployment affects land
23 carbon stocks and sink strength (see section 7.4.4).

24 As detailed in Chapter 7, the technical potential for gross removals realised through A/R in 2050 is 0.5–
25 10.1 GtCO₂-eq yr⁻¹, and for improved forest management the potential is 1–2.1 GtCO₂-eq yr⁻¹ (including
26 both CDR and emissions reduction). Technical potential for SCS in 2050 is estimated to be 0.6–9.4
27 GtCO₂-eq yr⁻¹, for agroforestry it is 0.3–9.4 GtCO₂-eq yr⁻¹, and for biochar it is 0.2–6.6 GtCO₂-eq yr⁻¹.
28 Peatland and coastal wetland restoration have a technical potential of 0.5–2.1 GtCO₂-eq yr⁻¹ in 2050,
29 with an estimated 80% of the potential being CDR. Note that these potentials reflect only biophysical
30 and technological conditions and become reduced when factoring in economic, environmental, socio-
31 cultural and institutional constraints (Table 12.6).

32 *Costs:* Costs across technologies vary substantially (Smith et al. 2016) and were estimated to be 15–
33 400 USD tCO₂⁻¹ for BECCS, 0–240 USD tCO₂⁻¹ for A/R, -45–100 USD tCO₂⁻¹ for SCS and 10–345 USD
34 tCO₂⁻¹ for biochar. Fuss et al. (2018), estimated abatement cost ranges for BECCS, A/R, SCS and
35 biochar to be 100–200, 5–50, 0–100, and 30–120 tCO₂-eq⁻¹ respectively, corresponding to 2100
36 potentials. Ranges for economic potential (<100 USD tCO₂⁻¹) reported in Chapter 7 are 0.5–3.0 GtCO₂
37 yr⁻¹ (A/R); 0.6–1.9 GtCO₂ yr⁻¹ (improved forest management); 0.7–2.5 GtCO₂ yr⁻¹ (SCS); 0.4–1.1
38 GtCO₂ yr⁻¹ (agroforestry); 0.3–1.8 GtCO₂ yr⁻¹ (biochar); 0.2–0.8 GtCO₂ yr⁻¹ (peatland and coastal
39 wetland restoration).

40 *Risks, impacts, and co-benefits:* a brief summary of risks, impacts and co-benefits is provided here and
41 more detail is provided in chapter 7 and Section 12.5. A/R and biomass production for BECCS and
42 biochar potentially compete for land, water and other resources, implying possible adverse outcomes
43 for ecosystem health, biodiversity, livelihoods and food security (medium evidence, high agreement)
44 Smith et al. 2016; Heck et al. 2018; Hurlbert et al. 2019; Mbow et al. 2019) (Chapter 7). SCS requires

1 addition of nitrogen and phosphorus to maintain stoichiometry of soil organic matter, leading to a
2 potential risk of eutrophication (Fuss et al. 2018). Apart from possible negative effects associated with
3 biomass supply, adverse side-effects from biochar are relatively low if the biomass is uncontaminated
4 (Tisserant and Cherubini 2019).

5 Possible climate risks relate to direct and/or indirect land carbon losses (A/R, BECCS, biochar),
6 increased N₂O emissions (BECCS, SCS), saturation and non-permanence of carbon storage (A/R, SCS)
7 (Jia et al. 2019; Smith et al. 2019b) (Chapter 7), and potential CO₂ leakage from deep geological
8 reservoirs (BECCS) (Chapter 6). Land cover change associated with A/R and biomass supply for
9 BECCS and biochar may cause albedo changes that reduce mitigation effectiveness (Jia et al. 2019;
10 Fuss et al. 2018). Potentially unfavourable albedo change resulting from biochar use can be minimised
11 by incorporating biochar into the soil (Fuss et al. 2018)(Chapter 7)

12 Concerning co-benefits, A/R and biomass production for BECCS or biochar could improve soil carbon,
13 nutrient and water cycling (robust evidence, high agreement), and contribute to market opportunities,
14 employment and local livelihoods, economic diversification, energy security, and technology
15 development and transfer (medium evidence, high agreement) (Chapter 7)(Fuss et al. 2018). It may
16 contribute to reduction of other air pollutants, health benefits, and reduced dependency on imported
17 fossil fuels. A/R can improve biodiversity if native and diverse species are used, and (Fuss et al. 2018).
18 For biochar, additional co-benefits include increased crop yields and reduced drought impacts, reduced
19 CH₄ and N₂O emissions from soils (Section 7.4.5.2) (Joseph et al., 2021). SCS can improve soil quality
20 and resilience and improve agricultural productivity and food security (Frank et al. 2017; Smith et al.
21 2019c).

22 *Role in Mitigation Pathways:* Biomass use for BECCS in 2050 is 61 EJ yr⁻¹ (13–208 EJ yr⁻¹, 5-95
23 percentile range) in scenarios limiting warming to 1.5°C with no or limited overshoot (C1, excluding
24 traditional energy). This corresponds to 5.3 GtCO₂ yr⁻¹ (1.1-18 GtCO₂ yr⁻¹) CDR, if assuming 28 kg C
25 GJ⁻¹ biomass carbon content and 85% capture rate in BECCS systems. In scenarios likely to limit
26 warming to 2°C (C3), biomass use for BECCS in 2050 is 28 EJ yr⁻¹ (0–96 EJ yr⁻¹, 5-95 percentile
27 range), corresponding to 2.4 GtCO₂ yr⁻¹ (0-8.3 GtCO₂ yr⁻¹) CDR. Cumulative net CO₂ removals on
28 managed land (CDR through A/R minus land C losses due to deforestation) in the period 2020-2100 is
29 262 GtCO₂ (17–397 GtCO₂) and 209 GtCO₂ (20–415 GtCO₂) in C1 and C3 scenarios, respectively (5-
30 95 percentile range).

31 Uncertainties remain in two main areas: the availability of land and biomass, which is affected by many
32 factors (see Chapter 7) (Anandarajah et al. 2018), and the role of other mitigation measures including
33 CDR methods other than A/R and BECCS. Strong near-term climate change mitigation to limit
34 overshoot, and deployment of other CDR methods than A/R and BECCS, may significantly reduce the
35 contribution of these CDR methods in scenarios limiting warming to 1.5°C or 2°C (Köberle 2019;
36 Hasegawa et al. 2021).

37 *Trade-offs and spill-overs:* Some land-based biological CDR methods, such as BECCS and A/R,
38 demand land. Combining mitigation strategies has the potential to increase overall carbon sequestration
39 rates (Humpenöder et al. 2014). However, these CDR methods may also compete for resources (Frank
40 et al. 2017). Land-based mitigation approaches currently propose the use of forests (i) as a source of
41 woody biomass for bioenergy and various biomaterials, and (ii) for carbon sequestration in vegetation,
42 soils, and forest products. Forests are therefore required to provide both provisioning (biomass
43 feedstock) and regulating (carbon sequestration) ecosystem services. This multifaceted strategy has the
44 potential to result in trade-offs (Makkonen et al. 2015). Some land-based mitigation options could
45 conflict with biodiversity goals, e.g., A/R using monoculture plantations can reduce species richness

1 when introduced into (semi-)natural grasslands (Smith et al. 2019a; Dooley et al. 2021). When trade-
2 offs exist between biodiversity protection and mitigation objectives, biodiversity is typically given a
3 lower priority, especially if the mitigation option is considered risk-free and economically feasible
4 (Pörtner et al. 2021). Approaches that promote synergies, such as sustainable forest management
5 (SFM), reducing deforestation rates, cultivation of perennial crops for bioenergy in sustainable farming
6 practices, and mixed-species forests in A/R, can mitigate biodiversity impacts and even improve
7 ecosystem capacity to support biodiversity while mitigating climate change (Pörtner et al. 2021)
8 (Section 12.5). Systematic land-use planning could help to deliver land-based mitigation options that
9 also limit trade-offs with biodiversity (Longva et al. 2017) (Cross-Working Group Box 3: Mitigation
10 and Adaptation via the Bioeconomy).

11 Status, costs, potentials, risk and impacts, co-benefits, trade-offs and spill-over effects and the role in
12 mitigation pathways of A/R, biochar, SCS, peatland and coastal wetland restoration, agroforestry and
13 forest management are summarised in Table 12.6. See also 12.5.

1 **Table 12.6 Summary of status, costs, potentials, risk and impacts, co-benefits, trade-offs and spill over effects and the role in mitigation pathways for CDR**
 2 **methods. TRL = Technology Readiness Level. Author judgement ranges (assessed by authors in the literature) are shown, with full literature ranges shown in**
 3 **brackets**

CDR option	Status (TRL)	Cost (USD tCO ₂ ⁻¹)	Mitigation Potential (GtCO ₂ yr ⁻¹)	Risk & Impacts	Co-benefits	Trade-offs and spill over effects	Role in modelled mitigation pathways	Section
DACCS	6	100–300 (84–386)	5–40	Increased energy and water use.	Water produced (solid sorbent DAC designs only).	Potentially increased emissions from water supply and energy generation.	In a few IAMs; DACCS complements other CDR methods.	{12.3.1.1}
Enhanced weathering	3–4	50–200 (24–578)	2–4 (<1–95)	Mining impacts; air quality impacts of rock dust when spreading on soil.	Enhanced plant growth, reduced erosion, enhanced soil carbon, reduced pH, soil water retention.	Potentially increased emissions from water supply and energy generation.	In a few IAMs; EW complements other CDR methods.	{12.3.1.2}
Ocean alkalinity enhancement	1–2	40–260	1–100	Increased seawater pH and saturation states and may impact marine biota. Possible release of nutritive or toxic elements and compounds. Mining impacts.	Limiting ocean acidification.	Potentially increased emissions of CO ₂ and dust from mining, transport and deployment operations.	No data.	{12.3.1.3}
Ocean fertilisation	1–2	50–500	1–3	Nutrient redistribution, restructuring of the ecosystem, enhanced oxygen consumption and acidification in deeper waters, potential for decadal-to-millennial-scale return to the atmosphere of nearly all the extra carbon	Increased productivity and fisheries, reduced upper ocean acidification.	Subsurface ocean acidification, deoxygenation; altered meridional supply of macro-nutrients as they are utilized in the iron-fertilized region and become unavailable for transport to, and	No data.	{12.3.1.3}

				removed, risks of unintended side effects.		utilization in other regions, fundamental alteration of food webs, biodiversity		
Blue carbon management in coastal wetlands	2–3	Insufficient data, estimates range from ~ 100 to ~ 10000	<1	If degraded or lost, coastal blue carbon ecosystems are likely to release most of their carbon back to the atmosphere; potential for sediment contaminants, toxicity, bioaccumulation and biomagnification in organisms; issues related to altering degradability of coastal plants; use of subtidal areas for tidal wetland carbon removal; effect of shoreline modifications on sediment redeposition and natural marsh accretion; abusive use of coastal blue carbon as means to reclaim land for purposes that degrade capacity for carbon removal.	Provide many non-climatic benefits and can contribute to ecosystem-based adaptation, coastal protection, increased biodiversity, reduced upper ocean acidification; could potentially benefit human nutrition or produce fertiliser for terrestrial agriculture, anti-methanogenic feed additive, or as an industrial or materials feedstock.	If degraded or lost, coastal blue carbon ecosystems are likely to release most of their carbon back to the atmosphere. The full delivery of the benefits at their maximum global capacity will require years to decades to be achieved	Not incorporated in IAMs, but in some bottom-up studies: small contribution.	{12.3.1.3}, Chapter 7, Section 7.4
BECCS	5–6	15–400	0.5–11	Competition for land and water resources, to grow biomass feedstock. Biodiversity and carbon stock loss if from unsustainable biomass harvest.	Reduction of air pollutants; fuel security, optimal use of residues, additional income, health benefits and if implemented well can enhance biodiversity, soil health and land carbon	Competition for land with biodiversity conservation and food production	Substantial contribution in IAMs and bottom -up sectoral studies	Chapter 7, Section 7.4

Afforestation/Reforestation	8–9	0–240	0.5–10	Reversal of carbon removal through wildfire, disease, pests may occur. Reduced catchment water yield and lower groundwater level if species and biome are inappropriate.	Enhanced employment and local livelihoods, improved biodiversity, improved renewable wood products provision, soil carbon and nutrient cycling. Possibly less pressure on primary forest.	Inappropriate deployment at large scale can lead to competition for land with biodiversity conservation and food production.	Substantial contribution in IAMs and also in bottom-up sectoral studies.	Chapter 7, Section 7.4
Biochar	6–7	10–345	0.3–6.6	Particulate and GHG emissions from production; biodiversity and carbon stock loss from unsustainable biomass harvest.	Increased crop yields and reduced non-CO ₂ emissions from soil; and resilience to drought.	Environmental impacts associated particulate matter; competition for biomass resource.	In development - not yet in global mitigation pathways simulated by IAMs.	Chapter 7, Section 7.4
Soil Carbon Sequestration in croplands and grasslands	8–9	45–100	0.6–9.3	Risk of increased nitrous oxide emissions due to higher levels of organic nitrogen in the soil; risk of reversal of carbon sequestration.	Improved soil quality, resilience and agricultural productivity.	Attempts to increase carbon sequestration potential at the expense of production. Net addition per hectare is very small; hard to monitor.	In development - not yet in global mitigation pathways simulated by IAMs; in bottom-up studies: with medium contribution.	Chapter 7, Section 7.4
Peatland and coastal wetland restoration	8–9	Insufficient data	0.5–2.1	Reversal of carbon removal in drought or future disturbance. Risk of increased methane emissions.	Enhanced employment and local livelihoods, increased productivity of fisheries, improved biodiversity, soil carbon and nutrient cycling.	Competition for land for food production on some peatlands used for food production.	Not in IAMs but some bottom-up studies with medium contribution.	Chapter 7, Section 7.4

Agroforestry	8–9	Insufficient data	0.3–9.4	Risk that some land area lost from food production; requires high skills.	Enhanced employment and local livelihoods, variety of products improved soil quality, more resilient systems.	Some trade-off with agricultural crop production, but enhanced biodiversity, and resilience of system.	No data from IAMs, but in bottom-up sectoral studies with medium contribution.	Chapter 7, Section 7.4
Improved Forest management	8–9	Insufficient data	0.1–2.1	If improved management is understood as merely intensification involving increased fertiliser use and introduced species, then it could reduce biodiversity and increase eutrophication.	In case of sustainable forest management, it leads to enhanced employment and local livelihoods, enhanced biodiversity, improved productivity.	If it involves increased fertiliser use and introduced species it could reduce biodiversity and increase eutrophication and upstream GHG emissions.	No data from IAMs, but in bottom-up sectoral studies with medium contribution.	Chapter 7, Section 7.4

SUBJECT TO FINAL

1 12.3.3 CDR governance and policies

2 As shown in Cross-Chapter Box 8 in this Chapter, CDR fulfils multiple functions in different
3 phases of ambitious mitigation: (1) further reducing net CO₂ or GHG emission levels in the
4 near-term; (2) counterbalancing residual emissions (from hard-to-transition sectors like
5 transport, industry, or agriculture) to help reach net zero CO₂ or GHG emissions in the mid-
6 term; (3) achieving and sustaining net-negative CO₂ or GHG emissions in the long-term. While
7 inclusion of emissions and removals on managed land (LULUCF) is mandatory for developed
8 countries under UNFCCC inventory rules (Grassi et al. 2021), not all Annex I countries have
9 included land-based biological removals when setting domestic mitigation targets in the past,
10 but updated NDCs for 2030 indicate a shift, most notably in the European Union (Gheuens and
11 Oberthür 2021; Schenuit et al. 2021). The early literature on CDR governance and policy has
12 been mainly conceptual rather than empirical, focusing on high-level principles (see the
13 concerns listed in introduction of Section 12.3) and the representation of CDR in global
14 mitigation scenarios (see Section 3.2.2). However, with the widespread adoption of net zero
15 targets and the recognition that CDR is a necessary element of mitigation portfolios to achieve
16 net zero CO₂ or GHG emissions, countries with national net zero emissions targets have begun
17 to integrate CDR into modelled national mitigation pathways, increase research, development
18 & demonstration (RD&D) efforts on CDR methods, and consider CDR-specific incentives and
19 policies (Honegger et al. 2021b; Schenuit et al. 2021), (Box 12.1). Nevertheless, this increasing
20 consideration of CDR has not yet extended to net-negative targets and policies to achieve these.
21 While the use of CDR at levels that would lead to net negative CO₂ or GHG emissions in the
22 long-term has been assumed in most global mitigation scenarios that limit warming to 1.5°C,
23 net-negative emissions trajectories and BECCS as the main CDR method modelled to achieve
24 these have not been mirrored by corresponding UNFCCC decisions so far (Fridahl 2017;
25 Mohan et al. 2021). Likewise, only a few national long-term mitigation plans or legal acts
26 already entail a vision for net-negative GHG emissions (Buylova et al. 2021), for example
27 Finland, Sweden, Germany and Fiji).

28 For countries with emissions targets aiming for net zero or lower, the core governance question
29 is not whether CDR should be mobilised or not, but which CDR methods governments want to
30 see deployed by whom, by when, at which volumes and in which ways (Bellamy and Geden
31 2019; Minx et al. 2018). The choice of CDR methods and the scale and timing of their
32 deployment will depend on the respective ambitions for gross emission reductions, how
33 sustainability and feasibility constraints are managed, and how political preferences and social
34 acceptability evolve (Bellamy 2018; Forster et al. 2020; Fuss et al. 2020; Waller et al. 2020;
35 Clery et al. 2021; Iyer et al. 2021; Rogelj et al. 2021). As examples of emerging CDR
36 policymaking at (sub-)national levels show, policymakers are beginning to incorporate CDR
37 methods beyond those currently dominating global mitigation scenarios, i.e. BECCS and
38 afforestation/reforestation (Box 12.1) (Bellamy and Geden 2019; Buylova et al. 2021; Schenuit
39 et al. 2021; Uden et al. 2021). CDR policymaking is faced with the need to consider method-
40 specific timescales of CO₂ storage, as well as challenges in MRV and accounting, potential co-
41 benefits, adverse side effects, interactions with adaptation and trade-offs with SDGs (Table
42 12.6) (Dooley and Kartha 2018; McLaren et al. 2019; Buck et al. 2020; Honegger et al. 2020;
43 Brander et al. 2021; Dooley et al. 2021; Mace et al. 2021). Therefore, CDR governance and
44 policymaking is expected to focus on responsibly incentivising RD&D and targeted

1 deployment, building on both technical and governance experience with already widely
2 practiced CDR methods like afforestation/reforestation (Lomax et al. 2015; Field and Mach
3 2017; Bellamy 2018; Carton et al. 2020; VonHedemann et al. 2020), as well as learning from
4 two decades of slow-moving CCS deployment (Buck 2021; Martin-Roberts et al. 2021; Wang
5 et al. 2021). For some less well understood methods and implementation options, such as ocean
6 alkalisation or enhanced weathering, investment in RD&D can help in understanding the
7 risks, rewards, and uncertainties of deployment (Nemet et al. 2018; Fajardy et al. 2019; Burns
8 and Corbett 2020; Goll et al. 2021).

9

10 **START BOX 12.1 HERE**

11 **Box 12.1 Case Study: Emerging CDR policy, research and development in the United** 12 **Kingdom**

13 Climate change mitigation policies in the UK have been motivated since 2008 by a domestic,
14 legally-binding framework. This framework includes a 2050 target for net greenhouse gas
15 emissions, interim targets and an independent advisory body called the Climate Change
16 Committee (Muinzer 2019). It has led successive UK governments to publish mitigation plans
17 to 2050, causing policy to be more forward-looking (Averchenkova et al. 2021).

18 The UK's targets include emissions and removals from LULUCF. In 2008 the target for 2050
19 was an economy-wide net emissions reduction of at least 80% below 1990 levels. Even the
20 first government plans to achieve this target proposed deployment of removal methods,
21 specifically afforestation and wood in construction, increased soil carbon and BECCS (HM
22 Government 2011).

23 Adoption of the Paris Agreement in 2015 caused the government to change the legislated 2050
24 target to a reduction of at least 100% (i.e. net zero). Since then, removal of CO₂ and other
25 greenhouse gases has received greater prominence as a distinct topic. The most recent national
26 plan (published October 2021) proposes deployment not only of the methods mentioned above,
27 but also DACCS, biochar and enhanced weathering. The government has committed to amend
28 accounting of UK targets to include a wider range of removal methods beyond LULUCF, and
29 set a target of 5 MtCO₂ yr⁻¹ from methods such as BECCS, DACCS and enhanced weathering
30 by 2030. It is consulting on markets and incentives for deployment, and exploring new
31 requirements for MRV (HM Government 2021).

32 In parallel to these policy developments, the UK funds research into technical, environmental
33 and social aspects of removal (Lezaun et al. 2021). Research on some elements (e.g., forestry,
34 CCS, soils, bioenergy) have been funded for well over a decade, but the first programme
35 dedicated to greenhouse gas removal ran during 2017-2021. This has been followed by two
36 new programmes with greater focus on demonstration, totalling £100m over four years (HM
37 Government 2021). A wide variety of methods is supported in these programmes, covering
38 approaches such as CO₂ capture from seawater and capture of methane from cattle, in addition
39 to those included already in national mitigation scenarios.

1 Deployment of removal methods has lagged expectations, as national targets for tree planting
2 are not being met and infrastructure for CO₂ transport and storage is not yet in place (Climate
3 Change Committee 2021). While public awareness around carbon removal is low, studies
4 indicate support in general, provided it is perceived as enhancing rather than impeding action
5 to reduce emissions (Cox et al. 2020a).

6 **END BOX 12.1 HERE**

7 Since the enhancement of carbon sinks is a form of climate change mitigation (Honegger et al. 2021a),
8 CDR governance challenges will in many respects be similar to those around emissions reduction
9 measures, as will policy instruments like RD&D funding, carbon pricing, tax or investment credits,
10 certification schemes, and public procurement (see Sections 13.4, 13.6, 14.4, 14.5). Effectively
11 integrating CDR into mitigation portfolios can build on already existing rules, procedures and
12 instruments for emissions abatement (Torvanger 2019; Fridahl et al. 2020; Zakkour et al. 2020;
13 Honegger et al. 2021b; Mace et al. 2021; Rickels et al. 2021). Additionally, to accelerate RD&D and to
14 incentivise CDR deployment a political commitment to formal integration into existing climate policy
15 frameworks is required (*robust evidence, high agreement*) (Lomax et al. 2015; Geden et al. 2018;
16 Honegger and Reiner 2018; VonHedemann et al. 2020; Schenuit et al. 2021) To avoid that CDR is
17 misperceived as a substitute for deep emissions reductions, the prioritisation of emissions cuts can be
18 signalled and achieved with differentiated target setting for reductions and removals (Geden et al. 2019;
19 McLaren et al. 2019). Similarly, sub-targets are conceivable for different types of CDR, to prioritise
20 preferred methods according to characteristics such as removal processes or timescales of storage
21 (Smith 2021).

22 IPCC guidance on quantifying removals is available for land-based biological CDR methods (IPCC
23 2006, 2019), but has yet to be developed for other CDR methods (Royal Society and Royal Academy
24 of Engineering 2018). Challenges with development of estimation algorithms, data collection, and
25 attribution between sectors and countries will need to be overcome (Luisetti et al. 2020; Wedding et
26 al. 2021). Trusted methodologies for MRV, required to enable private sector participation will need to
27 address the permanence, leakage, and saturation challenges with land and ocean-based biological
28 methods (Mace et al. 2021). Protocols that also capture social and ecological co-benefits, could
29 encourage the adoption of biological CDR methods such as SCS, biochar, A/R and blue carbon
30 management (*robust evidence, high agreement*) (VonHedemann et al. 2020; Macreadie et al. 2021).

31 Private capital and companies, impact investors, and philanthropy will play a role in technical
32 demonstrations and bringing down costs, as well as creating demand for carbon removal products on
33 voluntary markets, which companies may purchase to fulfil corporate social responsibility-driven
34 targets (Friedmann 2019; Fuss et al. 2020; Joppa et al. 2021). Niche markets can provide entry points
35 for limited deployment of novel CDR methods (Cox and Edwards 2019), but targeting currently existing
36 revenue streams by using CO₂ captured from the atmosphere in Enhanced Oil Recovery and other
37 utilisation routes (Mackler et al. 2021; Meckling and Biber 2021) is contested, and highlights the
38 importance of choosing appropriate system boundaries when assessing supply chains (Tanzer and
39 Ramírez 2019; Brander et al. 2021). While the private sector will play a distinct role in scaling CDR,
40 governments will need to commit to developing infrastructure for the transport and storage of CO₂,
41 including financing, permitting, and regulating liabilities (Sanchez et al. 2018; Mace et al. 2021;
42 Mackler et al. 2021).

43 International governance considerations include global technology transfer around CDR
44 implementation options (Batres et al. 2021); land use change that could affect food production and land
45 condition, and cause conflict around land tenure and access (Dooley and Kartha 2018; Hurlbert et al.

1 2019; Milne et al. 2019); and efforts to create sustainable and just supply chains for CDR (Fajardy and
2 Mac Dowell 2020; Tan et al. 2021), such as resources used for BECCS, enhanced weathering, or ocean
3 alkanisation. International governance would be particularly important for methods posing
4 transboundary risks, especially for ocean-based methods. Specific regulations have so far only been
5 developed in the context of the London Protocol, an international treaty that explicitly regulates ocean
6 fertilisation and allows parties to govern other marine CDR methods like ocean alkalinity enhancement
7 (GESAMP 2019; Burns and Corbett 2020; Boettcher et al. 2021)(see Section 14.4.5).

8 Engagement of civil society organisations and publics will be important for shaping CDR policy and
9 deployment (*medium evidence, high agreement*). Public awareness of CDR and its role in national net
10 zero emissions strategies is generally very low (Cox et al. 2020a), and perceptions differ across
11 countries and between methods (Bertram and Merk 2020; Spence et al. 2021; Sweet et al. 2021; Wenger
12 et al. 2021). When awareness increases, social processes will shape political attitudes on CDR (Shrum
13 et al. 2020), as will efforts to frame particular CDR methods as ‘natural’ or ‘technological’ (Osaka et
14 al. 2021), and the policy instruments chosen to support CDR (Bellamy et al. 2019). Lack of confidence
15 in CDR implementation options from both publics and investors, and lack of trust in project developers
16 (Cox et al. 2020b) have hampered support for CCS (Thomas et al. 2018) and is expected to affect
17 deployment of CDR methods with geological storage (Gough and Mander 2019). On local and regional
18 scales, CDR projects will need to consider air and water quality, impacts to human health, energy needs,
19 land use and ecological integrity, and local community engagement and procedural justice. Bottom-up
20 and community driven strategies are important for deploying equitable carbon removal projects
21 (Hansson et al. 2021; Batres et al. 2021).

23 12.4 Food systems

24 12.4.1 Introduction

25 This section complements Chapter 7 by reviewing recent estimates of food system emissions
26 and assessing options beyond the agriculture, forestry and land use sectors to mitigate food
27 systems GHG emissions. A food system approach enables identification of cross-sectoral
28 mitigation opportunities including both technological and behavioural options. Further, a
29 system approach permits evaluation of policies that do not necessarily directly target primary
30 producers or consumers, but other food system actors with possibly higher mitigation
31 efficiency. A food system approach was introduced in the IPCC Special Report on Climate
32 Change and Land (SRCCL) (Mbow et al. 2019). Besides major knowledge gaps in the
33 quantification of food system GHG emissions (Section 12.4.2), the SRCCL authors identified
34 as major knowledge gaps the understanding of the dynamics of dietary change (including
35 behavioural patterns, the adoption of plant-based dietary patterns, and interaction with human
36 health and nutrition of sustainable healthy diets and associated feedbacks); and instruments and
37 mechanisms to accelerate transitions towards sustainable and healthy food systems.

38 Sufficient food and adequate nutrition are fundamental human needs (HLPE 2020; Ingram
39 2020). Food needs to be grown and processed, transported and distributed, and finally prepared
40 and consumed. Food systems range from traditional, involving only few people and short
41 supply chains, to modern food systems, comprising complex webs involving large numbers of
42 stakeholders and processes that grow and transform food commodities into food products and
43 distribute them globally (HLPE 2017; Gómez and Ricketts 2013). A ‘food system’ includes all

1 food chain activities (production, processing, distribution, preparation, consumption of food)
2 and the management of food loss and wastes. It also includes institutions and infrastructures
3 influencing any of these activities, as well as people and systems impacted (HLPE 2017; FAO
4 2018a). Food choices are determined by the food environment consisting of the “physical,
5 economic, political and socio-cultural context in which consumers engage with the food system
6 to acquire, prepare and consume food” (HLPE 2017). Food system outcomes encompass food
7 and nutrition, productivity, profit and livelihood of food producers and other actors in food
8 value chains, but also social outcomes and the impact on the environment (Zurek et al. 2018).
9 ‘Sustainable healthy diets’ have been defined by FAO and WHO (FAO and WHO 2019) as
10 “dietary patterns that promote all dimensions of individuals’ health and wellbeing; have low
11 environmental pressure and impact; are accessible, affordable, safe and equitable; and are
12 culturally acceptable.”

13 The SRCCL estimated overall global anthropogenic emissions from food systems to range
14 between 10.8 and 19.1 GtCO₂-eq yr⁻¹, equivalent to 21-37% of total anthropogenic emissions
15 (Rosenzweig et al. 2020a; Mbow et al. 2019). The authors identified major knowledge gaps for
16 the GHG emission inventories of food systems, particularly in providing disaggregated
17 emissions from the food industry and transportation. The food system approach taken in the
18 SRCCL (Mbow et al. 2019) evaluates the synergies and trade-offs of food system response
19 options and its implications for food security, climate change adaptation and mitigation. This
20 integrated framework allows the identification of fundamental attributes of responses to
21 maximise co-benefits, while avoiding maladaptation measures and adverse side effects. A food
22 system approach supports the design of interconnected climate policy responses to tackle
23 climate change, incorporating perspectives of producers and consumers. The SRCCL (Mbow
24 et al. 2019) found that the technical mitigation potential by 2050 of demand-side responses at
25 0.7–8.0 GtCO₂-eq yr⁻¹ is comparable to supply-side options at 2.3–9.6 GtCO₂-eq yr⁻¹. This
26 shows that mitigation actions need to go beyond food producers and suppliers to incorporate
27 dietary changes and consumers’ behavioural patterns and reveals that producers and consumers
28 need to work together to reduce GHG emissions.

29 Though total production of calories is sufficient for the world population (Wood et al. 2018;
30 Benton et al. 2019), availability and access to food is unequally distributed, and there is a lack
31 of nutrient-dense foods, fruit and vegetables (Berners-Lee et al. 2018; Kc et al. 2018). In 2019,
32 close to 750 million people were food insecure. An estimated 2 billion people lacked adequate
33 access to safe and nutritious food in both quality and quantity (FAO et al. 2020). Two billion
34 adults are overweight or obese through inadequate nutrition, with an upward trend globally
35 (FAO et al. 2019). Low intake of fruit and vegetables is further aggravated by high intake rates
36 of refined grains, sugar and sodium together leading to a high risk of non-communicable
37 diseases such as cardiovascular disease and type 2 diabetes (Springmann et al. 2016; Clark et
38 al. 2018, 2019; GBD 2017 Diet Collaborators et al. 2019; Willett et al. 2019) (*robust evidence,*
39 *high agreement*). At least 340 million children under 5 years of age experience lack of vitamins
40 or other essential bio-available nutrients, including almost 200 million suffering from stunting,
41 wasting or overweight (UNICEF 2019).

42 Bodirsky et al. (Bodirsky et al. 2020) find that global prevalence of overweight will increase
43 to 39–52% of world population in 2050 (from 29% in 2010; range across the Socioeconomic

1 Pathways studied), and 13–20% obese people (9% in 2010). The prevalence of underweight
2 people was predicted to approximately halve, with absolute numbers stagnating at 0.4–0.7
3 billion. Although many studies represent future pathways of diets and food systems, there are
4 few holistic and consistent narratives and quantification of the future pathways of diets and
5 food systems (Mora et al. 2020; Mitter et al. 2020). Alternative pathways for improved diets
6 and food systems have been developed, emphasising climate, environmental and health co-
7 benefits (Bajželj et al. 2014; Hedenus et al. 2014; Damerau et al. 2016; Weindl et al. 2017a,b;
8 Springmann et al. 2018a; Bodirsky et al. 2020; Prudhomme et al. 2020; Hamilton et al. 2021),
9 reduced food waste and closing yield gaps (Pradhan et al. 2014; Bajželj et al. 2014), nitrogen
10 management (Bodirsky et al. 2014), urban and peri-urban agriculture (Kriewald et al. 2019)
11 and different sustainability targets (Henry et al. 2018b). The FAO has examined three
12 alternative food system scenarios: “business as usual”, “towards sustainability”, and “stratified
13 societies” (FAO 2018b). Others have identified research priorities or changes in legislation
14 needed to support adoption of improved food systems (Mylona et al. 2018).

15 Malnutrition aggravates susceptibility of children to various infectious diseases (Farhadi and
16 Ovchinnikov 2018; França et al. 2009), and infectious diseases can also decrease nutrient
17 uptake, thereby promoting malnutrition (Farhadi and Ovchinnikov 2018). Contamination of
18 food with bacteria, viruses, parasites and microbial toxins can cause foodborne illnesses
19 (Abebe et al. 2020; Ricci et al. 2017; Gallo et al. 2020), foodborne substances such as food
20 additives and specific proteins can cause adverse reactions, and contamination with toxic
21 chemical substances used in agriculture and food processing, can lead to poisoning or chronic
22 diseases (Gallo et al. 2020). Further, health risks from food systems may originate from the use
23 of antibiotics in livestock production and the occurrence of anti-microbial resistance in
24 pathogens (ECDC et al. 2015; Bennani et al. 2020), or zoonotic diseases such as COVID-19
25 (Vågsholm et al. 2020; Gan et al. 2020; Patterson et al. 2020).

26 Modern food systems are highly consolidated, through vertical and horizontal integration
27 (Swinnen and Maertens 2007; Folke et al. 2019). This consolidation has led to uneven
28 distribution of power across the food value chain, with influence concentrated among a few
29 actors in the post-farm gate food supply chain (e.g., large food processors and retailers), and
30 has contributed to a loss of indigenous agriculture and food systems, for example on Pacific
31 Islands (Vogliano et al. 2020). While agricultural producers contribute a higher proportion of
32 GHG emissions compared with other actors in the supply chain, they have relatively little
33 power to change the system (Leip et al. 2021; Clapp 2019; Group of Chief Scientific Advisors
34 2020).

35 In 2016, the agriculture, fisheries, and forestry sectors employed 29% of working people;
36 employment within these sectors was 4% in developed countries, down from 9% in 1995, and
37 57% in least developed countries, down from 71% in 1995 (World Bank 2021). Employment
38 in other (non-agriculture) food system sectors, such as the food processing industry and service
39 sectors, differs between food systems. The share of total non-farm food system employment
40 ranges from 10% in traditional food systems (e.g., Sub-Saharan Africa), to over 50% in food
41 systems in transition (e.g., Brazil), to high shares (80%) in modern food systems (e.g., U.S.)
42 (Townsend et al. 2017). The share of the food expenditures that farmers receive is decreasing;
43 at the global level, this share has been estimated at 27% in 2015 (Yi et al. 2021).

1

2 12.4.2 GHG emissions from food systems

3 12.4.2.1 Sectoral contribution of GHG emissions from food systems

4 New calculations using EDGAR.v6 (Crippa et al. 2021a) and FAOSTAT (FAO 2021) databases provide
5 territorial-based food system GHG emissions by country globally for the time period 1990 to 2018
6 (Crippa et al. 2021b). The data are calculated based on a combination of country-specific data and
7 aggregated information as described by Crippa et al. (2021b) and Tubiello et al. (2021). The data show
8 that, in 2018, 17 GtCO₂-eq yr⁻¹ (95% confidence range 13–23 GtCO₂-eq yr⁻¹, calculated according to
9 Solazzo et al. (2020) were associated with the production, processing, distribution, consumption of food
10 and management of food system residues. This corresponded to 31% (range 23–42%) of total
11 anthropogenic GHG emissions of 54 GtCO₂-eq yr⁻¹. Based on the IPCC sectoral classification (Table
12 12.7 and Figure 12.5), the largest contribution of food systems GHG emissions in 2018 was from
13 agriculture, i.e. livestock and crop production systems (6.3 GtCO₂-eq yr⁻¹, range 2.6–11.9) and land use,
14 land use change and forestry (LULUCF) (4.0 GtCO₂-eq yr⁻¹, range 2.1–5.9) (Figure 12.5). Emissions
15 from energy use were 3.9 GtCO₂-eq yr⁻¹ (3.6–4.4), waste management 1.7 GtCO₂-eq yr⁻¹ (0.9–2.6), and
16 industrial processes and product use 0.9 GtCO₂-eq yr⁻¹ (0.6–1.1). The share of GHG emissions from
17 food systems generated outside the AFOLU (agriculture and LULUCF) sectors has increased over
18 recent decades, from 28% in 1990 to 39% in 2018.

19 *Energy.* Emissions from energy use occur throughout the food supply chain. In 2018, the main
20 contributions came from energy industries supplying electricity and heat (970 MtCO₂-eq yr⁻¹),
21 manufacturing and construction (920 MtCO₂-eq yr⁻¹, of which 29% was attributable to the food,
22 beverage, and tobacco industry), and transport (760 MtCO₂-eq yr⁻¹). These emissions were almost
23 entirely as CO₂. Energy emissions from forestry and fisheries amounted to 480 MtCO₂-eq yr⁻¹, with
24 91% of emissions as CO₂. Emissions from residential and commercial fuel combustion contributed 250
25 MtCO₂-eq yr⁻¹ (79% of emissions as CO₂, and with emissions of 1.7 MtCH₄ yr⁻¹) and 130 MtCO₂-eq yr⁻¹
26 ¹ (with 98% of emissions as CO₂), respectively.

27 Refrigeration uses an estimated 43% of energy in the retail sector (Behfar et al. 2018) and significantly
28 increases fuel consumption during distribution. Besides being energy intensive, supermarket
29 refrigeration also contributes to GHG emissions through leakage of refrigerants (F-gases), although
30 their contribution to food system GHG emissions is estimated to be minor (Crippa et al. 2021b). The
31 cold chain accounts for approximately 1% of global GHG emissions, but as the number of refrigerators
32 per capita in developing countries is reported to be one order of magnitude lower than the number in
33 developed countries (19 m³ versus 200 m³ refrigerated storage capacity per 1000 inhabitants), the
34 importance of refrigeration to total GHG emissions is expected to increase (James and James 2010).
35 Although refrigeration gives rise to GHG emissions, both household refrigeration and effective cold
36 chains could contribute to a substantial reduction in losses of perishable food and thus in emissions
37 associated with food provision (University of Birmingham 2018; James and James 2010). A trade-off
38 exists between reducing food waste and increased refrigeration emissions, with the benefits depending
39 on type of produce, location and technologies used (Wu et al. 2019; Sustainable Cooling for All 2018).

40 Transport has overall a minor importance for food system GHG emissions, with a share of 5% to 6%
41 (Poore and Nemecek 2018a; Crippa et al. 2021b). The largest contributor to food system transport GHG
42 emissions was road transport (92%), followed by marine shipping (4%), rail (3%), and aviation (1%).
43 Only looking at energy needs, air or road transport consumes one order of magnitude higher energy
44 (road: 70–80 MJ t⁻¹ km⁻¹; aviation: 100–200 MJ t⁻¹ km⁻¹) than marine shipping (10–20 MJ t⁻¹ km⁻¹) or

1 rail (8–10 MJ t⁻¹ km⁻¹) (FAO 2011). For specific food products with high water content, relatively low
 2 agricultural emissions and high average transport distances, the share of transport in total GHG
 3 emissions can be over 40% (e.g., bananas, with total global average GHG emissions of 0.7 kgCO₂-eq
 4 kg⁻¹) (Poore and Nemecek 2018a), but transport is a minor source of GHG emissions for most food
 5 products (Poore and Nemecek 2018a).

6 *Industry.* Direct industrial emissions associated with food systems are generated by the refrigerants
 7 industry (580 MtCO₂-eq yr⁻¹ as F-gases) and the fertiliser industry for ammonia production (280
 8 MtCO₂-eq yr⁻¹ as CO₂) and nitric acid (60 MtCO₂-eq yr⁻¹ as N₂O). The industry sector data account for
 9 CO₂ stored in urea (-50 MtCO₂-eq yr⁻¹). Packaging contributed about 6% of total food system emissions
 10 (0.98 GtCO₂-eq yr⁻¹, 91% as CO₂, with CH₄ emissions of 2.8 Mt CH₄ yr⁻¹). Major emissions sources are
 11 pulp and paper (60 MtCO₂-eq yr⁻¹) and aluminium (30 MtCO₂-eq yr⁻¹), with ferrous metals, glass, and
 12 plastics making a smaller contribution. High shares of emissions from packaging are found for
 13 beverages and some fruit and vegetables (Poore and Nemecek 2018a).

14 *Waste.* Management of waste generated in the food system (including food waste, wastewater,
 15 packaging waste etc.) leads to biogenic GHG emissions, and contributed 1.7 GtCO₂-eq yr⁻¹ to food
 16 systems' GHG emissions in 2018. Of these emissions, 55% were from domestic and commercial
 17 wastewater (30 MtCH₄ yr⁻¹ and 310 ktN₂O yr⁻¹), 36% from solid waste management (20 MtCH₄ yr⁻¹
 18 and 310 ktN₂O yr⁻¹), and 8% from industrial wastewater (4 MtCH₄ yr⁻¹ and 80 ktN₂O yr⁻¹). Emissions
 19 from waste incineration and other waste management systems contributed 1%.

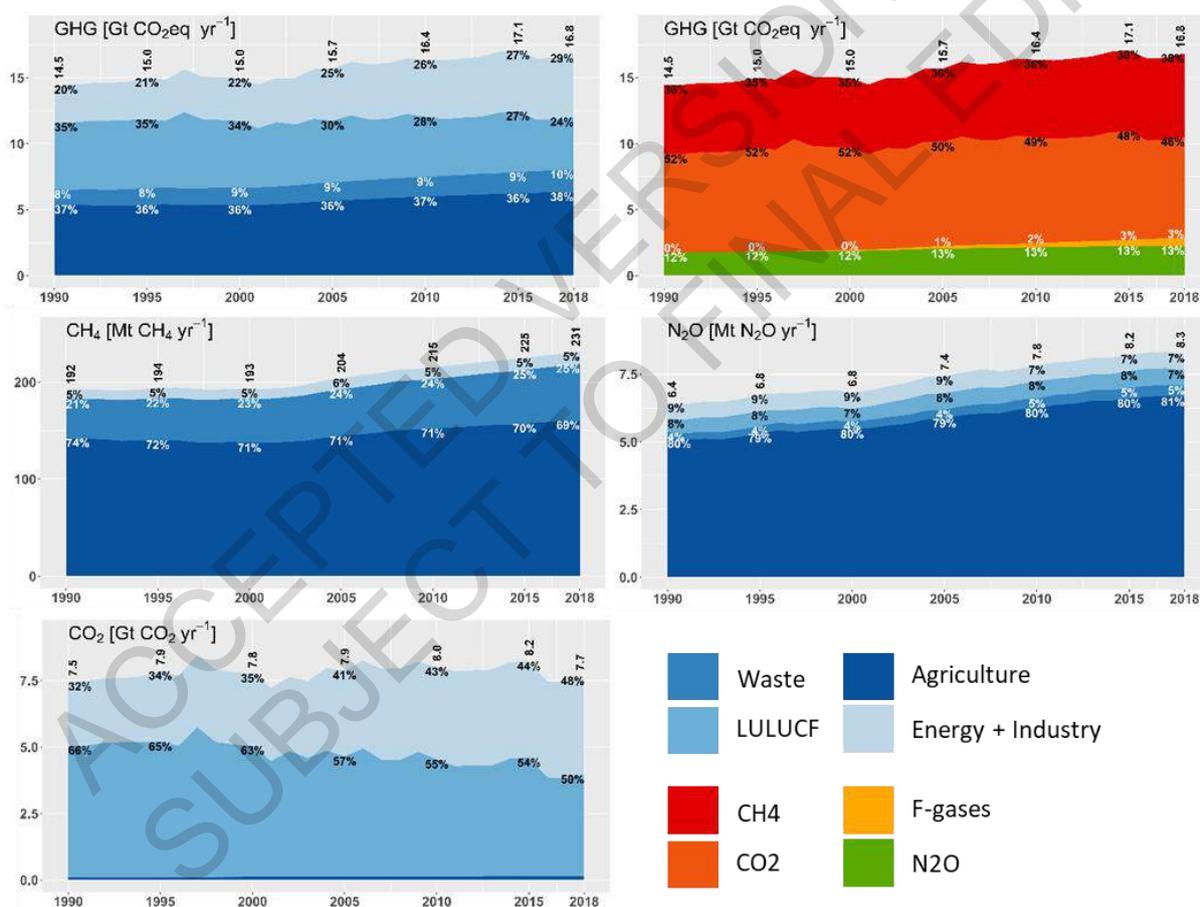

20 **Table 12.7: GHG emissions from food systems by sector according to IPCC classification in Mt gas yr⁻¹**
 21 **and food systems' share of total anthropogenic GHG emissions in 1990 and 2015.**

Sector	CO ₂	CH ₄	N ₂ O	F- gases	GHG	CO ₂	CH ₄	N ₂ O	F- gases	GHG

 8 **sectors. Source: Crippa et al. (2021b).**

9

10 **12.4.2.2 GHG intensities of food commodities**

11 There is high variability in the GHG emissions of different food products and production systems
 12 (Figure 12.6). GHG emissions intensities – measured using attributional Life Cycle Assessment,

1 considering the full supply-chain, expressed as CO₂-eq per kg of product or per kg of protein – are
2 generally highest for ruminant meat, cheese, and certain crustacean species (e.g., farmed shrimp and
3 prawns, trawled lobster) (Nijdam et al. 2012; Clark and Tilman 2017; Clune et al. 2017; Hilborn et al.
4 2018; Poore and Nemecek 2018) (*robust evidence, high agreement*). Generally, beef from dairy systems
5 has a lower footprint (8–23 kgCO₂-eq (100g protein)⁻¹ than beef from beef herds (17–94 kgCO₂-eq
6 (100g protein)⁻¹ (Figure 12.6, re-calculated from Poore and Nemecek (2018) using AR6 GWPs based
7 on a 100 year horizon) (*medium evidence, high agreement*). The wide variation in beef emissions
8 reflects differences in production systems, which range from intensive feedlots with stock raised largely
9 on grains through to rangeland and transhumance production systems. Dairy systems are generally more
10 intensive production systems, with higher digestibility feed than beef systems. Further, emissions from
11 dairy systems are shared between milk and meat, which brings GHG footprints of beef from dairy herds
12 beef closer to those of meat from monogastric animals with emissions intensities of pork (4.4–13
13 kgCO₂-eq per 100g protein) and poultry meat (2.3–11 kgCO₂-eq per 100g protein) (Poore and Nemecek
14 2018a).

15 Emission intensities for farmed fish ranged from 2.4–11 kgCO₂-eq per 100g protein (Poore and
16 Nemecek 2018a). For Norwegian seafood, large differences have been found ranging from 1.1 kgCO₂-
17 eq per kg edible product for herring to more than 8 kgCO₂-eq per kg edible product for salmon shipped
18 by road and ferry from Oslo to Paris (Winther et al. 2020). For capture fish, large differences in
19 emissions have been found, ranging from 0.2–7.9 kgCO₂-eq per kg landed fish (Parker et al. 2018),
20 although an environmental comparison of capture fish to farmed foods should include other indicators
21 such as overfishing. Plant-based foods generally have lower GHG emissions (-2.2–4.5 kgCO₂-eq per
22 100g protein) than farmed animal based foods (Clune et al. 2017; Hilborn et al. 2018; Clark and Tilman
23 2017; Nijdam et al. 2012; Poore and Nemecek 2018a) (*robust evidence, high agreement*). Several plant-
24 based foods are associated with emissions from land use change, for example, palm oil, soy and coffee
25 (Poore and Nemecek 2018a), although emissions intensities are context-specific (Meijaard et al. 2020)
26 and for plant-based proteins, GHG footprints per serving remain lower than those of animal source
27 proteins (Kim et al. 2019).

28 In traditional production systems, especially in developing countries, livestock serve multiple functions,
29 providing draught power, fertiliser, investment and social status, besides constituting an important
30 source of nutrients (Weiler et al. 2014). In landscapes dominated by forests or cropland, semi-natural
31 pastures grazed by ruminants provide heterogeneity that supports biodiversity (Röös et al. 2016).
32 Grazing on marginal land and the use of crop residues and food waste can provide human-edible food
33 with lower demands for cropland (Röös et al. 2016; van Zanten et al. 2018; Van Hal et al. 2019). Animal
34 protein requires more land than vegetable protein, so switching consumption from animal to vegetable
35 proteins could reduce the pressure on land resources and potentially enable additional mitigation
36 through expansion of natural ecosystems, storing carbon while supporting biodiversity, or reforestation
37 to sequester carbon and enhance wood supply capacity for the production of biobased products
38 substituting fossil fuels, plastics, cement, etc. (Searchinger et al. 2018; Schmidinger and Stehfest 2012;
39 Hayek et al. 2021). At the same time, alternatives to animal-based meat and other livestock products
40 are being developed (Figure 12.6). Their increasing visibility in supermarkets and catering services, as
41 well as falling production prices, could make meat substitutes competitive in one to two decades
42 (Gerhardt et al. 2019). However, uncertainty around their uptake creates uncertainty around their effect
43 on future GHG emissions.

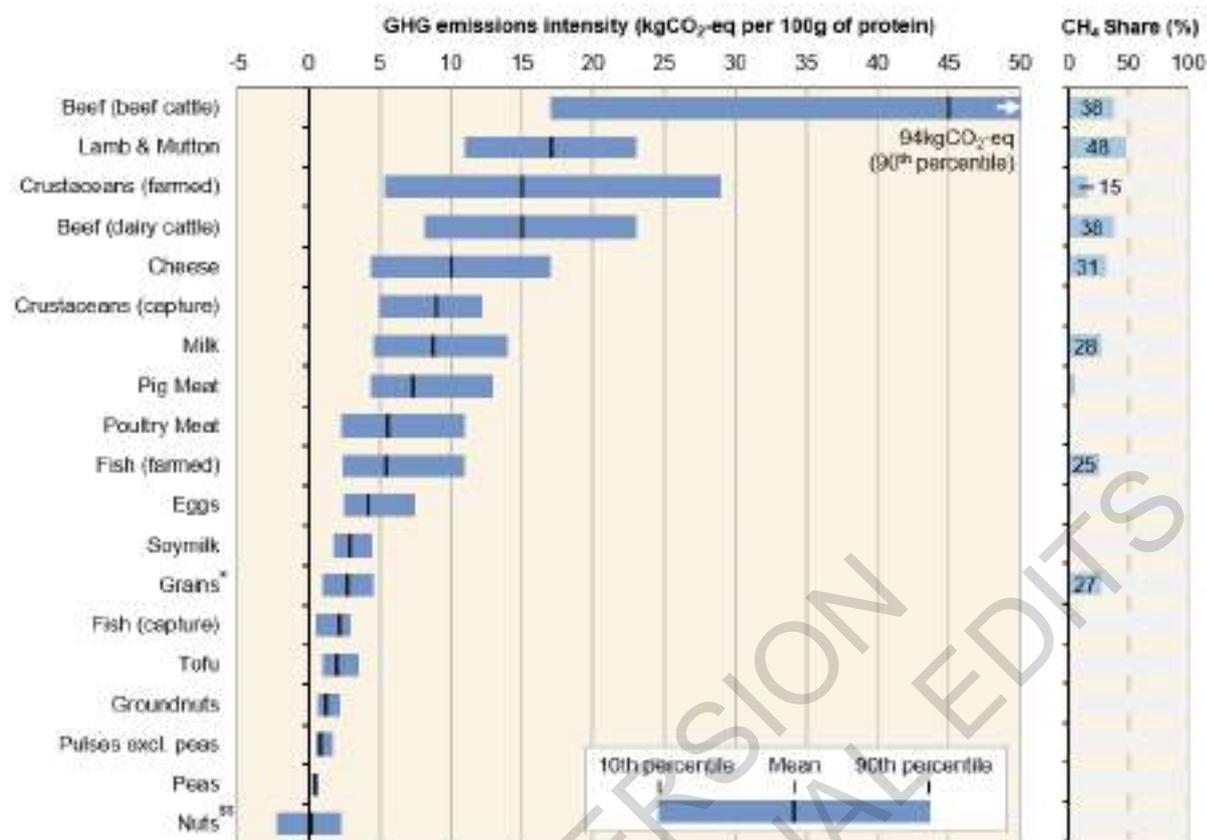

Figure 12.6: Ranges of GHG intensities [kgCO₂-eq per 100 g of protein, 10th-90th percentile] in protein-rich foods, quantified via a meta-analysis of attributional Life Cycle Assessment studies using economic allocation

Aggregation of CO₂, CH₄, and N₂O emissions in Poore and Nemecek, (2018) updated to use IPCC-AR6 100-year GWP. Data for capture fish, crustaceans, and cephalopods from Parker et al. (2018), with post-farm data from (Poore and Nemecek 2018a), where the ranges represent differences across species groups. CH₄ emissions include emissions from manure management, enteric fermentation, and flooded rice only.

*Grains are not generally classed as protein-rich, but they provide ~41% of global protein intake. Here grains are a weighted average of wheat, maize, oats, and rice by global protein intake (FAO Food Balance Sheets).

**Conversion of annual to perennial crops can lead to carbon sequestration in woody biomass and soil, shown as negative emissions intensity.

12.4.2.3 Territorial national per capita GHG emissions from food systems

Food systems are connected to other societal systems, such as the energy system, financial system, and transport system (Leip et al. 2021). Also, food systems are dynamic and continuously changing and adapting to existing and anticipated future conditions. Food production systems are very diverse and vary by farm size, intensity level, farm specialisation, technological level, production methods (e.g., organic, conventional, etc.), with environmental and social consequences (Herrero et al. 2017; Fanzo 2017; Václavík et al. 2013; Herrero et al. 2021).

1 Various frameworks have been proposed to assess sustainability of food systems, including metrics and
2 indicators on environmental, health, economic and equity issues, pointing to the importance of
3 recognizing the multi-dimensionality of food system outcomes (Béné et al. 2020; Chaudhary et al. 2018;
4 Gustafson et al. 2016; Eme et al. 2019; Hallström et al. 2018; Hebinck et al. 2021; Zurek et al. 2018).
5 Data platforms are being developed, but so far comprehensive data for evidence-based food system
6 policy are lacking (Fanzo et al. 2020).

7 To visualise several food systems dimensions in a GHG context, Figure 12.7 shows GHG emissions
8 per capita and year for regional country aggregates (Crippa et al. 2021a,b), indicated by the size of the
9 bubbles. The GHG emissions presented here are based on territorial accounting similar to the UNFCCC
10 GHG inventories: emissions are assigned to the country where they occur, not where food is consumed
11 (Section 12.4.2.1 and Crippa et al., 2021a, b). The colours of the bubbles indicate the relative
12 contribution of one of the following risk factors to deaths, according to the classification used in the
13 Global Burden of Disease Study: Child and maternal malnutrition (red, deficiencies of iron, zinc or
14 Vitamin A, or low birth weight or child growth failure), Dietary risks (yellow, for example diets low in
15 vegetables, legumes, whole grains or diets high in red and processed meat and sugar-sweetened
16 beverages) or High body-mass index (blue). The combined contribution of these three risk factors to
17 total deaths varies strongly and is between 28% and 88% of total deaths. Figure 12.7 shows that dietary
18 risk factors are prevalent throughout all regions. Though not a complete measure of the health impact
19 of food, these were selected as a proxy for nutritional adequacy and balance of diets, avoidance of food
20 insecurity, over- or mal-nutrition and associated non communicable diseases (GBD 2017 Diet
21 Collaborators 2018; GBD 2017 Diet Collaborators et al. 2019).

22 The data are plotted in a matrix with share of GHG emissions from energy use (Crippa et al. 2021b) on
23 the y-axis and the wholesale cost of food (Springmann et al. 2021) on the x-axis. The share of GHG
24 emissions from energy use is taken as a proxy for the structure of food supply in a region (Section
25 12.4.1), and the cost for food as a proxy for the structure of the demand side and the access to (healthy)
26 food (Chen et al. 2016; Hirvonen et al. 2019; Finaret and Masters 2019; HLPE 2020; Springmann et al.
27 2021), though acknowledging the limitations of such a simplification.

28 While total food system emissions in 2018 range between 0.9 and 8.5 tCO₂-eq cap⁻¹ yr⁻¹ between
29 regions, the share of energy emissions relative to energy and land-based (agriculture and food system
30 land use change) emissions ranges between 3% and 78%. Regional expenditures for food range from
31 3.0–8.8 USD cap⁻¹ day⁻¹ (Figure 12.7), though there is high variability within countries and the costs of
32 nutrient-adequate diets often exceeds those of diets delivering adequate energy (Bai et al. 2020;
33 Hirvonen et al. 2019; FAO et al. 2020). Thus, low-income households in industrialised countries can
34 also be affected by food insecurity (Penne and Goedemé 2020).

35

36

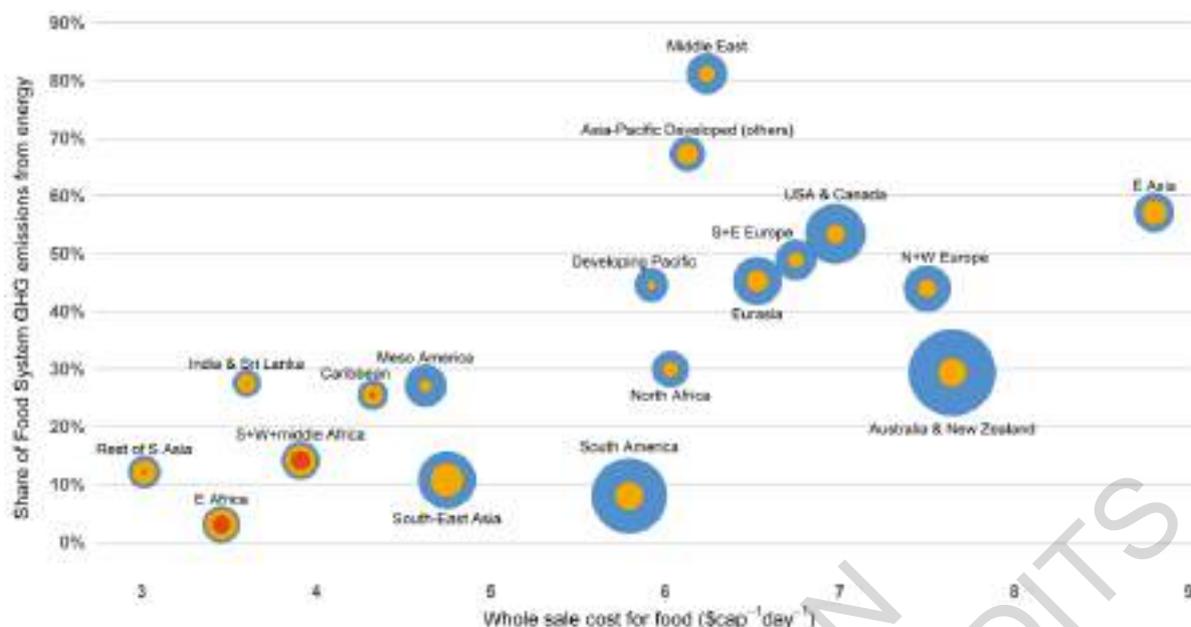

Figure 12.7: Regional differences in health outcome, territorial per capita GHG emissions from national food systems, and share of food system GHG emission from energy use.

GHG emissions are calculated according to the IPCC Tier 1 approach and are assigned to the country where they occur, not necessarily where the food is consumed. Health outcome is expressed as relative contribution of each of the following risk factors to their combined risk for deaths: Child and maternal malnutrition (red), Dietary risks (yellow) or High body-mass index (blue).

Source: cost for food (whole sale price) per capita (Springmann et al. 2021); Territorial food system GHG emissions: EDGAR v.6 (Crippa et al. 2021a), recalculated according to Crippa et al. (2021) using AR6-GWPs; Deaths attributed to dietary factors: (IHME 2018; GBD 2017 Diet Collaborators et al. 2019).

12.4.3 Mitigation opportunities

GHG emissions from food systems can be reduced by targeting direct or indirect GHG emissions in the supply chain including enhanced carbon sequestration, by introducing sustainable production methods such as agro-ecological approaches which can reduce system-level GHG emissions of conventional food production and also enhance resilience (HLPE 2019), substituting food products with high GHG intensities with others of lower GHG intensities, by reducing food over-consumption or by reducing food loss and waste. The substitution of food products with others that are more sustainable and/or healthier is often called 'dietary shift'.

Clark et al. (2020) showed that even if fossil fuel emissions were eliminated immediately, food system emissions alone would jeopardize the achievement of the 1.5°C target and threaten the 2°C target. They concluded that both demand-side and supply-side strategies are needed, including a shift to a diet with lower GHG intensity and rich in plant-based 'conventional' foods (e.g., pulses, nuts), or new food products that could support dietary shift. Such dietary shift needs to overcome socio-cultural, knowledge, and economic barriers to significantly achieve GHG mitigation (Section 12.4.5).

Food losses occur at the farm, post-harvest and food processing/wholesale stages of a food supply chain, while in the final retail and consumption stages the term food waste is used (HLPE 2014). Typically, food losses are linked to technical issues such as lack of infrastructure and storage while food waste is

1 often caused by socio-economic and behavioural factors. Mitigation opportunities through reducing
2 food waste and loss exist in all food supply chain stages and are described in the sub-sections below.

3 Food system mitigation opportunities are divided into five categories as given in Table 12.8:

- 4 • Food production from agriculture, aquaculture, and fisheries (Chapter 7.4 and Section 12.4.3.1)
- 5 • Controlled environment agriculture (Section 12.4.3.2)
- 6 • Emerging food production technologies (Section 12.4.3.3)
- 7 • Food processing industries (Section 12.4.3.4)
- 8 • Storage and distribution (Section 12.4.3.5)

9 Food system mitigation opportunities can be either incremental or transformative (Kugelberg et al.
10 2021). Incremental options are based on mature technologies, for which processes and causalities are
11 understood, and their implementation is generally accepted by society. They do not require a substantial
12 change in the way food is produced, processed, or consumed and might lead to a (slight) shift in
13 production systems or preferences. Transformative mitigation opportunities have wider food system
14 implications and usually coincide with a significant change in food choices. They are based on
15 technologies that are not yet mature and are expected to require further innovation (Klerkx and Rose
16 2020), and/or mature technologies that might already be part of some food systems but are not yet
17 widely accepted and have transformative potential if applied at large scale, e.g. consumption of insects
18 (Raheem et al. 2019a). Many emerging technologies might be seen as a further step in agronomic
19 development where land-intensive production methods relying on the availability of naturally available
20 nutrients and water are successively replaced with crop variants and cultivation practices reducing these
21 dependencies at the cost of larger energy input (Winiwarter et al. 2014). Others suggest a shift to agro-
22 ecological approaches combining new scientific insights with local knowledge and cultural values
23 (HLPE 2019). Food system transformation can lead to regime shifts or (fast) disruptions (Pereira et al.
24 2020) if driven by events that are out of control of private or public measures and have a ‘crisis’
25 character (e.g., BSE, Skuce et al. 2013).

26 Table 12.8 summarises the main characteristics of food system mitigation opportunities, their effect on
27 GHG emissions, and associated co-benefits and adverse effects.

1 **Table 12.8: Food system mitigation opportunities**

2 \$ Direct and indirect GHG effects: D – Direct emissions except emissions from energy use, E – Energy demand, M – Material demand, FL – food losses, FW – food waste; direction of effect on
 3 GHG mitigation: (+) increased mitigation, (0) neutral, (-) decreased mitigation.
 4 & Co-benefits/Adverse effects: H - health aspects, A - Animal welfare, R - resource use, L - Land demand, E – Ecosystem services; (+) co-benefits, (-) adverse effects.

Food system mitigation options (I: incremental; T: transformative)		Direct and indirect effect on GHG mitigation (+/0/-) \$	Co-benefits / Adverse effects &	Source
Food from agricultural, aquaculture and fisheries	(I) Dietary shift, in particular increased share of plant-based protein sources	D+ ↓ GHG footprint	A+ Animal welfare L+ Land sparing H+ Good nutritional properties, potentially ↓ risk from zoonotic diseases, pesticides and antibiotics	1-5
	(I/T) Digital agriculture	D+ ↑ logistics	L+ Land sparing R+ ↑ resource use efficiencies	6-7
	(T) Gene technology	D+ ↑ productivity or efficiency	H+ ↑ nutritional quality E0 ↓ use of agrochemicals; ↑ probability of off-target impacts	7-11
	(I) Sustainable intensific. land use optimisation	D+ ↓ GHG footprint E0 Mixed effects	L+ Land sparing R- Might ↑ pollution/biodiversity loss	7, 12
	(I) Agroecology	D+ ↓ GHG/area, positive micro-climatic effects E+ ↓ energy, possibly ↓ transport FL+ Circular approaches	E+ Focus on co-benefits/ecosystem services R+ Circular, ↑ nutrient and water use efficiencies	13-17
Controlled environment agriculture	(T) Soilless agriculture	D+ ↑ productivity, weather independent FL+ Harvest on demand E- Currently ↑ energy demand, but ↓ transport, building spaces can be used for renewable energy	R+ Controlled loops ↑ nutrient and water use efficiency L+ Land sparing H+ Crop breeding can be optimised for taste and/or nutritional quality	18-24

Food system mitigation options (I: incremental; T: transformative)		Direct and indirect effect on GHG mitigation (+/0/-) ^{\$}	Co-benefits / Adverse effects ^{&}	Source
Emerging Food Production technologies	(T) Insects	D0 Good feed conversion efficiency FW+ Can be fed on food waste	H0 Good nutritional qualities but attention to allergies and food safety issues required	25-28
	(I/T) Algae and bivalves	D+ ↓ GHG footprints	A+ Animal welfare L+ Land sparing H+ Good nutritional qualities; risk of heavy metal and pathogen contamination R+ Biofiltration of nutrient-polluted waters	29-32
	(I/T) Plant-based alternatives to animal-based food products	D+ No emissions from animals, ↓ inputs for feed	A+ Animal welfare L+ Land sparing H+ Potentially ↓ risk from zoonotic diseases, pesticides and antibiotics; but ↑ processing demand	31-33
	(T) Cellular agriculture (including cultured meat, microbial protein)	D+ No emissions from animals, high protein conversion efficiency E- ↑ energy need FLW+ ↓ food loss & waste	A+ Animal welfare R+ ↓ emissions of reactive nitrogen or other pollutants H0 Potentially ↓ risk from zoonotic diseases, pesticides and antibiotics; ↑ research on safety aspects needed	3, 24, 34-42
Food processing and packaging	(I) Valorisation of by-products, FLW logistics and management	M+ Substitution of bio-based materials FL+ ↓ of food losses		43-44
	(I) Food conservation	FW+ ↓ of food waste E0 ↑ energy demand but also energy savings possible (e.g., refrigeration, transport)		45-46

Food system mitigation options (I: incremental; T: transformative)		Direct and indirect effect on GHG mitigation (+/0/-) ^{\$}	Co-benefits / Adverse effects ^{&}	Source
	(I) Smart packaging and other technologies	FW+ ↓ of food waste M0 ↑ material demand and ↑ material-efficiency E0 ↑ energy demand; energy savings possible	H+ Possibly ↑ freshness/reduced food safety risks	46-49
	(I) Energy efficiency	E+ ↓ energy		50
Storage and distribution	(I) Improved logistics	D+ ↓ transport emissions		46-47
		FL+ ↓ losses in transport		51-53
		FW- Easier access to food could ↑ food waste		
	(I) Specific measures to reduce food waste in retail and food catering	FW+↓ of food waste E+ ↓ downstream energy demand M+ ↓ downstream material demand		54-56
	(I) Alternative fuels/transport modes	D+ ↓ emissions from transport		
	(I) Energy efficiency	E+ ↓ energy in refrigeration, lightening, climatisation		57-58
(I) Replacing refrigerants	D+ ↓ emissions from the cold chain		50, 59-60

ACCEPTED VERSION
SUBJECT TO FINAL EDITS

1 **12.4.3.1 Food from agriculture, aquaculture, and fisheries**

2 Agricultural food production systems range from smallholder subsistence farms to large animal
3 production factories, in open spaces, greenhouses, rural areas or urban settings.

4 *Dietary shift.* Studies demonstrate that a shift to diets rich in plant-based foods, particularly pulses, nuts,
5 fruits & vegetables, such as vegetarian, pescatarian or vegan diets, could lead to substantial reduction
6 of greenhouse gas emissions as compared to current dietary patterns in most industrialized countries,
7 while also providing health benefits and reducing mortality from diet-related non-communicable
8 diseases (Ernstoff et al. 2020; Semba et al. 2020; Theurl et al. 2020; Costa Leite et al. 2020; Chen et al.
9 2019; Jarmul et al. 2020; Willett et al. 2019; Bodirsky et al. 2020; Hamilton et al. 2021; Springmann et
10 al. 2018a).

11 Pulses such as beans, chickpeas, or lentils, have a protein composition complementary to cereals,
12 providing together all essential amino acids (McDermott and Wyatt 2017; Foyer et al. 2016). Bio-
13 availability of proteins in foods is influenced by several factors, including amino-acid composition,
14 presence of anti-nutritional factors, and preparation method (Hertzler et al. 2020; Weindl et al. 2020;
15 Semba et al. 2021). Soy beans, in particular, have a well-balanced amino acid profile with high bio-
16 availability (Leinonen et al. 2019). Pulses are part of most traditional diets (Semba et al. 2021) and
17 supply up to 10-35% of protein in low-income countries, but consumption decreases with increasing
18 income and they are globally only a minor share of the diet (McDermott and Wyatt 2017). Pulses play
19 a key role in crop rotations, fixing nitrogen and breaking disease cycles, but yields of pulses are
20 relatively low and have seen small yield increases relative to those of cereals (Barbieri et al. 2021;
21 McDermott and Wyatt 2017; Foyer et al. 2016; Semba et al. 2021).

22 *Technological innovations* have made food production more efficient since the onset of agriculture
23 (Winiwarter et al. 2014; Herrero et al. 2020). Emerging technologies include digital agriculture (using
24 advanced sensors, big data), gene technology (crop bio-fortification, genome editing, crop innovations),
25 sustainable intensification (automation of processes, improved inputs, precision agriculture) (Herrero
26 et al. 2020), or multi-trophic aquaculture approaches (Sanz-Lazaro and Sanchez-Jerez 2020; Knowler
27 et al. 2020), though literature on aquaculture and fisheries in the context of GHG mitigation is limited.

28 Such technologies may contribute to a reduction of GHG emission at the food system level enhanced
29 provision of food, better consideration of ecosystem services, or contribute to nutrition sensitive
30 agriculture, for example, by increasing the nutritional quality of staple crops, increasing the palatability
31 of leguminous crops such as lupines, or the agronomic efficiency or resilience of crops with good
32 nutritional characteristics.

33 For details on agricultural mitigation opportunities refer to Chapter 7.4.

34 **12.4.3.2 Controlled-environment agriculture**

35 Controlled-environment agriculture is mainly based on hydroponic or aquaponic cultivation systems
36 that do not require soil. Aquaponics combine hydroponics with a re-circulating aquaculture
37 compartment for integrated production of plants and fish (Junge et al. 2017; Maucieri et al. 2018), while
38 aeroponics is a further development of hydroponics that replaces water as a growing medium with a
39 mist of nutrient solution (Al-Kodmany 2018). Aquaponics could potentially produce proteins in urban
40 farms, but the technology is not yet mature and its economic and environmental performance is unclear
41 (O'Sullivan et al. 2019; Love et al. 2015).

1 Controlled-environment agriculture is often undertaken in urban environments to take advantage of
2 short supply chains (O’Sullivan et al. 2019), and might use abandoned buildings or be integrated in
3 supermarkets, producing for example herbs ‘on demand’.

4 Optimising growing conditions, hydroponic systems achieve higher yields than un-conditioned
5 agriculture (O’Sullivan et al. 2019); and yields can be further enhanced in CO₂-enriched atmospheres
6 (Armanda et al. 2019; Shamshiri et al. 2018). By using existing spaces or modular systems that can be
7 vertically stacked, this technology minimises land demand, however it is energy intensive and requires
8 large financial investments. So far, only a few crops are commercially produced in vertical farms,
9 including lettuce and other leafy greens, herbs and some vegetables due to their short growth period
10 and high value (Benke and Tomkins 2017; Beacham et al. 2019; O’Sullivan et al. 2019; Armanda et al.
11 2019). Through breeding, other crops could reach commercial feasibility, or crops with improved taste
12 or nutritional characteristics can be grown (O’Sullivan et al. 2019).

13 In controlled-environment agriculture, photosynthesis is fuelled by artificial light through LEDs or a
14 combination of natural light with LEDs. Control of the wave band and light cycle of the LEDs and
15 micro-climate can be used to optimise photosynthetic activity, yield and crop quality (Gómez and
16 Gennaro Izzo 2018; Shamshiri et al. 2018).

17 Co-benefits of controlled-environment agriculture include minimising water and nutrient losses as well
18 as agro-chemical use (Farfan et al. 2019; Shamshiri et al. 2018; O’Sullivan et al. 2019; Armanda et al.
19 2019; Al-Kodmany 2018; Ruff-Salís et al. 2020) (*robust evidence, high agreement*). Water is recycled
20 in a closed system and additionally some plants generate fresh water by evaporation from grey or black
21 water, and high nutrient use efficiencies are possible. Food production from controlled-environment
22 agriculture is independent of weather conditions and able to satisfy some consumer demand for locally-
23 produced fresh and diverse produce throughout the year (O’Sullivan et al. 2019; Al-Kodmany 2018;
24 Benke and Tomkins 2017).

25 Controlled-environment agriculture is a very energy intensive technology (mainly for cooling) and its
26 GHG intensity depends therefore crucially on the source of the energy. Options for reducing GHG
27 intensity include reducing energy use through improved lighting and cooling efficiency or by employing
28 low-carbon energy sources, potentially integrated into the building structure (Benke and Tomkins
29 2017).

30 Comprehensive studies assessing the GHG balance of controlled-environment agriculture are lacking.
31 The overall GHG emissions from controlled-environment agriculture is therefore uncertain and depends
32 on the balance of reduced GHG emissions from production and distribution and reduced land
33 requirements, versus increased external energy needs.

34 **12.4.3.3 Emerging foods and production technologies**

35 A diverse range of novel food products and production systems are emerging, that are proposed to
36 reduce GHG emissions from food production, mainly by replacing conventional animal-source food
37 with alternative protein sources. Assessments of the potential of dietary changes are given in Chapter
38 5.3 and Chapter 7.4. Here, we assess the GHG intensities of emerging food production technologies.
39 This includes products such as insects, algae, mussels and products from bio-refineries, some of which
40 have been consumed in certain societies and/or in smaller quantities (Pikaar et al. 2018; Jönsson et al.
41 2019; Govorushko 2019; Raheem et al. 2019a; Souza Filho et al. 2019). The novel aspect considered
42 here is the scale at which they are proposed to replace conventional food with the aim to reduce both
43 negative health and environmental impact. To fully realize the health benefits, dietary shifts should also

1 encompass a reduction in consumption of added sugars, salt, and saturated fats, and potentially harmful
2 additives (Curtain and Grafenauer 2019; Fardet and Rock 2019; Petersen et al. 2021).

3 Meat analogues have attracted substantial venture capital, and production costs have dropped
4 considerably in the last decade, with some reaching market maturity (Mouat and Prince 2018; Santo
5 et al. 2020), but there is uncertainty whether they will ‘disrupt’ the food market or remain niche
6 products. According to Kumar et al. (2017), the demand for plant-based meat analogues is expected to
7 increase as their production is relatively cheap and they satisfy consumer demands with regard to health
8 and environmental concerns as well as ethical and religious requirements. Consumer acceptance is still
9 low for some options, especially insects (Aiking and de Boer 2019) and cultured meat (Siegrist and
10 Hartmann 2020; Chriki and Hocquette 2020).

11 Insects. Farmed edible insects have a higher feed conversion ratio than other animals farmed for food,
12 and have short reproduction periods with high biomass production rates (Halloran et al. 2016). Insects
13 have good nutritional qualities (Parodi et al. 2018). They are suited as a protein source for both humans
14 and livestock, with high protein contents and favourable fatty acid composition (Raheem et al. 2019b;
15 Fasolin et al. 2019). If used as feed, they can grow on food waste and manure; if used as food, food
16 safety concerns/regulations can restrict the use of manure (Raheem et al. 2019b) or food waste (Varelas
17 2019) as growing substrates, and the dangers of pathogenic or toxigenic microorganisms and incidences
18 of anti-microbial resistance need to be managed (Garofalo et al. 2019).

19 Algae and bivalves have a high protein content and a favourable nutrient profile and can play a role in
20 providing sustainable food. Bivalves are high in omega-3 fatty acids and vitamin B12 and therefore
21 well-suited as replacement of conventional meats, and have a lower GHG footprint (Willer and Aldridge
22 2020; Parodi et al. 2018). Micro- and macro algae are rich in omega-3 and omega-6 fatty acids, anti-
23 oxidants and vitamins (Peñalver et al. 2020; Parodi et al. 2018; Torres-Tiji et al. 2020). Kim et al. (2019)
24 show that diets with modest amounts of low-food chain animals such as forage fish, bivalves, or insects
25 have similar GHG intensities to vegan diets. Algae and bi-valves can be used to filter nutrients from
26 waters, though care is required to avoid accumulation of hazardous substances (Willer and Aldridge
27 2020; Gentry et al. 2020).

28 Plant-based meat, milk and egg analogues. Demand for plant-based proteins is increasing and
29 incentivising the development of protein crop varieties with improved agronomic performance and/or
30 nutritional quality (Santo et al. 2020). There is also an emerging market for meat replacements based
31 on plant proteins, such as pulses, cereals, soya, algae and other ingredients mainly used to imitate the
32 taste, texture and nutritional profiles of animal-source food (Boukid 2021; Kumar et al. 2017).
33 Currently, the majority of plant-based meat analogues is based on soy (Semba et al. 2021). While other
34 products still serve a ‘niche’ market, their share is growing rapidly and some studies project a sizeable
35 share within a decade (Kumar et al. 2017; Jönsson et al. 2019). In particular, plant-based milk
36 alternatives have seen large increases in the market share (Jönsson et al. 2019). A LCA of 56 plant-
37 based meat analogues showed mean GHG intensities (farm to factory) of 0.21–0.23 kgCO₂-eq per 100
38 g of product or 20 g of protein for all assessed protein sources (Fresán et al. 2019). Higher footprints
39 were found in the meta-review by Santo et al. (2020). Including preparation, Meija et al. (2019) found
40 higher emissions for burgers and sausages as compared to minced products.

41 Cellular agriculture. The use of fungi, algae and bacteria is an old process (beer, bread, yoghurt) and
42 serves, among others, for the preservation of products. The concept of cellular agriculture (Mattick
43 2018) covers bio-technological processes that use micro-organisms to produce acellular (fermentation
44 based cellular agriculture) or cellular products. Yeasts, fungi or bacteria can synthesise acellular
45 products such as haem, milk and egg proteins, or protein-rich animal feed, other food ingredients, and

1 pharmaceutical and material products (Rischer et al. 2020; Mendly-Zambo et al. 2021). Cellular
2 products include cell tissues such as muscle cells to grow cultured meat, fish or other cells (Post 2012;
3 Rischer et al. 2020) and products where the micro-organisms will be eaten themselves (Pikaar et al.
4 2018; Sillman et al. 2019; Schade et al. 2020). Single cell proteins, combined with photovoltaic
5 electricity generation and direct air capture of carbon dioxide are proposed as highly land- and energy-
6 efficient alternatives to plant-based protein (Leger et al. 2021). Some microbial proteins are produced
7 in a ‘bioreactor’ and use Haber-Bosch nitrogen and vegetable sugars or atmospheric CO₂ as source of
8 N and C (Simsa et al. 2019; Pikaar et al. 2018). Cultured meat is currently in the research stage and
9 some challenges remain, such as the need for animal-based ingredients to ensure fast/effective growth
10 of muscle cells, tissue engineering to create different meat products, the production at scale and at
11 competitive costs, and regulatory barriers (Rubio et al. 2019; Stephens et al. 2018; Post et al. 2020; Post
12 2012; Tuomisto 2019). Only a few studies to date have quantified the GHG emissions of microbial
13 proteins or cultured meat, suggesting GHG emissions at the level of poultry meat (Tuomisto and
14 Teixeira de Mattos 2011; Mattick et al. 2015; Souza Filho et al. 2019; Tuomisto 2019).

15 A review of LCA studies on different plant-based, animal source and nine ‘future food’ protein sources
16 (Parodi et al. 2018) concluded that insects, macro-algae, mussels, myco-proteins and cultured meat
17 show similar GHG intensities per unit of protein (mean values ranging 0.3–3.1 kgCO₂-eq per 100 g of
18 protein), comparable to milk, eggs, and tuna (mean values ranging 1.2–5.4 kgCO₂-eq per 100 g of
19 protein); while *chlorella* and *spirulina* consume more energy per unit of protein and were associated
20 with higher GHG emissions (mean values ranging 11–13 kgCO₂-eq per 100 g of protein). As the main
21 source of GHG emissions from insects and cellular agriculture foods is energy consumption, their GHG
22 intensity improves with increased use of low-carbon energy (Smetana et al. 2015; Pikaar et al. 2018;
23 Parodi et al. 2018).

24 Future foods offer other benefits such as lower land requirements, controlled systems with reduced
25 losses of water and nutrients, increased resilience, and possibly reduced hazards from pesticide and
26 antibiotics use and zoonotic diseases, although more research is needed including allergenic and other
27 safety aspects, and possibly reduced protein bioavailability (Tzachor et al. 2021; Alexander et al. 2017;
28 Stephens et al. 2018; Parodi et al. 2018; Santo et al. 2020; Fasolin et al. 2019; Chriki and Hocquette
29 2020; Hadi and Brightwell 2021) (*medium evidence, high agreement*). Research is needed also on the
30 effect of processing (Wickramasinghe et al. 2021), though a randomized crossover trial comparing
31 appetizing plant foods with meat alternatives found several beneficial and no adverse effects from the
32 consumption of the plant-based meats (Crimarco et al. 2020).

33 **12.4.3.4 Food processing and packaging**

34 Food processing includes preparation and preservation of fresh commodities (fruit and vegetables, meat,
35 seafood and dairy products), grain milling, production of baked goods, and manufacture of pre-prepared
36 foods and meals. Food processors range from small local operations to large multi-national food
37 producers, producing food for local to global markets. The importance of food processing and
38 preservation is particularly evident in developing countries lacking cold chains for the preservation and
39 distribution of fresh perishable products such as fresh fish (Adeyeye 2017; Adeyeye and Oyewole
40 2016).

41 Mitigation in food processing largely focuses on reducing food waste and fossil energy usage during
42 the processing itself, as well as in the transport, packaging and storage of food products for distribution
43 and sale (Silva and Sanjuán 2019). Reducing food waste provides emissions savings by reducing
44 wastage of primary inputs required for food production. Another mitigation route, contributing to the
45 circular economy (Sections 12.6.1.2 and Cross-Working Group Box 3 in this Chapter), is by valorisation

1 of food processing by-products through recovery of nutrients and/or energy. No global analyses of the
2 emissions savings potential from the processing step in the value chain could be found.

3 Reduced food waste during food processing can be achieved by seeking alternative processing routes
4 (Atuonwu et al. 2018), improved communication along the food value chain (Göbel et al. 2015),
5 optimisation of food processing facilities, reducing contamination, and limiting damages and spillage
6 (HLPE 2014). Optimisation of food packaging also plays an important role in reducing food waste, in
7 that it can extend product shelf life; protect against damage during transport and handling; prevent
8 spoilage; facilitate easy opening and emptying; and communicate storage and preparation information
9 to consumers (Molina-Besch et al. 2019).

10 Developments in smart packaging are increasingly contributing to reducing food waste along the food
11 value chain. Strategies for reducing the environmental impact of packaging include using less, and more
12 sustainable, materials and a shift to re-usable packaging (Coelho et al. 2020). Active packaging
13 increases shelf life through regulating the environment inside the packaging, including levels of oxygen,
14 moisture and chemicals released as the food ages (Emanuel and Sandhu 2019). Intelligent packaging
15 communicates information on the freshness of the food through indicator labels (Poyatos-Racionero et
16 al. 2018), and data carriers can store information on conditions such as temperature along the entire
17 food chain (Müller and Schmid 2019).

18 LCA can be used to evaluate the benefits and trade-offs associated with different processing or
19 packaging types (Silva and Sanjuán 2019). Some options, such as aluminium, steel and glass, require
20 high energy investment in manufacture when produced from primary materials, with significant savings
21 in energy through recycling being possible (Camaratta et al. 2020). However, these materials are inert
22 in landfill. Other packaging options, such as paper and biodegradable packaging, may require a lower
23 energy investment during manufacture, but may require larger land area and can release methane when
24 consigned to anaerobic landfill where there is no methane recovery. Nevertheless, packaging accounts
25 for only 1-12% (typically around 5%) of the GHG emissions in the life cycle of a food system (Wohner
26 et al. 2019; Crippa et al. 2021b), suggesting that its benefits can often outweigh the emissions associated
27 with the packaging itself.

28 The second component of mitigation in food processing relates to reduction in fossil energy use.
29 Opportunities include energy efficiency in processes (also discussed in Chapter 11.3), the use of heat
30 and electricity from low-carbon energy sources in processing (Chapter 6), through off-grid thermal
31 processing (sun drying, food smoking) and improving logistics efficiencies. Energy intensive processes
32 with energy saving potential include milling and refining (oil seeds, corn, sugar), drying, and food safety
33 practices such as sterilisation and pasteurisation (Niles et al. 2018). Packaging also plays a role: reduced
34 transport energy can be achieved through reducing the mass of goods transported and improving
35 packing densities in transport vehicles (Lindh et al. 2016; Molina-Besch et al. 2019; Wohner et al.
36 2019). Choice of packaging also influences refrigeration energy requirements during transport and
37 storage.

38 *12.4.3.5 Storage and distribution*

39 Transport mitigation options along the supply chain include improved logistics, the use of alternative
40 fuels and transport modes, and reduced transport distances. Logistics and alternative fuels and transport
41 modes are discussed in Chapter 10. Transport emissions might increase with increasing demand for a
42 diversity of foods as developing countries become more affluent. New technologies that enable food on
43 demand or online food shopping systems might further increase emissions from food transport;
44 however, the consequences are uncertain and might also entail a shift from individual traffic to bulk
45 transport. The impact on food waste is also uncertain as more targeted delivery options could reduce

1 food waste, but easier access to a wider range of food could also foster over-supply and increase food
2 waste. Mitigation opportunities in food transport are inherently linked to decarbonisation of the
3 transport sector (Chapter 10).

4 Retail and the food service industry are the main factors shaping the external food environment or ‘food
5 entry points’; they are the “physical spaces where food is obtained; the built environment that allows
6 consumers to access these spaces” (HLPE 2017). These industries have significant influence on
7 consumers’ choices and can play a role in reducing GHG emissions from food systems. Opportunities
8 are available for optimisation of inventories in response to consumer demands through advanced IT
9 systems (Niles et al. 2018), and for discounting foods close to sell-by dates, which can both serve to
10 reduce food spoilage and wastage (Buisman et al. 2019).

11 As one of the highest contributors to energy demand at this stage in the food value chain, refrigeration
12 has received a strong focus in mitigation. Efficient refrigeration options include advanced refrigeration
13 temperature control systems, and installation of more efficient refrigerators, air curtains and closed
14 display fridges (Chaomuang et al. 2017). Also related to reducing emissions from cooling and
15 refrigeration is the replacement of hydrofluorocarbons which have very high GWPs with lower GWP
16 alternatives (Niles et al. 2018). The use of propane, isobutane, ammonia, hydrofluoroolefins and CO₂
17 (refrigerant R744) are among those that are being explored, with varying success (McLinden et al.
18 2017). In recent years, due to restrictions on high GWP-refrigerants, a considerable growth in the market
19 availability of appliances and systems with non-fluorinated refrigerants has been seen (Eckert et al.
20 2021)

21 Energy efficiency alternatives generic to buildings more broadly are also relevant here, including
22 efficient lighting, HVAC systems and building management, with ventilation being a particularly high
23 energy user in retail, that warrants attention (Kolokotroni et al. 2015).

24 In developing countries particularly, better infrastructure for transportation and expansion of processing
25 and manufacturing industries can significantly reduce food losses, particularly of highly perishable food
26 (Niles et al. 2018; FAO 2019a).

27 **12.4.4 Enabling food system transformation**

28 Food system mitigation potentials in AFOLU are assessed in Chapter 7.4, and food system mitigation
29 potentials linked to demand side measures are assessed in Chapter 5. Studies suggest that using supply
30 and demand-side policies are implemented in combination makes ambitious mitigation targets easier to
31 achieve (Latka et al. 2021a; Temme et al. 2020; Global Panel on Agriculture and Food Systems for
32 Nutrition 2020; Clark et al. 2020) (*high agreement; limited evidence*).

33 The trends in the global and national food systems towards a globalisation of food supply chains and
34 increasing dominance of supermarkets and large corporate food processors (Dries et al. 2004; Neven
35 and Reardon 2004; Baker and Friel 2016; Andam et al. 2018; Popkin and Reardon 2018; Reardon et al.
36 2019; Pereira et al. 2020) has led to environmental, food insecurity and malnutrition problems. Studies
37 therefore call for a transformation of current global and national food systems to solve these problems
38 (Schösler and Boer 2018; McBey et al. 2019; Kugelberg et al. 2021). This has not yet been successful,
39 including due to insufficient coordination between relevant food system policies (Weber et al. 2020)
40 (*medium evidence, high agreement*).

41 Different elements of food systems are currently governed by separate policy areas that in most
42 countries scarcely interact or cooperate (iPES Food 2019; Termeer et al. 2018). This
43 compartmentalisation makes the identification of synergetic and antagonistic effects difficult and faces

1 the possibility of failure due to unintended and unanticipated negative impacts on other policy areas
2 and consequently lack of agreement and social acceptance (Mylona et al. 2018; Brouwer et al. 2020;
3 Mausch et al. 2020; Hebinck et al. 2021) (Section 12.4.5). This could be overcome through cooperation
4 across several policy areas (Sections 12.6.2; 13.7), in particular agriculture, nutrition, health, trade,
5 climate, environment policies, and an inclusive and transparent governance structure (Bhunoo 2019;
6 Diercks et al. 2019; Herrero et al. 2021; iPES Food 2019; Termeer et al. 2018; Mausch et al. 2020;
7 Kugelberg et al. 2021), making use of potential spill-over effects (Kanter et al. 2020; OECD 2021).

8 Transformation of food systems may come from technological, social or institutional innovations that
9 start as niches but can potentially lead to rapid changes, including changes in social conventions
10 (Centola et al. 2018; Benton et al. 2019).

11 Where calories and ruminant animal-source food are consumed in excess of health guidelines, reduction
12 of excess meat (and dairy) consumption is amongst the most effective measures to mitigate GHG
13 emissions, with a high potential for environment, health, food security, biodiversity, and animal welfare
14 co-benefits (Stylianou et al. 2021; Chai et al. 2019; Semba et al. 2020; Willett et al. 2019; Chen et al.
15 2019; Hamilton et al. 2021; Hedenus et al. 2014; Kim et al. 2019; Theurl et al. 2020; Springmann et al.
16 2018a) (*robust evidence, high agreement*). Dietary changes are relevant for several SDGs, apart from
17 SDG 13 (climate action), including SDG 2 (zero hunger), SDG 3 (good health and well-being), SDG 6
18 (clean water and sanitation), SDG 12 (responsible consumption and production), SDG 14 (life below
19 water) and SDG 15 (life on land) (Bruce M et al. 2018; Vanham et al. 2019; Mbow et al. 2019; Herrero
20 et al. 2021) (Section 12.6.1). However, behavioural change towards diets of lower environmental impact
21 and higher nutritional qualities faces barriers both from agricultural producers and consumers
22 (Apostolidis and McLeay 2016; Aiking and de Boer 2018; de Boer et al. 2018; Milford et al. 2019), and
23 requires policy packages that combine informative instruments with behavioural, administrative and/or
24 market-based instruments, and are attentive to the needs of, and engage, all food system stakeholders
25 including civil society networks, and change the food environment (see Section 12.4.1) (Stoll-
26 Kleemann and Schmidt 2017; Kraak et al. 2017; El Bilali 2019; Cornelsen et al. 2015; iPES Food 2019;
27 Milford et al. 2019; Temme et al. 2020) (*robust evidence, high agreement*).

28 Table 12.9 summarizes the implications of a range of policy instruments discussed in more detail in the
29 following sub-sections and highlights the benefits of integrated policy packages. Furthermore, Table
30 12.9 assesses transformative potential, environmental effectiveness, feasibility, distributional effect,
31 cost, and cost-benefits and trade-offs of individual policy instruments, as well as their potential role as
32 part of coherent policy packages. Table 12.9 shows that information and behavioural policy instruments
33 can have significant but small effects in changing diets (*robust evidence, medium agreement*), but are
34 mutually enforcing and might be essential to lower barriers and increase acceptance of market-based
35 and administrative instruments (*medium evidence, high agreement*).

36 The policy instruments are assessed in relation to shifting food consumption and production towards
37 increased sustainability and health. This includes lowering GHG emissions, although not in all cases is
38 this the primary focus of the instrument, and in some cases lowering GHG emission may not even be
39 explicitly mentioned.

1

Table 12.9: Assessment of food system policies targeting (post-farm gate) food chain actors and consumers

	Level	Transformative potential Environ. effective.	Feasibility	Distributional effects	Cost	Co-benefits ^s and adverse side-effect	Implications for coordination, coherence and consistency in policy package ^{&}
Integrated food policy packages	NL			can be controlled	Cost efficient	+ balanced, addresses multiple sustainability goals	Reduces cost of uncoordinated interventions; increases acceptance across stakeholders and civil society (<i>robust evidence, high agreement</i>)
Taxes on food products	GN			regressive	low ^{#1}	- unintended substitution effects	High enforcing effect on other food policies; higher acceptance if compensation or hypothecated taxes (<i>medium evidence, high agreement</i>)
GHG taxes on food	GN			regressive	low ^{#2}	-unintended substitution effects +high spillover effect	Supportive, enabling effect on other food policies, agricultural/fishery policies; requires changes in power distribution and trade agreements (<i>medium evidence, medium agreement</i>)
Trade policies	G			impacts global distribution	complex effects	+ counters leakage effects +/- effects on market structure and jobs	Requires changes in existing trade agreements (<i>medium evidence, high agreement</i>)
Investment into research & innovation	GN			none	medium	+ high spillover effect + converging with digital society	Can fill targeted gaps for coordinated policy packages (e.g. monitoring methods) (<i>robust evidence, high agreement</i>)
Food and marketing regulations	N				low		Can be supportive; might be supportive to realise innovation; voluntary standards might be less effective (<i>medium evidence, medium agreement</i>)

Organisational level procurement policies	NL					low	+ can address multiple sustainability goals	Enabling effect on other food policies; reaches large share of population (<i>medium evidence, high agreement</i>)
Sustainable food-based dietary guidelines	GN L				none	low	+ can address multiple sustainability goals	Little attention so far on environmental aspects; can serve as benchmark for other policies (labels, food formulation standards, etc.) (<i>medium evidence, medium agreement</i>).
Food labels/information	GN L				education level relevant	low	+ empowers citizens + increases awareness + multiple objectives	Effective mainly as part of a policy package; incorporation of other objectives (e.g. animal welfare, fair trade...); higher effect if mandatory (<i>medium evidence, medium agreement</i>).
Nudges	NL				none	low	+ possibly counteracting information deficits in population subgroups	High enabling effect on other food policies, (<i>medium evidence, high agreement</i>)

1

2 **Colour code:** **Effect of measures:** negative ■, none/unclear ■, slightly positive ■, positive ■; **Level:** G: global/multinational, N: national, L: local; **#1** Minimum level
3 to be effective 20% price increase; **#2** Minimum level to be effective 50-80USD per tCO₂eq. \$ In addition, all interventions are assumed to address health and climate
4 change mitigation. **&** Requires coordination between policy areas, participation of stakeholders, transparent methods and indicators to manage trade-offs and prioritisation
5 between possibly conflicting objectives; and suitable indicators for monitoring and evaluation against objectives.

6

1 **12.4.4.1 Market based instruments**

2 *Taxes and subsidies:* Food-based taxes have largely been implemented to reduce non-communicable
3 diseases and sugar intake, particularly those targeting sugar-sweetened beverages (WHO 2019). Many
4 health-related organisations recommend the introduction of such taxes to improve the nutritional quality
5 of marketed products and consumers' diets (Park and Yu 2019; Wright et al. 2017; WHO 2019), even
6 though the impacts of food taxes are complex due to cross-price and substitution effects and supplier
7 reactions (Blakely et al. 2020; Gren et al. 2019; Cornelsen et al. 2015) and their regressive effect (WHO
8 2019). Subsidies and taxes are found to be effective in changing dietary behaviour at levels above 20%
9 price increase (Niebylski et al. 2015; Mozaffarian et al. 2018; Nakhimovsky et al. 2016; Hagenaars et
10 al. 2017; Cornelsen et al. 2015), even though longer term effects are scarcely studied (Cornelsen et al.
11 2015) and effects of sugar tax with tax rates lower than 20% have been observed for low-income groups
12 (Temme et al. 2020).

13 Modelling results show only small consumption shifts with moderate meat price increases; and high
14 price increases are required to reach mitigation targets, even though model predictions become highly
15 uncertain due to lack of observational data (Zech and Schneider 2019; Fellmann et al. 2018; Bonnet et
16 al. 2018; Mazzocchi 2017; Latka et al. 2021b). Taxes applied at the consumer level are found to be
17 more effective than levying the taxes at the production side (Springmann et al. 2017).

18 Unilateral taxes on food with high GHG intensities have been shown to induce increases in net export
19 flows, which could reduce global prices and increase global demand. Indirect effects on GHG mitigation
20 therefore could be reduced by up to 70–90% of national results (Fellmann et al. 2018; Zech and
21 Schneider 2019) (*limited evidence, high agreement*). The global mitigation potential for GHG taxation
22 of food products at 52 USD kgCO₂-eq⁻¹ has been estimated at 1 GtCO₂-eq yr⁻¹ (Springmann et al. 2017).

23 Studies have shown that taxes can improve the nutritional quality of diets and reduce GHG emissions
24 from the food system, particularly if accompanied by other policies that increase acceptance and
25 elasticity, and reduce regressive and distributional problems (Niebylski et al. 2015; Hagenaars et al.
26 2017; Mazzocchi 2017; Springmann et al. 2017; Wright et al. 2017; Henderson et al. 2018; Säll 2018;
27 FAO et al. 2020; Penne and Goedemé 2020) (*robust evidence, high agreement*).

28 *Trade:* Since the middle of the last century, global trade of agricultural products has contributed to
29 boosting productivity and reducing commodity prices, while also incentivising national subsidies for
30 farmers to remain competitive in the global market (Benton et al. 2019). Trade liberalisation has been
31 coined as an essential element of sustainable food systems, and as one element required to achieve
32 sustainable development, that can shift pressure to regions where the resources are less scarce (Traverso
33 and Schiavo 2020; Wood et al. 2018). However, Clapp (2017) argues that the main economic benefit
34 of trade liberalisation flows to large transnational firms. Benton and Bailey (2019) argue that low food
35 prices in the second half of last century contributed to both yield and food waste increases, and to a
36 focus on staple crops to the disadvantage of nutrient dense foods. However, global trade can also
37 contribute to economic benefits such as jobs and income, reduce food insecurity and facilitate access to
38 nutrients (Wood et al. 2018; Hoff et al. 2019; Traverso and Schiavo 2020; Geyik et al. 2021) and has
39 contributed to increased food supply diversity (Kummu et al. 2020). The relevance of trade for food
40 security, and adaptation and mitigation of agricultural production, has also been discussed in Mbow et
41 al. (2019).

42 Trade policies can be used to protect national food system measures, by requiring front-of-package
43 labels, or to impose border taxes on unhealthy products (Thow and Nisbett 2019). For example, in the
44 frame of the Pacific Obesity Prevention in Communities (OPIC), the Fijian government implemented
45 three measures (out of seven proposed) that eliminated import duties on fruits and vegetables, and

1 imposed 15% import duties on unhealthy oils (Latu et al. 2018). Trade agreements, however, have the
2 potential to undermine national efforts to improve public health (Unar-Munguía et al. 2019). GHG
3 mitigation efforts in food supply chains can be counteracted by GHG leakage, with a general increase
4 of environmental and social impact in developing countries exporting food products, and a decrease in
5 the developed countries importing food products (Wiedmann and Lenzen 2018; Sandström et al. 2018;
6 Fellmann et al. 2018). The demand for agricultural commodities has also been associated with tropical
7 deforestation, though a robust estimate on the extent of embodied deforestation in food commodities is
8 not available (Pendrill et al. 2019).

9 *Investment into research & innovation:* El Bilali (2019) assessed research gaps in the food system
10 transition literature and found a need to develop comparative studies that enable the assessment of
11 spatial variability and scalability of food system transitions. The author found also that the role of
12 private industry and corporate business is scarcely researched, although they could play a major role in
13 food system transitions.

14 The InterAcademy Partnership assessed how research can contribute to providing the required evidence
15 and opportunities for food system transitions, with a focus on climate change impacts and mitigation
16 (IAP 2018). The project builds on four regional assessments of opportunities and challenges on food
17 and nutrition security in Africa (NASAC 2018), the Americas (IANAS 2018), Asia (AASSA 2018),
18 and Europe (EASAC 2017). The Partnership concludes with a set of research questions around food
19 systems, that need to be better understood: (i) how are sustainable food systems constituted in different
20 contexts and at different scales, (ii) how can transition towards sustainable food systems be achieved,
21 and (iii) how can success and failure be measured along sustainability dimensions including climate
22 mitigation?

24 **12.4.4.2 Regulatory and administrative instruments**

25 *Marketing regulations:* Currently, 16 countries regulate marketing of unhealthy food to children, mainly
26 on television and in schools (Taillie et al. 2019), and many other efforts are ongoing across the globe
27 (European Commission 2019). The aim to counter the increase in obesity in children and target products
28 high in saturated fats, trans-fatty acids, free sugars and/or salt (WHO 2010) was endorsed by 192
29 countries (Kovic et al. 2018). Nutrition and health claims for products are used by industry to increase
30 sales, for example in the sport sector or for breakfast cereals. They can be informative, but can also be
31 misleading if misused for promoting unhealthy food (Ghosh and Sen 2019; Sussman et al. 2019;
32 Whalen et al. 2018).

33 Strong statutory marketing regulations can significantly reduce the exposure of children to, and sales
34 of, unhealthy food compared with voluntary restrictions (Kovic et al. 2018; Temme et al. 2020). Data
35 on effectiveness of marketing regulations with a broader food sustainability scope are not available. On
36 the other hand, regulations that mobilise private investment into emerging food production technologies
37 can be instrumental in curbing the cost and making them competitive (Bianchi et al. 2018a).

38 *Voluntary sustainability standards:* Voluntary sustainability standards are developed either by a public
39 entity or by private organisations to respond to consumers' demands for social and environmental
40 standards (Fiorini et al. 2019). For example, the Dutch "Green Protein Alliance", an alliance of
41 government, industry, NGOs and academia, formulated a goal to shift the ratio of protein consumption
42 from 60% animal source proteins currently to 40% by 2050 (Aiking and de Boer 2020), and Cool Food
43 Pledge signatories (organisations that serve food, such as restaurants, hospitals and universities)
44 committed to a 25% reduction in GHG emissions by 2030, compared with 2015 (Cool Food 2020). For

1 firms, obtaining certification under such schemes can be costly, and costs are generally borne by the
2 producers and/or supply chain stakeholders (Fiorini et al. 2019). The effectiveness of private voluntary
3 sustainability standards is uncertain. Cazzolla Gatti et al. (2019) have investigated the effectiveness of
4 the Roundtable on Sustainable Palm Oil on halting forest loss and habitat degradation in Southeast Asia
5 and concluded that production of certified palm oil continued to lead to deforestation.

6 *Organisational procurement:* Green public procurement is a policy that aims to create additional
7 demand for sustainable products (Bergmann Madsen 2018; Mazzocchi and Marino 2019) or decrease
8 demand for less sustainable products (e.g., the introduction of “Meatless Monday” by the Norwegian
9 Armed Forces (Milford and Kildal 2019; Cheng et al. 2018; Wilts et al. 2019; Gava et al. 2018)). To
10 improve dietary choices, organisations can increase the price of unsustainable options while decreasing
11 the price of sustainable ones, or employ information or choice architecture measures (Goggins and Rau
12 2016; Goggins 2018). Procurement guidelines exist at global, national, organisational or local levels
13 (Neto and Gama Caldas 2018; Noonan et al. 2013). Procurement rules in schools or public canteens
14 increase the accessibility of healthy food and can improve dietary behaviour and decrease purchases of
15 unhealthy food (Cheng et al. 2018; Temme et al. 2020).

16 *Food regulations:* Novel foods based on insects, microbial proteins or cellular agriculture must go
17 through authorisation processes to ensure compliance with food safety standards before they can be
18 sold to consumers. Several countries have ‘novel food’ regulations governing the approval of foods for
19 human consumption. For example, the European Commission, in its update of the Novel Food
20 Regulation in 2015, expanded its definition of novel food to include food from cell cultures, or that
21 produced from animals by non-traditional breeding techniques (EU 2015).

22 For animal product analogues, regulatory pathways and procedures (Stephens et al. 2018) and
23 terminology issues (defining equivalence questions) (Carrenõ and Dolle 2018; Pisanello and Ferraris
24 2018) need clarification, as does their relation to religious rules (Chriki and Hocquette 2020).

25 Examples of legislation targeting food waste include the French ban on wasting food approaching best-
26 before dates, requiring its donation to charity organisations (Global Alliance for the Future of Food
27 2020). In Japan, the Food Waste Recycling Law set targets for food waste recycling for industries in
28 the food sector for 2020, ranging between 50% for restaurants and 95% for food manufacturers (Liu et
29 al. 2016).

30 **12.4.4.3 Informative instruments.**

31 *Sustainable Food-Based Dietary Guidelines:* National food based dietary guidelines (FBDGs) provide
32 science-based recommendations on food group consumption quantities. They are available for 94,
33 mostly upper- and middle-income countries globally (Wijesinha-Bettoni et al. 2021), adapted to
34 national cultural and socio-economic context, and can be used as a benchmark for food formulation
35 standards or public and private food procurement, or to inform citizens (Bechthold et al. 2018; Temme
36 et al. 2020). Most FBDGs are based on health considerations and only a few mention environmental
37 sustainability aspects (Bechthold et al. 2018; Ritchie et al. 2018; Ahmed et al. 2019; Springmann et al.
38 2020). Implementation of FBDGs so far focuses largely in the education and health sectors, with few
39 countries also using their potential for guiding food system policies in other sectors (Wijesinha-Bettoni
40 et al. 2021).

41 Despite the fact that 1.5 billion people follow a vegetarian diet from choice or necessity and the position
42 statements of various nutrition societies point out that vegetarian diets are adequate if well planned, few
43 FBDGs give recommendations for vegetarian diets (Costa Leite et al. 2020). An increase in
44 consumption of plant-based food is a recurring recommendation in FBDGs, though an explicit reduction

1 or limit of animal source proteins is not often included, with the exception of red or processed meat
2 (Temme et al. 2020). To account for changing dietary trends, however, FBDGs need to incorporate
3 sustainability aspects (Herforth et al. 2019). A healthy diet respecting planetary boundaries has been
4 proposed by Willett et al. (2019), though some authors have questioned the validity of the nutritional
5 (Zagmutt et al. 2019) or environmental implications, such as water use (Vanham et al. 2020). In October
6 2019, 14 global cities pledged to adhere to this ‘planetary health diet’ (C40 Cities 2019).

7 *Education on food/nutrition and environment:* Some consumers are reluctant to adopt sustainable
8 healthy dietary patterns because of a lack of awareness of the environmental and health consequences
9 of what they eat, but also out of suspicion towards alternatives that are perceived as not ‘natural’ and
10 that seem to be difficult to integrate into their daily dietary habits (Hartmann and Siegrist 2017;
11 Stephens et al. 2018; McBey et al. 2019; Siegrist and Hartmann 2020) or simply lack of knowledge on
12 how to prepare or eat unfamiliar foods (Aiking and de Boer 2020; El Bilali 2019; Temme et al. 2020).
13 Misconceptions may contribute, for example, the belief that packaging or ‘food miles’ dominate the
14 climate impact of food (Macdiarmid et al. 2016). However, spill-over effects can induce sustainable
15 behaviour from ‘entry points’ such as concerns about food waste (El Bilali 2019). Early-life experiences
16 are crucial determinants for adopting healthy and sustainable lifestyles (Bascopé et al. 2019; McBey et
17 al. 2019), so improved understanding of sustainability aspects in the education of public health
18 practitioners and in university education is proposed (Wegener et al. 2018). Investment in education,
19 particularly of women (Vermeulen et al. 2020), might lower the barrier for stronger policies to be
20 accepted and effective (McBey et al. 2019; Temme et al. 2020) (*medium evidence, high agreement*).

21 *Food labels:* Instruments to improve transparency and information on food sustainability aspects are
22 based on the assumption of the ‘rational’ consumer. Information gives the necessary freedom of choice,
23 but also the responsibility to make the ‘right choice’ (Kersh 2015; Bucher et al. 2016). Studies find a
24 lack of consumer awareness about the link between own food choices and environmental effect
25 (Greibitus et al. 2016; Leach et al. 2016; de Boer et al. 2018; Hartmann and Siegrist 2017) and so
26 effective messaging is required to raise awareness and acceptance of potentially stricter food system
27 policies.

28 Back-of-package labels usually provide detailed nutritional information (Temple 2019). Front-of-
29 package labels simplify and interpret the information: for example, the traffic light system or the Nutri-
30 Score label used in France (Kanter et al. 2018b) and the health star rating used in Australia and New
31 Zealand (Shahid et al. 2020) provide an aggregate rating based on product attributes such as energy,
32 sugar, saturated fat and fibre content; other labels warn against frequent consumption (e.g., in the 1990s
33 Finland introduced a mandatory warning for products high in salt; the keyhole label was introduced in
34 Sweden in 1989 (Storcksdieck genannt Bonsmann et al. 2020); and ‘high in’ (energy/ saturated fat/
35 sugar) labels were introduced in Chile in 2016 to reduce obesity (Corvalán et al. 2019)). Front-of-
36 package labels serve also as an incentive to industry to produce healthier or more sustainable products,
37 or can serve as a marketing strategy (Van Loo et al. 2014; Kanter et al. 2018b; Apostolidis and McLeay
38 2016). Carbon footprint labels can be difficult for consumers to understand (Hyland et al. 2017), and
39 simple, interpretative summary indicators used in front-of-package labels (e.g., traffic lights) are more
40 effective than more complex ones (Tørris and Mobekk 2019; Ikonen et al. 2019; Bauer and Reisch
41 2019; Temple 2019) (*robust evidence, high agreement*). Reviews find mixed results but overall a
42 positive effect of food labels in improving direct purchasing decisions (Sarink et al. 2016; Anastasiou
43 et al. 2019; Shangguan et al. 2019; Hieke and Harris 2016; Temple 2019), and in raising level of
44 awareness, thus possibly increasing success of other policy instruments (Al-Khudairy et al. 2019;
45 Samant and Seo 2016; Miller et al. 2019; Temple 2019; Apostolidis and McLeay 2016) (*medium
46 evidence, high agreement*).

1

2 **12.4.4.4 Behavioural instruments.**

3 *Choice architecture:* Information is more effective if accompanied by reinforcement through structural
4 changes or by changing the food environment, such as through product placement in supermarkets, to
5 overcome the intention-behaviour gap (Bucher et al. 2016; Broers et al. 2017; Tørris and Mobekk 2019).
6 Behavioural change strategies have also been shown to improve efficiencies of school food programs
7 (Marcano-Olivier et al. 2020).

8 Environmental considerations rank behind financial, health, or sensory factors for determining citizens'
9 food choices (Leach et al. 2016; Hartmann and Siegrist 2017; Rose 2018; Neff et al. 2018; Gustafson
10 et al. 2019). There is evidence that choice architecture (“nudging”) can be effective in influencing
11 purchase decisions, but regulators do not normally explore this option (Broers et al. 2017). Examples
12 of green nudging include making the sustainable option the default option, enhancing visibility,
13 accessibility of, or exposure to, sustainable products and reducing visibility and accessibility of un-
14 sustainable products, or increasing the salience of healthy sustainable choices through social norms or
15 food labels (Bucher et al. 2016; Wilson et al. 2016; Broers et al. 2017; Al-Khudairy et al. 2019; Bauer
16 and Reisch 2019; Ferrari et al. 2019; Weinrich and Elshiewy 2019; Cialdini and Jacobson 2021).
17 Available evidence suggests that choice architecture measures are relatively inexpensive and easy to
18 implement (Ferrari et al. 2019; Tørris and Mobekk 2019), they are a preferred solution if a restriction
19 of choices is to be avoided (Wilson et al. 2016; Kraak et al. 2017; Vecchio and Cavallo 2019), and can
20 be effective (Arno and Thomas 2016; Bianchi et al. 2018b; Cadario and Chandon 2018; Bucher et al.
21 2016) if embedded in policy packages (Wilson et al. 2016; Tørris and Mobekk 2019) (*medium evidence,*
22 *high agreement*).

23 Choice architecture measures are also facilitated by growing market shares of animal-free protein
24 sources taken up by discount chains and fast food companies, that enhance visibility of new products
25 and ease integration into daily life for consumers, particularly if sustainable products are similar to the
26 products they substitute (Slade 2018). This effect can be further increased by media and role models
27 (Elgaaied-Gambier et al. 2018).

28 **12.4.5 Food Systems Governance**

29 To support the policies outlined in Section 12.4.4, food system governance depends on the cooperation
30 of actors across traditional sectors in several policy areas, in particular agriculture, nutrition, health,
31 trade, climate, and environment (Termeer et al. 2018; Bhunnoo 2019; Diercks et al. 2019; iPES Food
32 2019; Rosenzweig et al. 2020b). Top-down integration, mandatory mainstreaming, or boundary-
33 spanning structures like public-private partnerships may be introduced to promote coordination
34 (Termeer et al. 2018). “Flow-centric” rather than territory-centric governance combined with private
35 governance mechanisms has enabled codes of conduct and certification schemes (Eakin et al. 2017),
36 for example the *Roundtable for Sustainable Palm Oil (RSPO)*, as well as commodity chain transparency
37 initiatives and platforms like *Trase* (Pirard et al. 2020; Meijaard et al. 2020). Trade agreements are an
38 emerging arena of governance in which improving GHG performance may be an objective, and trade
39 agreements can involve sustainability assessments.

40 Research on food system governance is mostly non-empirical or case study based, which means that
41 there is limited understanding of which governance arrangements work in specific social and ecological
42 contexts to produce particular food system outcomes (Delaney et al. 2018). Research has identified a
43 number of desirable attributes in food systems governance, including adaptive governance (Termeer et
44 al. 2018), a systems perspective (Whitfield et al. 2018), governance that considers food system

1 resilience (Moragues-Faus et al. 2017; Ericksen 2008; Meyer 2020), transparency, participation of civil
2 society (Duncan 2015; Candel 2014), and cross-scale governance (Moragues-Faus et al. 2017).

3 Food systems governance has multiple targets and objectives, not least contributing the achievement of
4 the SDGs. GHG emissions from food systems can be impacted by both interventions targeted at
5 different parts of the food system and interventions in other systems, such as reducing deforestation or
6 promoting reforestation (Lee et al. 2019). For example, policies targeting health can contribute to diet
7 shifts away from red meat, while also influencing GHG emissions (Springmann et al. 2018b; Semba et
8 al. 2020); national and local food self-sufficiency policies may also have GHG impacts (Loon et al.
9 2019; Kriewald et al. 2019). Cross-sectoral governance could enhance synergies between reduced GHG
10 emissions from food systems and other goals; however, integrative paradigms for cross-sectoral
11 governance between food and other sectors have faced implementation challenges (Delaney et al. 2018).
12 For example, in the late 2000s, the water-energy-food nexus emerged as a framework for cross-sectoral
13 governance, but has not been well-integrated into policy (Urbinatti et al. 2020), perhaps because of
14 perceptions that it is an academic concept, or that it takes a technical-administrative view of governance;
15 simply adopting the paradigm is not sufficient to develop effective nexus governance (Cairns and
16 Krzywoszynska 2016; Weitz et al. 2017; Pahl-Wostl et al. 2018). Other policy paradigms and
17 theoretical frameworks that aim to integrate food systems governance include system transition,
18 agroecology, multifunctionality in agriculture (Andrée et al. 2018), climate-smart agriculture (Taylor
19 2018) and the circular economy (Box 12.2). Cross-sectoral coordination on food systems and climate
20 governance could be aided by internal recognition and ownership by agencies, dedicated budgets for
21 cross-sectoral projects, and consistency in budgets (Pardoe et al. 2018); see also Box 12.1 and Box 12.2.

22 Food systems governance is still fragmented at national levels, which means that there may be a
23 proliferation of efforts that cannot be scaled and are ineffective (Candel 2014). National policies can be
24 complemented or possibly pioneered by initiatives at the local level (de Boer et al. 2018; Rose 2018).
25 The city-region has been proposed as a useful focus for food system governance (Vermeulen et al.
26 2020); for example, the Milan Urban Food Policy Pact involves 180 global cities committed to
27 integrative food system strategies (Candel 2019; Moragues-Faus 2021). Local food policy groups and
28 councils that assemble stakeholders from government, civil society, and the private sector have formed
29 trans-local networks of place-based local food policy groups, with over two hundred food policy
30 councils worldwide (Andrée et al. 2018). However, the fluidity and lack of clear agendas and
31 membership structures may hinder their ability to confront fundamental structural issues like
32 unsustainable diets or inequities in food access (Santo and Moragues-Faus 2019).

33 Early characterisations of food systems governance featured a binary distinction between global and
34 local scales, but this has been replaced by a relational approach where the local governance is seen a
35 process that relies on the interconnections between scales (Lever et al. 2019). Cross-scalar governance
36 is not simply an aggregation of local groups, but involves the telecoupling of distant systems; for
37 example, transnational NGO networks have been able to link coffee retailers in the global North with
38 producers in the global South via international NGOs concerned about deforestation and social justice
39 (Eakin et al. 2017). Global governance institutions like the *Committee on World Food Security* can
40 promote policy coherence globally and reinforce accountability at all levels (McKeon 2015), as can
41 norm-setting efforts like the ‘Voluntary Guidelines for the Responsible Governance of Tenure of Land,
42 Fisheries and Forests’ (FAO 2012). Global multi-stakeholder processes like the *UN Food Systems*
43 *Summit* can foster the development of principles for guiding further actions based on sound scientific
44 evidence. The European Commission’s *Farm to Fork* strategy aims to promote policy coherence in food
45 policy at EU and national levels, and could be the exemplar of a genuinely integrated food policy
46 (Schebesta and Candel 2020).

1 START BOX 12.2 HERE**2 Box 12.2: Case Study: The Finnish Food2030 Strategy**

3
4 Until 2016, the strategic goals of Finnish food policy were split between different programs and
5 Ministries, resulting in fragmented national oversight of the Finnish food system. To enable policy
6 coordination, a national food strategy was adopted in 2017 called Food2030 (Government of Finland
7 2017). Food2030 embodies a holistic food system approach and addresses multiple outcomes of the
8 food system, including the competitiveness of the food supply chain and the development of local,
9 organic and climate-friendly food production, as well as responsible and sustainable consumption.

10
11 The specific policy mix covers a range of policy instruments to enable changes in agro-food supply,
12 processing and societal norms (Kugelberg et al. 2021). The government provides targeted funding and
13 knowledge support to drive technological innovations on climate solutions to reduce emissions from
14 food and in the agriculture, forestry and land-use sectors. In addition, the Finnish government applies
15 administrative means, such as legislation, advice, guidance on public procurement and support schemes
16 to diversify and increase organic food production to 20% of arable land, which in turn improve the
17 opportunities of small-scale food production and steer public bodies to purchase local and organic food.
18 The Finnish government applies educational and informative instruments to enable a shift to healthy
19 and sustainable dietary behaviours. The policy objective is to reduce consumption of meat and replace
20 it with other sources of protein, aligned with nutrition recommendations and avoiding food waste. The
21 Ministry of Agriculture and Forestry, in collaboration with the Finnish Farmer's unions (MTK) and the
22 Union of Swedish-speaking Farmers and Forest Owners in Finland (SLC), ran a two-year multi-media
23 campaign in 2018 with key messages on sustainability, traceability and safety of the locally-produced
24 food (Ministry of Agriculture and Forestry 2021). A "Food Facts website project" (Luke 2021), funded
25 by the Ministry of Agriculture and Forestry in collaboration with the Natural Resources Institute Finland
26 and the Finnish Food Safety Authority, helps to raise knowledge about food, which could shape
27 responsible individual food behaviour, for example choosing local and sustainable foods and reducing
28 food waste.

29
30 A critical enabler for developing a shared food system strategy across sectors and political party
31 boundaries was the implementation of a one-year inclusive, deliberative and consensual stakeholder
32 engagement process. A wide range of stakeholders could exert real influence during the vision-building
33 process, resulting in strong agreement on key policy objectives, and subsequently an important leverage
34 point to policy change (Kugelberg et al. 2021). Moreover, cross-sectoral coordination of Food2030 and
35 the government's wider climate action programs are enabled by a number of institutional mechanisms
36 and collaborative structures, for example the Advisory board for the food chain, formally established
37 during the agenda-setting stage of Food2030, inter-ministerial committees to guide and assess policy
38 implementation, and Our common dining table, a multi-stakeholder partnership that assembles 18 food
39 system actors to engage in reflexive discussions about the Finnish food system.

40
41 Critical barriers to strategy and policy formulation include a lack of attention to integrated impact
42 assessments (Kugelberg et al. 2021), which blurs a transparent overview of potential trade-offs and
43 hidden conflicts. There were few policy evaluations from independent organisations to inform
44 policymaking, reducing the opportunities for more progressive policy approaches. Monitoring and food
45 policy evaluation is very close to the ministry in charge, which hampers critical thinking about policy
46 measures (Hildén et al. 2014). In addition, there is a lack of standardised indicators covering the whole
47 food system, which hinders comprehensive oversight of government's progress towards a sustainable
48 food system (Kanter et al. 2018a). Some of the problems related to monitoring, reporting and
49 verification (MRV) are typical for countries in the EU. To improve MRV will probably require

1 structural changes, such as efforts to build up institutional capacity and application of new technology,
2 development of standardised indicators covering the whole food system, regulations on transparency
3 and verification, and mechanisms to enable reflexive discussions between business, farmers, public,
4 NGOs and the government (Meadowcroft and Steurer 2018; Kanter et al. 2020).

5
6 **END BOX 12.2 HERE**

7 8 **12.5 Land-related impacts, risks and opportunities associated with** 9 **mitigation options**

10 **12.5.1 Introduction**

11 This Section provides a cross-sectoral perspective on land occupation and related impacts, risks and
12 opportunities associated with land-based mitigation options as well as mitigation options that are not
13 designated land-based, yet occupy land. It builds on Chapter 7, that covers mitigation in agriculture,
14 forestry and other land use (AFOLU), including future availability of biomass resources for mitigation
15 in other sectors. It complements Section 12.4, which covers mitigation inherent in the food system, as
16 well as Chapters 6, 9, 10 and 11 that cover mitigation in the energy, transport, building and industry
17 sectors, and Chapters 3 and 4 that cover land and biomass use, primarily in energy applications, in
18 mitigation and development pathways in the near- to mid-term (Chapter 4) and in pathways compatible
19 with long-term goals (Chapter 3).

20 The deployment of climate change mitigation options often affects land and water conditions, and
21 ecosystem capacity to support biodiversity and a range of ecosystem services (IPCC 2019; IPBES 2019)
22 (*robust evidence, high agreement*). It can increase or decrease terrestrial carbon stocks and sink strength,
23 hence impacting the mitigation effect positively or negatively. As for any other land uses, impacts, risks
24 and opportunities associated with mitigation options that occupy land depend on deployment strategy
25 and on contextual factors that vary geographically and over time (Doelman et al. 2018; Hurlbert et al.
26 2019; Smith et al. 2019a; Wu et al. 2020) (*robust evidence, high agreement*).

27 The SR1.5 found that large areas may be utilised for A/R and energy crops in modelled pathways
28 limiting warming to 1.5 C (Rogelj et al. 2018). The SRCCL investigated the implications of land-based
29 mitigation measures for land degradation, food security and climate change adaptation. It focussed on
30 identification of synergies and trade-offs associated with individual land-based mitigation measures
31 (Smith et al. 2019b). In this section we expand beyond the scope of the SRCCL assessment to include
32 also mitigation measures that occupy land while not considered land-based measures, we discuss ways
33 to minimise potential adverse effects, and we consider the potential for synergies through integrating
34 mitigation measures with other land uses, by applying a systems perspective that seeks to meet multiple
35 objectives from multi-functional landscapes. Mitigation measures with zero land occupation, e.g.,
36 offshore wind and kelp farming, are not considered,

37 **12.5.2 Land occupation associated with different mitigation options**

38 As reported in Chapter 3, in scenarios limiting warming to 1.5°C with no or limited overshoot, median
39 area dedicated for energy crops in 2050 is 1.99 (0.56 to 4.82) Mkm² and median forest area increased
40 3.22 (-0.67 to 8.90) Mkm² in the period 2019-2050 (5-95 percentile range, scenario category C1). For
41 comparison, the total global areas of forests, cropland and pasture (year 2015) are in the SRCCL
42 estimated at about 40 Mkm², 15.6 Mkm², and 27.3 Mkm², respectively (additionally, 21 Mkm² of
43 savannahs and shrublands are also used for grazing) (IPCC 2019). The SRCCL concluded that

1 conversion of land for A/R and bioenergy crops at the scale commonly found in pathways limiting
2 warming to 1.5°C or 2°C is associated with multiple feasibility and sustainability constraints, including
3 land carbon losses (*high confidence*). Pathways in which warming exceeds 1.5°C require less land-
4 based mitigation, but the impacts of higher temperatures on regional climate and land, including land
5 degradation, desertification, and food insecurity, become more severe (Smith et al. 2019b).

6 Depending on emission-reduction target, the portfolio of mitigation options chosen, and the policies
7 developed to support their implementation, different land-use pathways can arise with large differences
8 in resulting agricultural and forest area. Some response options can be more effective when applied
9 together (Smith et al. 2019c); for example, dietary change, efficiency increases, and reduced wastage
10 can reduce emissions as well as the pressure on land resources, potentially enabling additional land-
11 based mitigation such as A/R and cultivation of biomass crops for biochar, bioenergy and other bio-
12 based products. The SRCCL (Smith et al. 2019c) report that dietary change combined with reduction
13 in food loss and waste can reduce the land requirement for food production by up to 5.8 Mkm² (0.8–2.4
14 Mkm² for dietary change; about 2 Mkm² for reduced post-harvest losses, and 1.4 Mkm² for reduced
15 food waste (see also Sections 7.4 and 12.4 and Parodi et al. 2018; Springmann et al. 2018; Clark et al.
16 2020; Rosenzweig et al. 2020b). Stronger mitigation action in the near term targeting non-CO₂
17 emissions reduction and deployment of other CDR options (DACCS, enhanced weathering, ocean-
18 based approaches, see 12.3) can reduce the land requirement for land-based mitigation (Obersteiner et
19 al. 2018; van Vuuren et al. 2018).

20 Global Integrated Assessment Models (IAMs) provide insights about the roles of land-based mitigation
21 in pathways limiting warming to 1.5°C or 2°C; interaction between land-based and other mitigation
22 options such as wind and solar power; influence of land-based mitigation on food markets, land use and
23 land carbon; and the role of BECCS vis- à-vis other CDR options (See Chapter 3). However, IAMs do
24 not capture more subtle changes in land management and in the associated industrial/energy systems
25 due to relatively coarse temporal and spatial resolution, and limited representation of land quality and
26 feedstocks/management practices, interactions between biomass production and conversion systems,
27 and local context, e.g., governance of land use (Daioglou et al. 2019; Rose et al. 2020; Welfle et al.
28 2020; Calvin et al. 2021). A/R have generally been modelled as forests managed for carbon
29 sequestration alone, rather than forestry providing both carbon sequestration and biomass supply
30 (Calvin et al. 2021). Because IAMs do not include options to integrate new biomass production with
31 existing agricultural and forestry systems (Paré et al. 2016; Mansuy et al. 2018; Cossel et al. 2019;
32 Braghiroli and Passarini 2020; Moreira et al. 2020; Djomo et al. 2020; Strapasson et al. 2020; Rinke
33 Dias de Souza et al. 2021), they may over-estimate the total additional land area required for biomass
34 production. On the other hand, some integrated biomass production systems may prove less attractive
35 to landholders than growing biomass crops in large blocks, from logistic, economic, or other points of
36 view (Ssegane et al. 2016; Busch 2017; Ferrarini et al. 2017).

37 Land occupation associated with mitigation options other than A/R and bioenergy is rarely quantified
38 in global scenarios. Stressing large uncertainties (e.g., type of biomass used and share of solar PV
39 integrated in buildings), (Luderer et al. 2019) modelled land occupation and land transformation
40 associated with a range of alternative power system decarbonisation pathways in the context of a global
41 2°C climate stabilisation effort. On a per-MWh basis, bioelectricity with CCS was most land-intensive,
42 followed by hydropower, coal with CCS, and concentrated solar power (CSP), which in turn were
43 around five times as land-intensive as wind and solar photovoltaics (PV). A review of studies of power
44 densities (electricity generation per unit land area) confirmed the relatively larger land occupation
45 associated with biopower, although hydropower overlaps with biopower (van Zalk and Behrens 2018).
46 This study also quantifies the low land occupation of nuclear energy, similar to fossil energy sources.

1 The land occupation of PV depends on the share of ground-mounted vs. buildings-integrated PV, the
2 latter assumed to reach 75% share by 2050 in (Luderer et al. 2019). van de Ven et al. (2021) assumed a
3 3% share of urbanized land in 2050 available for rooftop PV, referring to (Capellán-Pérez et al. 2017;
4 Dupont et al. 2020) reporting 2-3% availability of urbanized surface area, when considering factors
5 such as roof slopes and shadows between buildings, and threshold relating to energy return on
6 investment. Referring to (De Castro et al. 2013; MacKay 2013; Ong et al. 2013; Smil; Capellán-Pérez
7 et al. 2017) state that land occupation of solar technologies is underestimated in studies assuming ideal
8 conditions, with real occupation being five to ten times higher.

9 Production of hydrogen and synthetic hydrocarbon fuels via electrolysis and hydrocarbon synthesis is
10 subject to conversion losses that vary depending on technology, system integration and source of
11 carbon (Wulf et al. 2020; Ince et al. 2021)(cross-ref 6.4.4.1 and 6.4.5.1). Indicative electricity-to-
12 hydrocarbon fuel efficiency loss is estimated at about 60% (Ueckerdt et al. 2021). The advantage of
13 smaller land occupation for solar, wind, hydro and nuclear, compared with biomass-based options, is
14 therefore smaller for hydrocarbon fuels than for electricity. Furthermore, biofuels are often co-
15 produced with other bio-based products, which further reduces their land occupation, although
16 comparisons are complicated by inconsistent approaches to allocating land occupation between co-
17 products (Ahlgren et al. 2015; Czyrnek-Delêtre et al. 2017).

18
19 Note that comparisons on a per-MWh basis do not reflect the GHG emissions associated with the power
20 options, or that the different options serve different functions in power systems. Reservoir hydropower
21 and biomass-based dispatchable power can complement other balancing options (e.g., battery storage,
22 grid extensions and demand-side management (Göransson and Johnsson 2018; Chapter 6) to provide
23 power stability and quality needed in power systems with large amounts of variable electricity
24 generation from wind and solar power plants. Furthermore, the requirements of transport in grids,
25 pipelines etc. differ. For example, electricity from buildings-integrated PV can be used in the same
26 location as it is generated.

27 The character of land occupation, and, consequently, the associated impacts (see 12.5.3), vary
28 considerably among mitigation options and also for the same option depending on geographic location,
29 scale, system design and deployment strategy (Olsson et al. 2019; Ioannidis and Koutsoyiannis 2020;
30 van de Ven et al. 2021). Land occupation associated with different mitigation options can be large
31 uniform areas (e.g., large solar farms, reservoir hydropower dams, or tree plantations), or more
32 distributed occupation, such as wind turbines, solar PV, and patches of biomass cultivation integrated
33 with other land uses in heterogeneous landscapes (Cacho et al. 2018; Jager and Kreig 2018; Correa et
34 al. 2019; Englund et al. 2020a). Studies with broader scope, covering total land use requirement induced
35 by plant infrastructure, provide a more complete picture of land footprints. For example, Wu et al.
36 (2021) quantified a land footprint by the infrastructure of a pilot solar plant being three times the onsite
37 land area. Sonter et al. (2020b) found significant overlap of mining areas (82% targeting materials
38 needed for renewable energy production) and biodiversity conservation sites and priorities, suggesting
39 that strategic planning is critical to address mining threats to biodiversity (See section 12.5.4) along
40 with recycling and exploration of alternative technologies that use that use abundant minerals (See
41 Chapter 11, Box Critical Minerals and The Future of Electro-Mobility and Renewables)

42 There are also situations where expanding mitigation is more or less decoupled from additional land
43 use. The use of organic consumer waste, harvest residues and processing side-streams in the agriculture
44 and forestry sectors can support significant volumes of bio-based products with relatively lower land-
45 use change risks than dedicated biomass production systems (Hanssen et al. 2019; Spinelli et al. 2019;
46 Mouratiadou et al. 2020). Such uses can provide waste management solutions while increasing the
47 mitigation achieved from the land that is already used for agricultural and forest production. Bioenergy

1 accounts for about 90% of renewable heat used in industrial applications, mainly in industries that can
2 use their own biomass waste and residues, such as the pulp and paper industry, food industry, and
3 ethanol production plants (see Chapters 6 and 11) (IEA 2020c). Heat and electricity produced on-site
4 from side-streams but not needed for the industrial processes can be sold to other users, e.g., district
5 heating systems. Surplus waste and residues can also be used to produce solid and liquid biofuels, or be
6 used as feedstock in other industries such as the petrochemical industry (IRENA 2018; Lock and Whittle
7 2018; Thunman et al. 2018; IRENA 2019; Haus et al. 2020; Chapters 6 and 11). Electrification and
8 improved process efficiencies can reduce GHG emissions and increase the share of harvested biomass
9 that is used for production of bio-based products (Johnsson et al. 2019; Madeddu et al. 2020; Lipiäinen
10 and Vakkilainen 2021; Rahnema Mobarakeh et al. 2021; Silva et al. 2021; Chapter 11). Besides
11 integrating solar thermal panels and solar PV into buildings and other infrastructure, floating solar PV
12 panels in, e.g., hydropower dams (Ranjbaran et al. 2019; Cagle et al. 2020; Haas et al. 2020; Lee et al.
13 2020; Gonzalez Sanchez et al. 2021), and over canals (Lee et al. 2020; McKuin et al. 2021) could
14 decouple renewable energy generation from land use while simultaneously reducing evaporation losses
15 and potentially mitigating aquatic weed growth and climate change impacts on water body temperature
16 and stratification (Cagle et al. 2020; Exley et al. 2021; Gadzanku et al. 2021; Solomin et al. 2021).

17

18 **12.5.3 Consequences of land occupation: biophysical and socioeconomic risks, impacts** 19 **and opportunities**

20 Land occupation associated with mitigation options can present challenges related to impacts and trade-
21 offs, but can also provide opportunities and in different ways support the achievement of additional
22 societal objectives, including adaptation to climate change. This section focuses on mitigation options
23 that have significant risks, impacts and/or co-benefits with respect to land resources, food security and
24 the environment. Bioenergy (with or without CCS), biochar and bio-based products require biomass
25 feedstocks that can be obtained from purpose-grown crops, residues from conventional agriculture and
26 forestry systems, or from biomass wastes, each with different implications for the land. Here we
27 consider separately (i) “biomass-based systems”, including dedicated biomass crops (e.g., perennial
28 grasses, short rotation woody crops) and biomass produced as a co-product of conventional agricultural
29 production (e.g. maize stover), and (ii) “afforestation/reforestation”, including forests established for
30 ecological restoration, plantations grown for forest products and agroforestry, where biomass may also
31 be a co-product. We then discuss impacts and opportunities common to both systems, before
32 considering impacts and opportunities associated with non-land-based mitigation options that
33 nevertheless occupy land.

34

35 Biomass-based systems

36 Mitigation options that are based on the use of biomass, that is, bioenergy/BECCS, biochar, wood
37 buildings, and other bio-based products, can have different positive and negative effects depending on
38 the character of the mitigation option, the land use, the biomass conversion process, how the bio-based
39 products are used and what other product they substitute (Leskinen et al. 2018; Howard et al. 2021;
40 Myllyviita et al. 2021). The impacts of the same mitigation option can therefore vary significantly and
41 the outcome in addition depends on previous land/biomass use (Cowie et al. 2021). As biomass-based
42 systems commonly produce multiple food, material and energy products, it is difficult to disentangle
43 impacts associated with individual bio-based products (Ahlgren et al. 2015; Djomo et al. 2017;
44 Obydenkova et al. 2021). As for other mitigation options, governance has a critical influence on
45 outcome, but larger scale and higher expansion rate generally translates into higher risk for negative
46 outcomes such as competition for scarce land, freshwater and phosphorous resources, displacement of

1 natural ecosystems, and diminishing capacity of agro-ecosystems to support biodiversity and essential
2 ecosystem services, especially if produced without sustainable land management and in inappropriate
3 contexts (Popp et al. 2017; Dooley and Kartha 2018; Hasegawa et al. 2018; Heck et al. 2018;
4 Humpenöder et al. 2018; Fujimori et al. 2019; Hurlbert et al. 2019; IPBES 2019; Smith et al. 2019b;
5 Drews et al. 2020; Hasegawa et al. 2020; Schulze et al. 2020; Stenzel et al. 2021) (*medium evidence,*
6 *high agreement*).

7 Removal of crop and forestry residues can cause land degradation through soil erosion and decline in
8 nutrients and soil organic matter (Cherubin et al. 2018) (*robust evidence, high agreement*). These risks
9 can be reduced by retaining a proportion of the residues to protect the soil surface from erosion and
10 moisture loss and maintain or increase soil organic matter (See Section 7.4.3.6); incorporating a
11 perennial groundcover into annual cropping systems (Moore et al. 2019); and by replacing nutrients
12 removed, such as by applying ash from bioenergy combustion plants (Kludze et al. 2013; Harris et al.
13 2015; Warren Raffa et al. 2015; de Jong et al. 2017) while safeguarding against contamination risks
14 (Pettersson et al. 2020) (*medium evidence, high agreement*). Besides topography, soil, and climate
15 conditions, sustainable residue removal rates also depend on the fate of extracted biomass. For example,
16 to maintain the same level of soil organic carbon, the harvest of straw, if used for combustion (which
17 would return no carbon to fields), was estimated to be only 26% of the rate that could be extracted if
18 used for anaerobic digestion involving return of recalcitrant carbon to fields (Hansen et al. 2020).
19 Similarly, biomass pyrolysis produces biochar which can be returned to soils to counteract C losses
20 associated with biomass extraction (Joseph et al. 2021; Lehmann et al. 2021).

21 Expansion of biomass crops, especially monocultures of exotic species, can pose risks to natural
22 ecosystems and biodiversity through introduction of invasive species and land use change, also
23 impacting the mitigation value (*robust evidence, high agreement*) ((Liu et al. 2014; El Akkari et al.
24 2018). Cultivation of conventional oil, sugar, and starch crops tends to have larger negative impact than
25 lignocellulosic crops (Núñez-Regueiro et al. 2020). Social and environmental outcomes can be
26 enhanced through integration of suitable plants (such as perennial grasses and short rotation woody
27 crops) into agricultural landscapes (within crop rotations or through strategic localization, e.g., as
28 contour belts, along fencelines and riparian buffers). Such integrated systems can provide shelter for
29 livestock, retention of nutrients and sediment, erosion control, pollination, pest and disease control, and
30 flood regulation (*robust evidence, high agreement*) (See Figure 12.8 below; Box 12.3 and Cross-
31 Working Group Box 3) (Berndes et al. 2008; Christen and Dalgaard 2013; Asbjornsen et al. 2014;
32 Holland et al. 2015; Ssegane et al. 2015; Dauber and Miyake 2016; Milner et al. 2016; Ssegane and
33 Negri 2016; Styles et al. 2016; Crews et al. 2018; Zalesny et al. 2019; Englund et al. 2020b, 2021).
34 (Zheng et al. 2016; Osorio et al. 2019). (Ferrarini et al. 2017; Henry et al. 2018a). Many of the land use
35 practices described above align with agroecology principles [cross ref WGII CCB Nature-Based
36 Solutions, WGII 5.14 box 5.11] and can simultaneously contribute to climate change mitigation, climate
37 change adaptation and reduced risk of land degradation (IPCC 2019) (*robust evidence, high agreement*).

38

Figure 12.8 Overview of opportunities related to selected land-based climate change mitigation options

Afforestation/Reforestation (A/R)

When A/R activities comprise the establishment of natural forests, the risk to land is primarily associated with potential displacement of previous land use to new locations, which could indirectly cause land use change including deforestation (see Sections 7.4.2 and 7.6.2.4). A/R (including agroforestry) aimed at providing timber, fibre, biomass, non-timber resources and other ecosystem services can provide renewable resources to society and long-term livelihoods for communities. Forest management and harvesting regimes around the world will adjust in different ways as society seeks to meet climate goals. The outcome depends on forest type, climate, forest ownership and the character and product portfolio of the associated forest industry (Lauri et al. 2019; Favero et al. 2020). How forest carbon stocks, biodiversity, hydrology, etc. are affected by changes in forest management and harvesting in turn depends on both management practices and the characteristics of the forest ecosystems (Eales et al. 2018; Griscom et al. 2018; Kondo et al. 2018; Nieminen et al. 2018; Thom et al. 2018; Runting et al. 2019; Tharammal et al. 2019) (*robust evidence, medium agreement*). As described above, the GHG savings achieved from producing and using bio-based products will in addition depend on the character of existing societal systems, including technical infrastructure and markets, as this determines the product substitution patterns.

Environmental and socio-economic co-benefits are enhanced when ecological restoration principles are applied (Gann et al. 2019) along with effective planning at landscape level and strong governance (Morgan et al., 2020). For example, restoration of natural vegetation and establishing plantations on degraded land enable organic matter to accumulate in the soil and have potential to deliver significant co-benefits for biodiversity, land resource condition and livelihoods (See Box 12.3 and Cross-Working Group Box 3). Tree planting and agroforestry on cleared land can deliver biodiversity benefits (Seddon et al. 2009; Kavanagh and Stanton 2012; Law et al. 2014), with biodiversity outcomes influenced by block size, configuration and species mix (Cunningham et al. 2015; Paul et al. 2016) (*robust evidence, high agreement*).

Risks and opportunities common to biomass production and A/R mitigation options

Biomass-based systems and A/R can contribute to addressing land degradation through land rehabilitation or restoration (Box 12.3). Land-based mitigation options that produce biomass for bioenergy/BECCS or biochar through land *rehabilitation* rather than land *restoration* imply a trade-off between production / carbon sequestration and biodiversity outcomes (Hua et al. 2016; Cowie et al.

1 2018). Restoration, seeking to establish native vegetation with the aim to maximise ecosystem integrity,
2 landscape connectivity, and conservation of on-ground C stock, will have higher biodiversity benefits
3 than rehabilitation measures (Lin et al. 2013). However, sequestration rate declines as forests mature,
4 and the sequestered C is vulnerable to loss through disturbance such as wildfire, so there is a higher risk
5 of reversal of the mitigation benefit compared with use of biomass for substitution of fossil fuels and
6 GHG-intensive building materials (Russell and Kumar 2017; Dugan et al. 2018; Anderegg et al. 2020).
7 Trade-offs between different ecosystem services, and between societal objectives including climate
8 change mitigation and adaptation, can be managed through integrated landscape approaches that aim to
9 create a mosaic of land uses, including conservation, agriculture, forestry and settlements (Freeman et
10 al. 2015; Nielsen 2016; Reed et al. 2016; Sayer et al. 2017) where each is sited with consideration of
11 land potential and socioeconomic objectives and context (Cowie et al. 2018) (*limited evidence, high
12 agreement*).

13 Impacts of biomass production and A/R on the hydrological cycle and water availability and quality,
14 depend on scale, location, previous land use/cover and type of biomass production system. For example,
15 extraction of logging residues in forests managed for timber production has little effect on hydrological
16 flows, while land use change to establish dedicated biomass production can have a significant effect
17 (Teter et al. 2018; Drews et al. 2020). Deployment of A/R can affect temperature, albedo and
18 precipitation locally and regionally, and can mitigate or enhance the effects of climate change in the
19 affected areas (Stenzel et al. 2021b) and Section 7.2.4). A/R activities can increase evapotranspiration
20 impacting groundwater and downstream water availability, but can also result in increased infiltration
21 to groundwater and improved water quality (Farley et al. 2005; Zhang et al. 2016, 2017; Lu et al. 2018)
22 and can be beneficial where historical clearing has caused soil salinisation and stream salinity
23 (Farrington and Salama 1996; Marcar 2016). There is *limited evidence* that very large-scale land use or
24 vegetation cover changes can alter regional climate and precipitation patterns, e.g., downwind
25 precipitation depends on upwind evapotranspiration from forests and other vegetation (Keys et al.
26 2016; Ellison et al. 2017; van der Ent and Tuinenburg 2017).

27 Another example of beneficial effects includes perennial grasses and woody crops planted to intercept
28 runoff and subsurface lateral flow, reducing nitrate entering groundwater and surface waterbodies (e.g
29 Woodbury et al. 2018; Femeena et al. 2018; Griffiths et al. 2019). In India, (Garg et al. 2011) found
30 desirable effects as a result of planting *Jatropha* on wastelands previously used for grazing (which could
31 continue in the *Jatropha* plantations): soil evaporation was reduced, as a larger share of the rainfall was
32 channelled to plant transpiration and groundwater recharge, and less runoff resulted in reduced soil
33 erosion and improved downstream water conditions. Thus, adverse effects can be reduced and synergies
34 achieved when plantings are sited carefully, with consideration of potential hydrological impacts (Davis
35 et al. 2013).

36 Several biomass conversion technologies can generate co-benefits for land and water. Anaerobic
37 digestion of organic wastes (e.g., food waste, manure) produces a nutrient-rich digestate and biogas that
38 can be utilised for heating and cooking or upgraded for use in electricity generation, industrial processes,
39 or as transportation fuel (See Chapter 6) (Parsaee et al. 2019; Hamelin et al. 2021). The digestate is a
40 rich source of nitrogen, phosphorus and other plant nutrients, and its application to farmland returns
41 exported nutrients as well as carbon (Cowie 2020b). Studies have identified potential risks, including
42 Mn toxicity, Cu and Zn contamination, and ammonia emission, compared with application of
43 undigested animal manure (Nkoa 2014). Although the anaerobic digestion process reduces pathogen
44 risk compared with undigested manure feedstocks, it does not destroy all pathogens (Nag et al. 2019).
45 Leakage of methane is a significant risk that needs to be managed, to ensure mitigation potential is
46 achieved (Bruun et al. 2014). Anaerobic digestion of wastewater, such as sugarcane vinasse, reduces
47 methane emissions and pollution loading as well as producing biogas (Parsaee et al. 2019).

1 Biorefineries can convert biomass to food, feed and biomaterials along with bioenergy (Aristizábal-
2 Marulanda and Cardona Alzate 2019; Schmidt et al. 2019). Biorefinery plants are
3 commonly characterised by high process integration to achieve high resource use efficiency, minimise
4 waste production and energy requirements, and maintain flexibility towards changing markets for raw
5 materials and products (Schmidt et al. 2019). Emerging technologies can convert biomass that is
6 indigestible for monogastric animals or humans (e.g., algae, grass, clover or alfalfa) into food and feed
7 products. For example, Lactic acid bacteria can facilitate the use of green plant biomass such as grasses
8 and clover to produce a protein concentrate suitable for animal feed and other products for material or
9 energy use (Lübeck and Lübeck 2019). Selection of crops suitable for co-production of protein feed
10 along with biofuels and other bio-based products can significantly reduce the land conversion pressure
11 by reducing the need to cultivate other crops (e.g., soybean) for animal feeding (Bentsen and Møller
12 2017; Solati et al. 2018). Thus, such solutions, using alternatives to high-input, high-emission grain-
13 based feed, can enable sustainable intensification of agricultural systems with reduced environmental
14 impacts (Jørgensen and Lærke 2016). The use of seaweed and algae as biorefinery feedstock can
15 facilitate recirculation of nutrients from waters to agricultural land, thus reducing eutrophication while
16 substituting purpose-grown feed (Thomas et al. 2021).

17 Pyrolysis can convert organic wastes, including agricultural and forestry residues, food waste, manure,
18 poultry litter and sewage sludge, into combustible gas and biochar, which can be used as a soil
19 amendment (Joseph et al. 2021; Schmidt et al. 2021; Chapter 7). Pyrolysis facilitates nutrient recovery
20 from biomass residues, enabling return to farmland as biochar, noting, however, that a large fraction of
21 nitrogen is lost during pyrolysis (Joseph et al. 2021). Conversion to biochar aids the logistics of
22 transport and land application of materials such as sewage sludge, by reducing mass and volume,
23 improving flow properties, stability and uniformity, and decreasing odour. Pyrolysis is well-suited for
24 materials that may be contaminated with pathogens, microplastics, per- and polyfluoroalkyl substances,
25 such as abattoir and sewage wastes, removing these risks, and reduces availability of heavy metals in
26 feedstock (Joseph et al. 2021). Applying biochar to soil sequesters biochar-carbon for hundreds to
27 thousands of years and can further increase soil carbon by reducing mineralisation of soil organic matter
28 and newly added plant carbon (Singh et al. 2012; Wang et al. 2016a; Weng et al. 2017; Lehmann et al.
29 2021). Biochars can improve a range of soil properties, but effects vary depending on biochar properties,
30 which are determined by feedstock and production conditions (Singh et al. 2012; Wang et al. 2016a),
31 and on the soil properties where biochar is applied (e.g. Razzaghi et al. 2020). Biochars can increase
32 nutrient availability, reduce leaching losses (Singh et al. 2010; Haider et al. 2017) and enhance crop
33 yields particularly in infertile acidic soils (Jeffery et al. 2017), thus supporting food security under
34 changing climate. Biochars can enhance infiltration and soil water-holding capacity, reducing runoff
35 and leaching, increasing water retention in the landscape and improving drought tolerance and resilience
36 to climate change (Quin et al. 2014; Omondi et al. 2016). (See Chapter 7 for review of biochar's
37 potential contribution to climate change mitigation).

38 Both A/R and dedicated biomass production could have adverse impacts on food security and cause
39 indirect land use change if deployed in locations used for food production (IPCC 2019). But the degree
40 of impact associated with a certain mitigation option also depends on how deployment takes place and
41 also the rate and total scale of deployment. The highest increases in food insecurity due to deployment
42 of land-based mitigation are expected to occur in Sub-Saharan Africa and Asia (Hasegawa et al. 2018).
43 The land area that could be used for bioenergy or other land-based mitigation options with low to
44 moderate risks to food security depends on patterns of socioeconomic development, reaching limits
45 between 1 and 4 million km² (IPCC 2019; Hurlbert et al. 2019; Smith et al. 2019c).

46 The use of less-productive, degraded/marginal lands has received attention as an option for biomass
47 production and other land-based mitigation that can improve the productive and adaptive capacity of

1 the lands (Liu et al. 2017; Qin et al. 2018; Dias et al. 2021; Kreig et al. 2021) (Section 7.4.4 and Cross-
2 Working Group Box 3). The potential is however uncertain as biomass growth rates may be low, a
3 variety of assessment approaches have been used, and the identification of degraded/marginal land as
4 “available” has been contested, as much low productivity land is used informally by impoverished
5 communities, particularly for grazing, or may be economically infeasible or environmentally
6 undesirable for development of energy crops (Baka 2013, 2014; Haberl et al. 2013; Fritz et al. 2013)
7 (*medium evidence, low agreement*).

8 As many of the SDGs are closely linked to land use, the identification and promotion of mitigation
9 options that rely on land uses described above can support a growing use of bio-based products while
10 advancing several SDGs, e.g., SDG2 “Zero hunger”, SDG6 “Clean water and sanitation”, SDG7
11 “Affordable and Clean Energy” and SDG15 “Life on Land” (Fritsche et al. 2017; IRP 2019; Blair et al.
12 2021). Policies supporting the target of Land Degradation Neutrality (LDN; SDG 15.3) encourage
13 planning of measures to counteract loss of productive land due to unsustainable agricultural practices
14 and land conversion, through sustainable land management, and strategic restoration and rehabilitation
15 of degraded land (Cowie et al. 2018). LDN can thus be an incentive for land-based mitigation measures
16 that build carbon in vegetation and soil, and can provide impetus for land use planning to achieve
17 multifunctional landscapes that integrate land-based mitigation with other land uses (see Box 12.3). The
18 application of sustainable land management practices that build soil carbon will enhance productivity
19 and resilience of crop and forestry systems, thereby enhancing biomass production (Henry et al. 2018a).
20 Non-bio-based mitigation options can enhance land-based mitigation: enhanced weathering, that is,
21 adding ground silicate rock to soil to take up atmospheric CO₂ through chemical weathering (Section
22 12.3), could supply nutrients and alleviate soil acidity, thereby boosting productivity of biomass crops
23 and A/R, particularly when combined with biochar application (Haque et al. 2019; De Oliveira Garcia
24 et al. 2020; Buss et al. 2021) Land rehabilitation and enhanced landscape diversity through production
25 of biomass crops could simultaneously contribute to climate change mitigation, climate change
26 adaptation, addressing land degradation, increasing biodiversity and improving food security in the
27 longer term (Mackey et al. 2020; Chapter 7).

28 Wind power

29 The land requirement and impacts (including visual and noise impacts) of on-shore wind turbines
30 depend on the size and type of installation, and location (Ioannidis and Koutsoyiannis 2020). Wind
31 power and agriculture can coexist in beneficial ways and wind power production on agriculture land is
32 well established (Fritsche et al. 2017; Miller and Keith 2018a). Spatial planning and local stakeholder
33 engagement can reduce opposition due to visual landscape impacts and noise (Frolova et al. 2019;
34 Hevia-Koch and Ladenburg 2019). Repowering, i.e., replacing with higher capacity wind turbines, can
35 mitigate additional land requirement associated with deployment towards higher share of wind in power
36 systems (Pryor et al. 2020).

37 Mortality and disturbance risks to birds, bats and insects are major ecological concerns associated with
38 wind farms (Thaxter et al. 2017; Cook et al. 2018; Heuck et al. 2019; Coppes et al. 2020; Choi et al.
39 2020; Fernández-Bellon 2020; Marques et al. 2020; Voigt 2021). Careful siting is critical (May et al.
40 2021), while painting blades to increase the visibility can also reduce mortality due to collision (May et
41 al. 2020). Theoretical studies have suggested that wind turbines could lead to warmer night temperatures
42 due to atmospheric mixing (Keith et al. 2004), later confirmed through observation (Zhou et al. 2013),
43 although Vautard et al. (2014) found limited impact at scales consistent with climate policies. More
44 recent studies report mixed results; indications that the warming effect could be substantial with
45 widespread deployment Miller and Keith 2018b and conversely limited impacts on regional climate at
46 20% of US electricity from wind. (Pryor et al. 2020).

1 Solar power

2 As for wind power, land impacts of solar power depend on the location, size and type of installation
3 (Ioannidis and Koutsoyiannis 2020). Establishment of large-scale solar farms could have positive or
4 negative environmental effects at the site of deployment, depending on the location. Solar PV and CSP
5 power installations can lock away land areas, displacing other uses (Mohan 2017). Solar PV can be
6 deployed in ways that enhance agriculture: for example, Hassanpour Adeh et al. (2018) found that
7 biomass production and water use efficiency of pasture increased under elevated solar panels. PV
8 systems under development may achieve significant power generation without diminishing agricultural
9 output (Miskin et al. 2019). Global mapping of solar panel efficiency showed that croplands, grasslands
10 and wetlands are located in regions with the greatest solar PV potential (Adeh et al. 2019). Dual-use
11 agrivoltaic systems are being developed that overcome previously recognised negative impact on crop
12 growth, mainly due to shadows (Armstrong et al. 2016; Marrou et al. 2013b,a), thus facilitating
13 synergistic co-location of solar photovoltaic power and cropping (Miskin et al. 2019; Adeh et al. 2019).
14 Assessment of the potential for optimising deployment of solar PV and energy crops on abandoned
15 cropland areas produced an estimate of the technical potential for optimal combination at 125 EJ per
16 year (Leirpoll et al. 2021).

17 Deserts can be well-suited for solar PV and CSP farms, especially at low latitudes where global
18 horizontal irradiance is high, as there is lower competition for land and land carbon loss is minimal,
19 although remote locations may pose challenges for power distribution (Xu et al. 2016). Solar arrays can
20 reduce the albedo, particularly in desert landscapes, which can lead to local temperature increases and
21 regional impacts on wind patterns (Millstein and Menon 2011). Modelling studies suggest that large-
22 scale wind and solar farms, for example in the Sahara (Li et al. 2018), could increase rainfall through
23 reduced albedo and increased surface roughness, stimulating vegetation growth and further increasing
24 regional rainfall (Li et al. 2018) (*limited evidence*). Besides impacts at the site of deployment, wind
25 and solar power affect land through mining of critical minerals required by these technologies (Viebahn
26 et al. 2015; McLellan et al. 2016; Carrara et al. 2020).

27 Nuclear power

28 Nuclear power has land impacts and risks associated with mining operations (Falck 2015; Winde et al.
29 2017; Srivastava et al. 2020) and disposal of spent fuel (IAEA 2006a; Ewing et al. 2016; Bruno et al.
30 2020), but the land occupation is small compared to many other mitigation options. Substantial volumes
31 of water are required for cooling (Liao et al. 2016), as for all thermal power plants, but most of this
32 water is returned to rivers and other water bodies after use (Sesma Martín and Rubio-Varas 2017).
33 Negative impacts on aquatic systems can occur due to chemical and thermal pollution loading (Fricko
34 et al. 2016; Raptis et al. 2016; Bonansea et al. 2020). The major risk to land from nuclear power is that
35 a nuclear accident leads to radioactive contamination. An extreme example, the 1986 Chernobyl
36 accident in Ukraine, resulted in radioactive contamination across Europe. Most of the fallout
37 concentrated near Belarus, Ukraine and Russia, where some 125,000 km² of land (more than a third of
38 which was in agricultural use) was contaminated. About 350,000 people were relocated away from
39 these areas (Sovacool 2008; IAEA 2006b). About 116,000 people were permanently evacuated from
40 the 4,200 km Chernobyl exclusion zone (IAEA 2006a). New reactor designs with passive and enhanced
41 safety systems reduce the risk of such accidents significantly (Section 6.4.2.4). An example of
42 alternatives to land reclamation for productive purposes, a national biosphere reserve has been
43 established around Chernobyl to conserve, enhance and manage carbon stocks and biodiversity
44 (Deryabina et al. 2015; Ewing et al. 2016), although invertebrate and plant populations area affected
45 (Mousseau and Møller 2014, 2020).

1 Hydropower

2 Reservoir hydropower projects submerge areas as dams are established for water storage. Hydropower
3 can be associated with significant and highly varying land occupation and carbon footprint (Poff and
4 Schmidt 2016; Scherer and Pfister 2016a; Ocko and Hamburg 2019; dos Santos et al. 2017). The
5 flooding of land causes CH₄ emissions due to the anaerobic decomposition of submerged vegetation
6 and there is also a loss of C sequestration due to mortality of submerged vegetation. The size of GHG
7 emissions depends on the amount of vegetation submerged. The carbon in accumulated sediments in
8 reservoirs may be released to the atmosphere as CO₂ and CH₄ upon decommissioning of dams, and
9 while uncertain, estimates indicate that these emissions can make up a significant part of the cumulative
10 GHG emissions of hydroelectric power plants (Almeida et al. 2019; Moran et al. 2018; Ocko and
11 Hamburg 2019). Positive radiative forcing due to lower albedo of hydropower reservoirs compared to
12 surrounding landscapes can reduce mitigation contribution significantly (Wohlfahrt et al. 2021).

13 Hydropower can have high water usage due to evaporation from dams (Scherer and Pfister 2016b).
14 Hydropower projects may impact aquatic ecology and biodiversity, necessitate the relocation of local
15 communities living within or near the reservoir or construction sites and affect downstream
16 communities (in positive or negative ways) (Barbarossa et al. 2020; Moran et al. 2018). Displacement
17 as well as resettlement schemes can have both socio-economic and environmental consequences
18 including those associated with establishment of new agricultural land (Nguyen et al. 2017; Ahsan and
19 Ahmad 2016). Dam construction may also stimulate migration into the affected region, which can lead
20 to deforestation and other negative impacts (Chen et al. 2015). Impacts can be mitigated through basin-
21 scale dam planning that considers GHG emissions along with social and ecological effects (Almeida et
22 al. 2019). Land occupation is minimal for run-of-river hydropower installations, but without storage
23 they have no resilience to drought and installations inhibit dispersal and migration of organisms (Lange
24 et al. 2018). Reservoir hydropower schemes can regulate water flows and reduce flood damage to
25 agricultural production (Amjath-Babu et al. 2019). On the other hand, severe flooding due to failure of
26 hydropower dams has caused fatalities, damage to infrastructure and loss of productive land (Lu et al.
27 2018; Zhang et al. 2016, 2017; Farley et al. 2005)(Farrington and Salama 1996; Marcar 2016; Kalinina
28 et al. 2018).

29

30 **12.5.4 Governance of land-related impacts of mitigation options**

31 The land sector (Chapter 7) contributes to mitigation via emissions reduction and enhancement of land
32 carbon sinks, and by providing biomass for mitigation in other sectors. Key challenges for governance
33 of land-based mitigation include social and environmental safeguards (Larson et al. 2018; Sills et al.
34 2017; Duchelle et al. 2017); insufficient financing (Turnhout et al. 2017); capturing co-benefits;
35 ensuring additionality, addressing non-permanence of carbon sequestration; monitoring, reporting, and
36 verification (MRV) of emissions reduction and carbon dioxide removals; and avoiding leakage or spill-
37 over effects. Governance approaches to addressing these challenges are discussed in section 7.6, and
38 include MRV systems and integrity criteria for project-level emissions trading; payments for ecosystem
39 services; land use planning and land zoning; certification schemes, standards and codes of practice.

40

41 With respect to renewable energy options that occupy land, the focus of governance has been directed
42 to technological adoption and, public acceptance (Sequeira and Santos 2018), rather than land use.
43 Recent work has found that spatial processes shape the emerging energy transition, creating zones of
44 friction between global investors, national and local governments, and civil society (McEwan 2017;

1 Jepson and Caldas 2017). For example, hydropower and ground-based solar parks in India have
2 involved enclosure of lands designated as degraded, displacing pastoral use by vulnerable communities,
3 constituting forms of spatial injustice (Yenneti et al. 2016). Hydropower leads to dam-induced
4 displacement, and though this can be addressed through compensation mechanisms, governance is
5 complicated by a lack of transparency in resettlement data (Kirchherr et al. 2016, 2019). Renewable
6 energy production is resulting in new land conflict frontiers where degraded land is framed as having
7 mitigation value such as for palm oil production and wind power in Mexico (Backhouse and Lehmann
8 2020); land use conflict as well as impacts on wildlife from large-scale solar installations have also
9 emerged in the southwestern United States (Mulvaney 2017). The renewable energy transition also
10 involves the extraction of critical minerals used in renewable energy technologies, such as lithium and
11 cobalt. Governance challenges include the lack of transparent greenhouse gas accounting for mining
12 activities (Lee et al. 2020a), and threats to biodiversity from land disturbance, which require strategic
13 planning to address (Sonter et al. 2020a). Strategic spatial planning is needed more generally to address
14 trade-offs between using land for renewable energy and food: for example, agriculture can be co-located
15 with solar photovoltaics (Barron-Gafford et al. 2019) or wind power (Miller and Keith 2018a).
16 Integrative spatial planning can integrate renewable energy with not just agriculture, but mobility and
17 housing (Hurlbert et al. 2019). Integrated planning is needed to avoid scalar pitfalls, and local and
18 regional contextualised governance solutions need to be sited within a planetary frame of reference
19 (Biermann et al. 2016). Greater planning and coordination are also needed to ensure co-benefits from
20 land-based mitigation (see Box 12.3) as well as from CDR and efforts to reduce food systems emissions.

21 In emerging domains for governance such as land-based mitigation, global institutions, private sector
22 networks and civil society organisations are also playing key roles in terms of norm-setting. The shared
23 languages and theoretical frameworks, or cognitive linkages (Pattberg et al. 2018) that arise with
24 polycentric governance can not only be helpful in creating expectations and establishing benchmarks
25 for (in)appropriate practices where enforceable ‘hard law’ is missing (Karlsson-Vinkhuyzen et al. 2018;
26 Gajevic Sayegh 2020), but can also form the basis of voluntary guidelines or niche markets (See also
27 the case study in Box 12.3) However, the ability to apply participatory processes for developing
28 voluntary guidelines and other participatory norm-setting endeavours varies from place to place. Social
29 and cultural norms shape the ability of women, youth, and different ethnic groups to participate in
30 governance fora, such as those around agroecological transformation (Anderson et al. 2019).
31 Furthermore, establishing new norms alone does not solve structural challenges such as lack of access
32 to food, confront power imbalances, or provide mechanisms to deal with uncooperative actors
33 (Morrison et al. 2019).

34 **START BOX 12.3 HERE**

35 **Box 12.3 Land Degradation Neutrality as a framework to manage trade-offs in land-based** 36 **mitigation**

37 The UNCCD introduced the concept of Land Degradation Neutrality (LDN), defined as “a state
38 whereby the amount and quality of land resources necessary to support ecosystem functions and
39 services and enhance food security remain stable or increase within specified temporal and spatial scales
40 and ecosystems” (UNCCD 2015), and it has been adopted as a target of Goal 15 of the SDGs, Life on
41 Land. At December 2020, 124 (mostly developing) countries have committed to pursue voluntary LDN
42 targets.

43
44 The goal of LDN is to maintain or enhance land-based natural capital, and its associated ecosystem
45 services such as provision of food and regulation of water and climate, while enhancing the resilience
46 of the communities that depend on the land. LDN encourages a dual-pronged approach promoting
47 sustainable land management (SLM) to avoid or reduce land degradation, combined with strategic effort

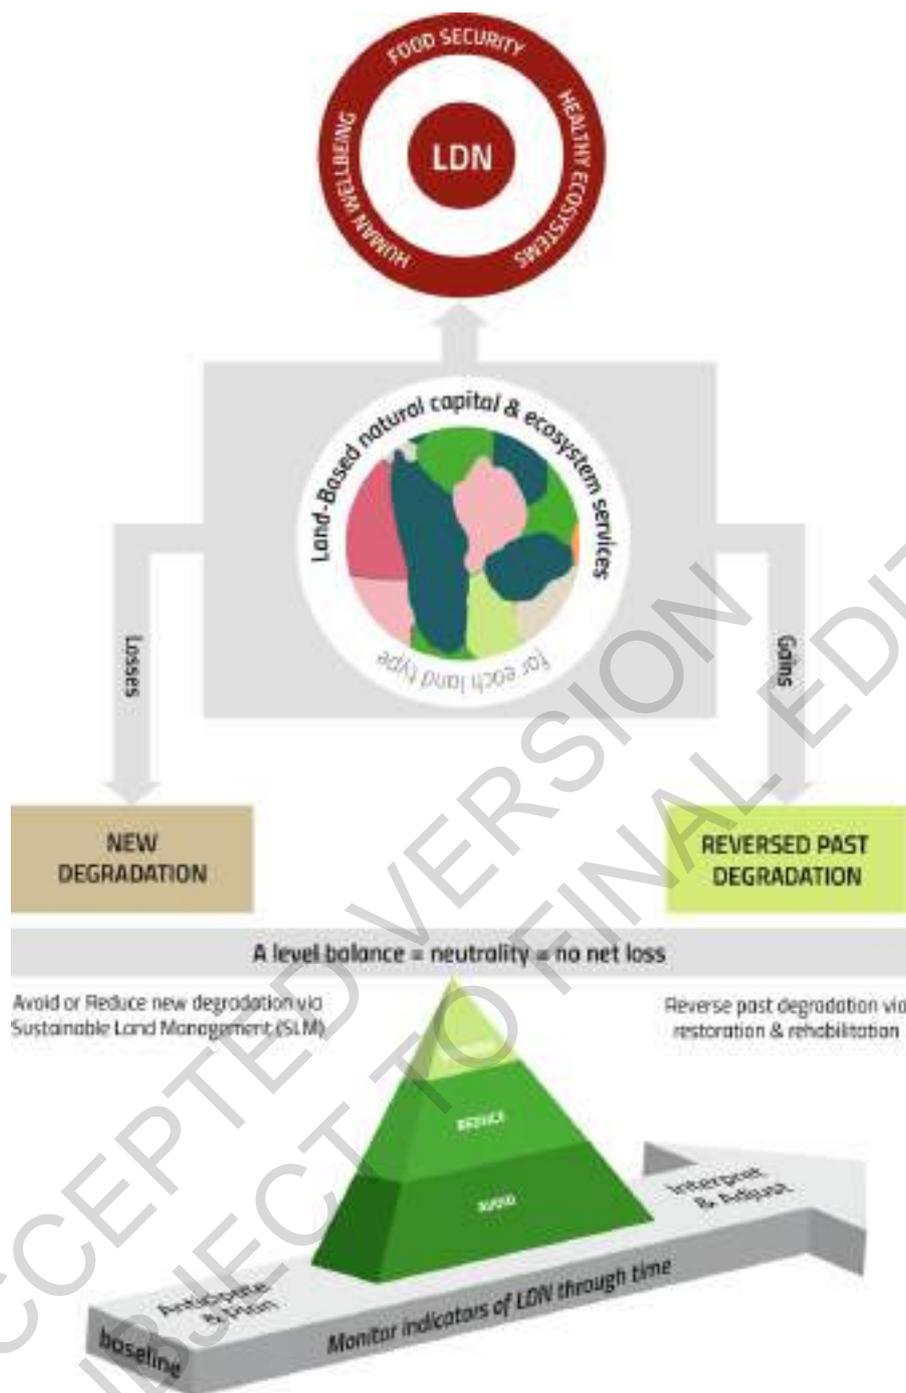

1 in land restoration and rehabilitation to reverse degradation on degraded lands and thereby deliver the
2 target of “no net loss” of productive land (Orr et al. 2017).

3
4 In the context of LDN, land restoration refers to actions undertaken with the aim of reinstating
5 ecosystem functionality, whereas land rehabilitation refers to actions undertaken with a goal of
6 provision of goods and services (Cowie et al. 2018). Restoration interventions can include destocking
7 to encourage regeneration of native vegetation; shelter belts of local species established from seed or
8 seedlings, strategically located to provide wildlife corridors and link habitat; and rewetting drained
9 peatland. “Farmer-managed natural regeneration” is a low-cost restoration approach in which
10 regeneration of tree stumps and roots is encouraged, stabilising soil and enhancing soil nutrients and
11 organic matter levels (Chomba et al. 2020; Lohbeck et al. 2020). Rehabilitation actions include
12 establishment of energy crops, or afforestation with fast-growing exotic trees to sequester carbon or
13 produce timber. Application of biochar can facilitate rehabilitation by enhancing nutrient retention and
14 water holding capacity, and stimulating microbial activity (Cowie 2020a).

15
16 SLM, rehabilitation and restoration activities undertaken towards national LDN targets have potential
17 to deliver substantial CDR through carbon sequestration in vegetation and soil. In addition, biomass
18 production, for bioenergy or biochar, could be an economically viable land use option for reversing
19 degradation, through rehabilitation. Alternatively, a focus on ecological restoration (Gann et al. 2019)
20 as the strategy for reversing degradation will deliver greater biodiversity benefits.

21
22 Achieving neutrality requires estimating the likely impacts of land-use and land management decisions,
23 to determine the area of land, of each land type, that is likely to be degraded (Orr et al. 2017). This
24 information is used to plan interventions to reverse degradation on an equal area of the same land type.
25 Therefore, pursuit of LDN requires concerted and coordinated efforts to integrate LDN objectives into
26 land-use planning and land management, underpinned by sound understanding of the human-
27 environment system and effective governance mechanisms.

28
29 Countries are advised to apply a landscape-scale approach for planning LDN interventions, in which
30 land uses are matched to land potential, and resilience of current and proposed land uses is considered,
31 to ensure that improvement in land condition is likely to be maintained (Cowie 2020a). A participatory
32 approach that enables effective representation of all stakeholders is encouraged, to facilitate equitable
33 outcomes from planning decisions, recognising that decisions on LDN interventions are likely to
34 involve trade-offs between various environmental and socio-economic objectives (Schulze et al. 2021).
35 Planning and implementation of LDN programmes provides a framework in which locally-adapted
36 land-based mitigation options can be integrated with use of land for production, conservation and
37 settlements, in multifunctional landscapes where trade-offs are recognised and managed, and
38 synergistic opportunities are sought. LDN is thus a vehicle to focus collaboration in pursuit of the
39 multiple land-based objectives of the multilateral environmental agreements and the SDGs.

END BOX 12.3 HERE

Table 12.10 collates risks, impacts and opportunities associated with different mitigation options that occupy land.

1 **Table 12.10 Summary of impacts, risks and co-benefits associated with land occupation by mitigation**
 2 **options considered in section 12.5.**

Mitigation option	Impacts and risks	Opportunities for co-benefits
<i>Non-bio-based options that may displace food production</i>		
Solar farms	Land use competition; Loss of soil carbon; heat island effect (scale dependent) {12.5.3, 12.5.4}	Target areas unsuitable for agriculture such as deserts {12.5.3}
Hydropower (dams)	Land use competition, displacement of natural ecosystems, CO ₂ and CH ₄ emissions {12.5.3, 12.5.4}	Water storage (including for irrigation) and regulation of water flows; Pumped storage can store excess energy from other renewable generation sources. {12.5.3}
<i>Non-bio-based options that can (to a varying degree) be integrated with food production</i>		
Wind turbines	May affect local/regional weather and climate (scale dependent) Impact on wildlife and visual impacts {12.5.3}	Design and siting informed by visual landscape impacts, relevant habitats, and flight trajectories of migratory birds. {12.5.3}
Solar panels	Land use competition {12.5.3}	Integration with buildings and other infrastructure. integration with food production is being explored {12.5.2}
Enhanced weathering	Disturbance at sites of extraction; Ineffective in low rainfall regions {12.3.1.2}	Increase crop yields and biomass production through nutrient supply and increasing pH of acid soils; synergies with biochar {12.5.3}
<i>Bio-based options that may displace existing food production</i>		
A/R	Land use competition, potentially leading to indirect land use change; reduced water availability; loss of biodiversity {12.5.3}	Strategic siting to minimise adverse impacts on hydrology, land use, biodiversity {12.5.3}
Biomass crops	Land use competition, potentially leading to indirect land use change; reduced water availability; reduced soil fertility; loss of biodiversity {12.5.3}	Strategic siting to minimise adverse impacts / enhance beneficial effects on land use, landscape variability, biodiversity, soil organic matter, hydrology and water quality {12.5.3}
<i>Bio-based options that can (to a varying degree) be combined with food production</i>		

Agroforestry	Competition with adjacent crops and pastures reduces yields {7.4.3.3}	Shelter for stock and crops, diversification, biomass production, increases soil organic matter and soil fertility. Increased biodiversity and perennial vegetation enhance beneficial organisms; can reduce need for pesticides {7.4.3.3, 12.5.3}
Soil carbon management in croplands and grasslands	Increase in nitrous oxide emissions if fertiliser used to enhance crop production; Reduced cereal production through increased crop legumes and pasture phases could lead to indirect land use change {7.4.3.1, 7.4.3.6}	Increasing soil organic matter improves soil health, increases crop and pasture yields, and resilience to drought, can reduce fertiliser requirement, nutrient leaching and need for land use change. {7.4.3.1}
Biochar addition to soil	Land use competition if biochar is produced from purpose-grown biomass. Loss of forest carbon stock and impacts on biodiversity if biomass is harvested unsustainably. {12.5.3}	Facilitate beneficial use of organic residues, to return nutrients to farmland. Increase land productivity to increase C sequestration in vegetation and soil. Increase nutrient-use efficiency, and reduce requirement for chemical fertiliser. {7.4.3.2, 12.5.3}
Harvest residue extraction and use for bioenergy, biochar and other bio-products	Decline in soil organic matter and soil fertility {12.5.3}	Retain portion of stubble; return nutrients e.g. as ash Utilising forest residues for bioenergy reduces fuel load and wildfire risk {7.4.3.2, 12.5.3}
Manure management (i.e., for biogas)	Risk of fugitive emissions Can contain pathogens {7.4.3.7, 12.5.3}	Biogas as renewable energy source. Apply digestate as soil amendment {12.5.3}
<i>Options that don't occupy land used for food production</i>		
Management of organic waste (food waste, bio-solids, organic component of MSW)	Can contain contaminants (heavy metals, persistent organic pollutants, pathogens) {12.5.3}	Processing using anaerobic digestion or pyrolysis produces renewable gas and soil amendment, enabling return of nutrients to farmland. (note that some feedstock nitrogen is lost in pyrolysis) {12.5.3}
A/R and biomass production on degraded non-forested land (e.g., abandoned agricultural land)	High labour and material inputs can be needed to restore productivity on degraded land. Abandoned land can support informal grazing and have significant biodiversity value. Reduced water availability. {12.5.3}	Application of biochar can re-establish nutrient cycling; bioenergy crops can add organic matter, restoring soil fertility, and can remove heavy metals, enabling food production. {7.4.3.2, 12.5.3}

11 Summary statement

12 The growing demand for biomass offers both opportunities and challenges to mitigate and adapt to
13 climate change and natural resource constraints (high confidence). Increased technology innovation,
14 stakeholder integration and transparent governance structures and procedures at local to global scales
15 are key to successful bioeconomy deployment maximizing benefits and managing trade-offs (high
16 confidence).

17 Limited global land and biomass resources accompanied by growing demands for food, feed, fibre, and
18 fuels, together with prospects for a paradigm shift towards phasing out fossil fuels, set the frame for
19 potentially fierce competition for land² and biomass to meet burgeoning demands even as climate
20 change increasingly limits natural resource potentials (*high confidence*).

21 Sustainable agriculture and forestry, technology innovation in bio-based production within a circular
22 economy and international cooperation and governance of global trade in products to reflect and
23 disincentivize their environmental and social externalities, can provide mitigation and adaptation via
24 bioeconomy development that responds to the needs and perspectives of multiple stakeholders to
25 achieve outcomes that maximize synergies while limiting trade-offs (*high confidence*).

26 Background

27 There is *high confidence* that climate change, population growth and changes in per capita consumption
28 will increase pressures on managed as well as natural and semi-natural ecosystems, exacerbating
29 existing risks to livelihoods, biodiversity, human and ecosystem health, infrastructure, and food systems
30 (Conijn et al. 2018; IPCC 2018, 2019; Lade et al. 2020). At the same time, many global mitigation
31 scenarios presented in IPCC assessment reports rely on large GHG emissions reduction in the AFOLU
32 sector and concurrent deployment of reforestation/afforestation and biomass use in a multitude of
33 applications (Rogelj et al. 2018; Hanssen et al. 2020; AR6 WG1 Ch.4 and Ch.5; AR6 WG3 Ch.3 and
34 Ch.7).

35 Given the finite availability of natural resources, there are invariably trade-offs that complicate land-
36 based mitigation unless land productivity can be enhanced without undermining ecosystem services
37 (e.g., Obersteiner et al. 2016; Campbell et al. 2017; Conijn et al. 2018; Caron et al. 2018; WRI 2018;
38 Heck et al. 2018; Smith et al. 2019). Management intensities can often be adapted to local conditions

FOOTNOTE² For lack of space the focus is on land only although the bioeconomy also includes sea-related bioresources.

1 with consideration of other functions and ecosystem services, but at a global scale the challenge remains
2 to avoid further deforestation and degradation of intact ecosystems, in particular biodiversity-rich
3 systems (AR6 WGII Cross-Chapter Box on NATURAL), while meeting the growing demands. Further,
4 increased land-use competition can affect food prices and impact food security and livelihoods (To and
5 Grafton 2015; Chakravorty et al. 2017), with possible knock-on effects related to civil unrest (Abbott
6 et al. 2017; D’Odorico et al. 2018).

7 *Developing new bio-based solutions while mitigating overall biomass demand growth*

8 Many existing bio-based products have significant mitigation potential. Increased use of wood in
9 buildings can reduce GHG emissions from cement and steel production while providing carbon storage
10 (Churkina et al. 2020). Substitution of fossil fuels with biomass in manufacture of cement and steel can
11 reduce GHG emissions where these materials are difficult to replace. Dispatchable power based on
12 biomass can provide power stability and quality as the contribution from solar and wind power increases
13 (See AR6 WG3 Ch.6), and biofuels can contribute to reducing fossil fuel emissions in the transport and
14 industry sectors (See AR6 WG3 Ch.10 and Ch.11). The use of bio-based plastics, chemicals and
15 packaging could be increased, and biorefineries can achieve high resource-use efficiency in converting
16 biomass into food, feed, fuels and other bio-based products (Aristizábal-Marulanda and Cardona Alzate
17 2019; Schmidt et al. 2019). There is also scope for substituting existing bio-based products with more
18 benign products. For example, cellulose-based textiles can replace cotton, which requires large amounts
19 of water, chemical fertilizers and pesticides to ensure high yields.

20 While increasing and diversified use of biomass can reduce the need for fossil fuels and other GHG-
21 intensive products, unfavourable GHG balances may limit the mitigation value. Growth in biomass use
22 may in the longer term also be constrained by the need to protect biodiversity and ecosystems’ capacity
23 to support essential ecosystem services. Biomass use may also be constrained by water scarcity and
24 other resource scarcities, and/or challenges related to public perception and acceptance due to impacts
25 caused by biomass production and use. Energy conservation and efficiency measures and deployment
26 of technologies and systems that do not rely on carbon, e.g., carbon-free electricity supporting, inter
27 alia, electrification of transport as well as industry processes and residential heating (IPCC 2018; UNEP
28 2019), can constrain the growth in biomass demand when countries seek to phase out fossil fuels and
29 other GHG-intensive products while providing an acceptable standard of living. Nevertheless, demand
30 for bio-based products may become high where full decoupling from carbon is difficult to achieve (e.g.,
31 aviation, bio-based plastics and chemicals) or where carbon storage is an associated benefit (e.g., wood
32 buildings, BECCS, biochar for soil amendments), leading to challenging trade-offs (e.g., food security,
33 biodiversity) that need to be managed in environmentally sustainable and socially just ways.

34 Changes on the demand side as well as improvements in resource-use efficiencies within the global
35 food and other bio-based systems can also reduce pressures on the remaining land resources. For
36 example, dietary changes toward more plant-based food (where appropriate) and reduced food waste
37 can provide climate change mitigation along with health benefits (Willett et al. 2019; WG3 Ch 7.4 and
38 Ch 12.4) and other co-benefits with regard to food security, adaptation and land use (Smith et al. 2019a;
39 Mbow et al. 2019; WG2 Ch.5). Advancements in the provision of novel food and feed sources (e.g.,
40 cultured meat, insects, grass-based protein feed and cellular agriculture) can also limit the pressures on
41 finite natural resources (Parodi et al. 2018; Zabaniotou 2018; WG3 Ch 12.4).

42 **Circular bioeconomy**

43
44
45 Circular economy approaches (AR6 WG3 Ch 12.6) are commonly depicted by two cycles, where the
46 biological cycle focuses on regeneration in the biosphere and the technical cycle focuses on reuse,

1 refurbishment and recycling to maintain value and maximize material recovery (Mayer et al. 2019a).
2 Biogenic carbon flows and resources are part of the biological carbon cycle, but carbon-based products
3 can be included in, and affect, both the biological and the technical carbon cycles (Velenturf et al. 2019;
4 Winans et al. 2017; Kirchherr et al. 2017). The integration of circular economy and bioeconomy
5 principles has been discussed in relation to organic waste management (Teigiserova et al. 2020), societal
6 transition and policy development (Bugge et al. 2019; European Commission 2018) as well as COVID-
7 19 recovery strategies (Palahí et al. 2020). To maintain the natural resource base, circular bioeconomy
8 emphasizes sustainable land use and the return of biomass and nutrients to the biosphere when it leaves
9 the technical cycle.

10
11 Biomass scarcity is an argument for adopting circular economy principles for the management of
12 biomass as for non-renewable resources. This includes waste avoidance, product reuse and material
13 recycling, which keep down resource use while maintaining product and material value. However, reuse
14 and recycling is not always feasible, e.g., when biofuels are used for transport and bio-based
15 biodegradable chemicals are used to reduce ecological impacts where losses to the environment are
16 unavoidable. A balanced approach to management of biomass resources could take departure in the
17 carbon cycle from a value-preservation perspective and the possible routes that can be taken for biomass
18 and carbon, considering a carbon budget defined by the Paris Agreement, principles for sustainable land
19 use and natural ecosystem protection.

20 21 *Land use opportunities and challenges in the bioeconomy*

22 Analyses of synergies and trade-offs between adaptation and mitigation in the agriculture and forestry
23 sectors show that outcomes depend on context, design and implementation, so actions have to be
24 tailored to the specific conditions to minimize adverse effects (Kongsager 2018). This is supported in
25 literature analyzing the nexus between land, water, energy and food in the context of climate change
26 which consistently concludes that addressing these different domains together rather than in isolation
27 would enhance synergies and reduce trade-offs (Obersteiner et al. 2016; D’Odorico et al. 2018; Soto
28 Golcher and Visseren-Hamakers 2018; Momblanch et al. 2019; Froese et al. 2019).

29 Nature-based solutions addressing climate change can provide opportunities for sustainable livelihoods
30 as well as multiple ecosystem services, such as flood risk management through floodplain restoration,
31 saltmarshes, mangroves or peat renaturation (UNEP 2021; AR6 WGII Cross-Chapter Box on
32 NATURAL). Climate-smart agriculture can increase productivity while enhancing resilience and
33 reducing GHG emissions inherent to production (Lipper et al. 2014; Singh and Chudasama 2021). (Bell
34 et al. 2018; FAO 2019b; Singh and Chudasama 2021) Similarly, climate-smart forestry considers the
35 whole value chain and integrates climate objectives into forest sector management through multiple
36 measures (from strict reserves to more intensively managed forests) providing mitigation and adaptation
37 benefits (Nabuurs et al. 2018; Verkerk et al. 2020) (AR6 WG3 Ch 7.3).

38 Agroecological approaches can be integrated into a wide range of land management practices to support
39 a sustainable bioeconomy and address equity considerations (HLPE 2019). Relevant land-use practices,
40 such as agroforestry, intercropping, organic amendments, cover crops and rotational grazing, can
41 provide mitigation and support adaption to climate change via food security, livelihoods, biodiversity
42 and health co-benefits (Bezner Kerr et al. 2019; Bharucha et al. 2020; Clark et al. 2019b; D’Annolfo et
43 al. 2017; Garibaldi et al. 2016; Ponisio et al. 2015; Renard and Tilman 2019; HLPE 2019; Sinclair et
44 al. 2019; Córdova et al. 2019; Mbow et al. 2019; Bezner Kerr et al. 2021; and AR6 WGII Chapter 2
45 Cross-Chapter Box NATURAL). Strategic integration of appropriate biomass production systems into
46 agricultural landscapes can provide biomass for bioenergy and other bio-based products while providing
47 co-benefits such as enhanced landscape diversity, habitat quality, retention of nutrients and sediment,

1 erosion control, climate regulation, flood regulation, pollination and biological pest and disease control
 2 (Christen and Dalgaard 2013; Asbjornsen et al. 2014; Englund et al. 2020; Cacho et al. 2018; Dauber
 3 and Miyake 2016; Holland et al. 2015; Milner et al. 2016; Ssegane et al. 2015; Ssegane and Negri 2016;
 4 Styles et al. 2016; Zalesny et al. 2019; Zumpf et al. 2017; HLPE 2019; Cubins et al. 2019; Alam and
 5 Dwivedi 2019; Olsson et al. 2019) (AR6 WGIII Chapter 12 Box 12.3 on UNCCD-LDN). Such
 6 approaches can help limit environmental impacts from intensive agriculture while maintaining or
 7 increasing land productivity and biomass output.

14 Transitions from conventional to new biomass production and conversion systems include challenges
 15 related to cross-sector integration and limited experience with new crops and land use practices,
 16 including needs for specialized equipment (Thornton and Herrero 2015; HLPE 2019; AR6 WG2
 17 Section 5.10). Introduction of agroecological approaches and integrated biomass/food crop production
 18 can result in lower food crop yields per hectare, particularly during transition phases, potentially causing
 19 indirect land use change, but can also support higher and more stable yields, reduce costs, and increase
 20 profitability under climate change (Muller et al. 2017; Seufert and Ramakutty 2017; Barbieri et al. 2019;
 21 HLPE 2019; Sinclair et al. 2019; Smith et al. 2019a, 2020). Crop diversification, organic amendments,
 22 and biological pest control (HLPE 2019) can reduce input costs and risks of occupational pesticide
 23 exposure and food and water contamination (González-Alzaga et al. 2014; EFSA 2017; Mie et al. 2017),
 24 reduce farmers' vulnerability to climate change (e.g., droughts and spread of pests and diseases affecting
 25 plant and animal health (Delcour et al. 2015; FAO 2020) and enhance provisioning and sustaining
 26 ecosystem services, such as pollination (D'Annolfo et al. 2017; Sinclair et al. 2019).

27 Barriers toward wider implementation include absence of policies that compensate land owners for
 28 providing enhanced ecosystem services and other environmental benefits, which can help overcome
 29 short term losses during the transition from conventional practices before longer term benefits can
 30 accrue. Other barriers include limited access to markets, knowledge gaps, financial, technological or
 31 labour constraints, lack of extension support and insecure land tenure (Jacobi et al. 2017; Kongsager
 32 2017; Hernández-Morcillo et al. 2018; Iiyama et al. 2018; HLPE 2019). Regional-level agroecology
 33 transitions may be facilitated by co-learning platforms, farmer networks, private sector, civil society
 34 groups, regional and local administration and other incentive structures (e.g. price premiums, access to
 35 credit, regulation) (Coe et al. 2014; Pérez-Marin et al. 2017; Mier y Terán Giménez Cacho et al. 2018;

1 HLPE 2019; Valencia et al. 2019; SAEPEA 2020). With the right incentives, improvements can be
2 made with regard to profitability, making alternatives more attractive to land owners.

3 *Governing the solution space*

4 Literature analysing the synergies and trade-offs between competing demands for land suggest that
5 solutions are highly contextualized in terms of their environmental, socioeconomic and governance-
6 related characteristics, making it difficult to devise generic solutions (Haasnoot et al. 2020). Aspects of
7 spatial and temporal scale can further enhance the complexity, for instance where transboundary effects
8 across jurisdictions or upstream-downstream characteristics need to be considered, or where climate
9 change trajectories might alter relevant biogeophysical dynamics (Postigo and Young 2021).
10 Nonetheless, there is broad agreement that taking the needs and perspectives of multiple stakeholders
11 into account in a transparent process during negotiations improves the chances of achieving outcomes
12 that maximize synergies while limiting trade-offs (Ariti et al. 2018; Metternicht 2018; Favretto et al.
13 2020; Kopáček 2021; Muscat et al. 2021). Yet differences in agency and power between stakeholders
14 or anticipated changes in access to or control of resources can undermine negotiation results even if
15 there is a common understanding of the overarching benefits of more integrated environmental
16 agreements and the need for greater coordination and cooperation to avoid longer-term losses to all
17 (Aarts and Leeuwis 2010; Weitz et al. 2017). There is also the risk that strong local participatory
18 processes can become disconnected from broader national plans, and thus fail to support the
19 achievement of national targets. Thus, connection between levels is needed to ensure that ambition for
20 transformative change is not derailed at local level (Aarts and Leeuwis 2010; Postigo and Young 2021).

21 Decisions on land uses between biomass production for food, feed, fibre or fuel, as well as nature
22 conservation or restoration and other uses (e.g., mining, urban infrastructure), depend on differences in
23 perspectives and values. Because the availability of land for diverse biomass uses is invariably limited,
24 setting priorities for land-use allocations therefore first depends on making the perspectives underlying
25 what is considered as ‘high-value’ explicit (Fischer et al. 2007; Garnett et al. 2015; De Boer and Van
26 Ittersum 2018; Muscat et al. 2020). Decisions can then be made transparently based on societal norms,
27 needs and the available resource base. Prioritization of land-use for the common good therefore requires
28 societal consensus-building embedded in the socioeconomic and cultural fabric of regions, societies
29 and communities. Integration of local decision-making with national planning ensures local actions
30 complement national development objectives.

31 International trade in the global economy today provides important opportunities to connect producers
32 and consumers, effectively buffering price volatilities and potentially offering producers countries
33 access to global markets, which can be seen as an effective adaptation measure (Baldos and Hertel 2015;
34 Costinot et al. 2016; Hertel and Baldos 2016; Gouel and Laborde 2021; AR6 WG2 Ch 5.11). But there
35 is also clear evidence that international trade and the global economy can enhance price volatility, lead
36 to food price spikes and affect food security due to climate and other shocks, as seen recently due to the
37 COVID-19 pandemic (Cottrell et al. 2019; WFP-FSIN 2020; Verschuur et al. 2021; AR6 WG2 Ch
38 5.12). The continued strong demand for food and other bio-based products, mainly from high- and
39 middle-income countries, therefore requires better cooperation between nations and global governance
40 of trade to more accurately reflect and disincentivize their environmental and social externalities. Trade
41 in agricultural and extractive products driving land-use change in tropical forest and savanna biomes is
42 of major concern because of the biodiversity impacts and GHG emissions incurred in their provision
43 (Hosonuma et al. 2012; Forest Trends 2014; Smith et al. 2014; Henders et al. 2015; Curtis et al. 2018;
44 Pendrill et al. 2019; Seymour and Harris 2019; Kissinger et al. 2021; AR6 WG2 CCP Tropical Forests).

1 In summary, there is significant scope for optimizing use of land resources to produce more biomass
2 while reducing adverse effects (*high confidence*). Context-specific prioritisation, technology innovation
3 in bio-based production, integrative policies, coordinated institutions and improved governance
4 mechanisms to enhance synergies and minimize trade-offs can mitigate the pressure on managed as
5 well as natural and semi-natural ecosystems (*medium confidence*). Yet, energy conservation and
6 efficiency measures, and deployment of technologies and systems that do not rely on carbon-based
7 energy and materials, are essential for mitigating biomass demand growth as countries pursue ambitious
8 climate goals (*high confidence*).

9 **END CROSS-WORKING BOX 3 HERE**

11 **12.6 Other cross-sectoral implications of mitigation**

12 This section presents further cross-sectoral considerations related to GHG mitigation. Firstly,
13 various cross-sectoral perspectives on mitigation actions are presented. Then, sectoral policy
14 interactions are presented. Finally, implications in terms of international trade spill-over effects
15 and competitiveness, and finance flows and related spill-over effects at the sectoral level are
16 addressed.

17 **12.6.1 Cross-sectoral perspectives on mitigation action**

18 Chapters 5 to 11 present mitigation measures applicable in individual sectors, and potential co-benefits
19 and adverse side effects³ of these individual measures. This section builds on the sectoral analysis of
20 mitigation action from a cross-sectoral perspective. Firstly, Section 12.6.1.1 brings together some of
21 the observations presented in the sectoral chapters to show how different mitigation actions in different
22 sectors can contribute to the same co-benefits and result in the same adverse side effects, thereby
23 demonstrating the potential synergistic effects. The links between these co-benefits and adverse side
24 effects and the SDGs is also demonstrated. In Section 12.6.1.2, the focus turns from sector-specific
25 mitigation measures to mitigation measures which have cross-sectoral implications, including measures
26 that have application in more than one sector and measures where implementation in one sector impacts
27 on implementation in another. Finally, Section 12.6.1.3 notes the cross-sectoral relevance of a selection
28 of General-Purpose Technologies, a topic that is covered further in Chapter 16.

29 **12.6.1.1 A cross-sectoral perspective on co-benefits and adverse side effects of mitigation measures, 30 and links the SDGs**

31 A body of literature has been developed which addresses the *co-benefits* of climate mitigation action,
32 (Karlsson et al. 2020). *Adverse side effects* of mitigation are also well documented. Co-benefits and
33 adverse side-effects in individual sectors and associated with individual mitigation measures are
34 discussed in the individual sector chapters (Sections 5.2, 6.7.7, 7.4, 7.6, 8.2, 8.4, 9.8, 10.1.1, 11.5.3), as
35 well as in previous IPCC General and Special Assessment reports. The term *co-impacts* has been
36 proposed to capture both the co-benefits and adverse side-effects of mitigation. An alternative framing
37 is one of multiple objectives, where climate mitigation is placed alongside other objectives when

FOOTNOTE³ Here, the term co-benefits is used to refer to the additional benefits to society and the environment that are realised in parallel with emissions reductions, while an understanding of adverse side effects highlights where policy and decision makers are required to make trade-offs between mitigation benefits and other impacts. The choice of language differs to some degree in other chapters.

1 assessing policy decisions (Ürge-Vorsatz et al. 2014; Mayrhofer and Gupta 2016; Cohen et al. 2017;
2 Bhardwaj et al. 2019).

3 The identification and assessment of co-benefits has been argued to serve a number of functions
4 (Section 1.4) including using them as a leverage for securing financial support for implementation,
5 providing justification of actions which provide a balance of both short and long-term benefits and
6 obtaining stakeholder buy-in (*robust evidence, low agreement*) (Karlsson et al. 2020). Assessment of
7 adverse side-effects has been suggested to be useful in avoiding unforeseen negative impacts of
8 mitigation and providing policy and decision makers with the information required to make informed
9 trade-offs between climate and other benefits of actions (Ürge-Vorsatz et al. 2014; Bhardwaj et al. 2019;
10 Cohen et al. 2019) (*high evidence, low agreement*).

11 Various approaches to identifying and organising co-impacts in specific contexts and across sectors
12 have been proposed towards providing more comparable and standardised analyses. However,
13 consistent quantification of co-impacts, including cost-benefit analysis, and the utilisation of the
14 resulting information, remains a challenge (Ürge-Vorsatz et al. 2014; Floater et al. 2016; Mayrhofer
15 and Gupta 2016; Cohen et al. 2019; Karlsson et al. 2020). This challenge is further exacerbated when
16 considering that co-impacts of a mitigation measure in one sector can either enhance or reduce the co-
17 impacts associated with mitigation in another, or the achievement of co-benefits in one geographic
18 location can lead to adverse side effects in another. For example, the production of lithium for batteries
19 for energy storage has the potential to contribute to protecting water resources and reducing wastes
20 associated with coal fired power in many parts of the world, but mining of lithium has the potential for
21 creating water and waste challenges if not managed properly (Agusdinata et al. 2018; Kaunda 2020).

22 While earlier literature has suggested that co-impacts assessments can support adoption of climate
23 mitigation action, a more recent body of literature has suggested limitations in such framing (Ryan
24 2015; Bernauer and McGrath 2016; Walker et al. 2018). Presenting general information on co-impacts
25 as a component of a mitigation analysis does not always lead to increased support for climate mitigation
26 action. Rather, the most effective framing is determined by factors relating to local context, type of
27 mitigation action under consideration and target stakeholder group. More work has been identified to
28 be required to bring context into planning co-impacts assessments and communication thereof (Ryan
29 2015; Bernauer and McGrath 2016; Walker et al. 2018) (*low evidence, low agreement*).

30 An area where the strong link between the cross-sectoral co-impacts of mitigation action and global
31 government policies is being clearly considered is in the achievement of the SDGs (Chapters 1 and 17,
32 individual sectoral chapters) (Obergassel et al. 2017; Doukas et al. 2018; Markkanen and Anger-Kraavi
33 2019; Smith et al. 2019; van Soest et al. 2019). Figure 12.9 demonstrates these relationships from a
34 cross-sectoral perspective. It shows the links between sectors which give rise to emissions, the
35 mitigation measures that can find application in the sector, co-benefits and adverse side effects of
36 mitigation measures and the SDGs (noting that the figure is not intended to be comprehensive). Such a
37 framing of co-impacts from a cross-sectoral perspective in the context of the SDGs could help to further
38 support climate mitigation action, particularly within the context of the Paris Agreement (Gomez-
39 Echeverri 2018) (*medium evidence, medium agreement*). Literature sources utilised in the compilation
40 of this diagram are presented in Supplementary Material 12.C.

Figure 12.9 Co-benefits and adverse side effects of mitigation actions with links to the SDGs.

The inner circle represents the sectors in which mitigation occurs. The second circle shows different generic types of mitigation actions (A to G), with the symbols showing which sectors they are applicable to. The third circle indicates different types of climate related co-benefits (green letters) and adverse side effects (red letters) that may be observed as a result of implementing each of the mitigation actions (as indicated by the letters A-G). Here I relates to climate resilience, II-IV economic co-impacts, V-VII environmental, VIII-XII social, and XIII political and institutional. The final circle maps co-benefits and adverse side-effects to the SDGs (Cohen et al. 2021).

12.6.1.2 Mitigation measures from a cross-sectoral perspective

Three aspects of mitigation from a cross-sectoral perspective are considered, following (Barker et al. 2007):

- mitigation measures used in more than one sector;
- implications of mitigation measures for interaction and integration between sectors; and
- competition among sectors for scarce resources.

A number of mitigation measures find application in more than one sector. Renewable energy technologies such as solar and wind may be used for grid electricity supply, as embedded generation in the buildings sector and for energy supply in the agriculture sector (Chapters 6, 7 and 8) (Shahsavari and Akbari 2018). Hydrogen and fuel cells, coupled with low carbon energy technologies for producing the hydrogen, is being explored in transport, urban heat, industry and for balancing electricity supply (Chapters 6, 8, 11) (Dodds et al. 2015; Staffell et al. 2019). Electric vehicles are considered an option for balancing variable power (Kempton and Tomić 2005; Liu and Zhong 2019). Carbon Capture and Storage (CCS) and Carbon Capture and Utilisation (CCU) has potential application in a number of

1 industrial processes (cement, iron and steel, petroleum refining and pulp and paper) (Chapters 6 and 11)
2 (Leeson et al. 2017; Garcia and Berghout 2019) and the fossil fuel electricity sector (Chapter 6). When
3 coupled with energy recovery from biomass, CCS can provide a carbon sink (BECCS) (Section 12.5).
4 On the demand side, energy efficiency options find application across the sectors (Chapters 6, 8, 9, 10,
5 and 11), as does reducing demand for goods and services (Chapter 5), and improving material efficiency
6 (Section 11.3.2).

7 A range of examples of where mitigation measures result in cross-sectoral interactions and integration
8 is identified. The mitigation potential of electric vehicles, including plug-in hybrid hybrids, is linked to
9 the extent of decarbonisation of the electricity grid, as well as to the liquid fuel supply emissions profile
10 (Lutsey 2015). Making buildings energy positive, where excess energy is used to charge vehicles, can
11 increase the potential of electric and hybrid vehicles (Zhou et al. 2019). Advanced process control and
12 process optimisation in industry can reduce energy demand and material inputs (Section 11.3), which
13 in turn can reduce emissions linked to resource extraction and manufacturing. Reductions in coal-fired
14 power generation through replacement with renewables or nuclear power result in a reduction in coal
15 mining and its associated emissions. Increased recycling results in a reduction in emissions from
16 primary resource extraction. CCU can contribute to the transition to more renewable energy systems
17 via power-to-X technologies, which enables the production of CO₂-based fuels/e-fuels and chemicals
18 using carbon dioxide and hydrogen (Breyer et al. 2015; Anwar et al. 2020). Certain reductions in the
19 AFOLU sector are contingent on energy sector decarbonisation. Trees and green roofs planted to
20 counter urban heat islands reduce the demand for energy for air conditioning and simultaneously
21 sequester GHGs (Kim and Coseo 2018; Kuronuma et al. 2018). Recycling of organic waste avoids
22 methane generation if the waste would have been disposed of in landfill sites, can generate renewable
23 energy if treated through anaerobic digestion and can reduce requirements for synthetic fertiliser
24 production if the nutrient value is recovered (Creutzig et al. 2015). Liquid transport biofuels links to the
25 land, energy and transport sectors (Section 12.5.2.2).

26 Demand-side mitigation measures, discussed in Chapter 5, also have cross-sectoral implications which
27 need to be taken into account when calculating mitigation potentials. Residential electrification has the
28 potential to reduce emissions associated with lighting and heating particularly in developing countries
29 where this is currently met by fossil fuels and using inefficient technologies, but will increase demand
30 for electricity (Chapters 5, 8 and Sections 6.6.2.3, 8.4.3.1). Many industrial processes can also be
31 electrified in the move away from fossil reductants and direct energy carriers (Chapter 11). The impact
32 of electrification on electricity sector emissions will depend on whether electricity generation is based
33 on fossil fuels in the absence of CCS or low carbon energy sources (Chapter 5).

34 At the same time, saving electricity in all sectors reduces the demand for electricity, thereby reducing
35 mitigation potential of renewables and CCS. Demand side flexibility measures and electrification of
36 vehicle fleets are supportive of more intermittent renewable energy supply options (Sections 6.3.7,
37 6.4.3.1 and 10.3.4). Production of maize, wheat, rice and fresh produce requires lower energy inputs on
38 a life cycle basis than poultry, pork and ruminant based meats (Section 12.4) (Clark and Tilman 2017).
39 They also require less land and area per kilocalorie or protein output (Clark and Tilman 2017; Poore
40 and Nemecek 2018), and so replacing meat with these products makes land available for sequestration,
41 biodiversity or other societal needs. However, production of co-products of the meat industry, such as
42 leather and wool, is reduced, resulting in a need for substitutes. Further discussion and examples of
43 cross-sectoral implications of mitigation, with respect to cost and potentials, are presented in Section
44 12.2. One final example on this topic included here is that of Circular Economy (Box 12.4).

45 Finally, in terms of competition among sectors for scarce resources, this issue is often considered in the
46 assessments of mitigation potentials linked to bioenergy and diets (vegetable vs. animal food products),

1 land use and water (Section 12.5, Cross-Working Group Box 3 in this Chapter) (*robust evidence, high*
2 *agreement*). It is, however, also relevant elsewhere. Constraints have been identified in the supply of
3 indium, tellurium, silver, lithium, nickel and platinum that are required for implementation of some
4 specific renewable energy technologies (Watari et al. 2018; Moreau et al. 2019). Other studies have
5 shown constraints in supply of cobalt, one of the key elements used in production of lithium-ion
6 batteries, which has been assessed for mitigation potential in energy, transport and buildings sectors
7 (Jaffe 2017; Olivetti et al. 2017) (*medium evidence, high agreement*), although alternatives to cobalt are
8 being developed (Olivetti et al. 2017; Watari et al. 2018).

9 **START BOX 12.4 HERE**

10 **Box 12.4: Circular Economy from a Cross-Sectoral Perspective**

11
12
13 Circular economy approaches consider the entire life cycle of goods and services, and seek to design
14 out waste and pollution, keep products and materials in use, and regenerate natural systems (The Ellen
15 MacArthur Foundation 2013; CIRAIG 2015). The use of Circular Economy for rethinking how
16 society's needs for goods and services is delivered in such a way as to minimise resource use and
17 environmental impact and maximise societal benefit has been discussed elsewhere in this assessment
18 report (Chapter 5 and Section 5.3.4). A wide range of potential application areas is identified, from food
19 systems to bio-based products to plastics to metals and minerals to manufactured goods. Circular
20 economy approaches are implicitly cross-sectoral, impacting the energy, industrial, AFOLU, waste and
21 other sectors. They will have climate and non-climate co-benefits and trade-offs. The scientific
22 literature mainly investigates incremental measures claiming but not demonstrating mitigation; highest
23 mitigation potential is found in the industry, energy, and transport sector; mid-range potential in the
24 waste and building sector; and lowest mitigation gains in agriculture (Cantzler et al. 2020). Circular
25 economy thinking has been identified to support increased resilience to the physical effects of climate
26 change and contribute to meeting other UN SDGs, notably SDG12 (responsible consumption and
27 production) (The Ellen MacArthur Foundation 2019).

28
29 Circular economy approaches to deployment of low-carbon infrastructure have been suggested to be
30 important to optimise resource use and mitigate environmental and societal impacts caused by
31 extraction and manufacturing of composite and critical materials as well as infrastructure
32 decommissioning (Jensen and Skelton 2018; Sica et al. 2018; Salim et al. 2019; Watari et al. 2019;
33 Jensen et al. 2020; Mignacca et al. 2020). The circular carbon economy is an approach inspired by the
34 circular economy principles that rely on a combination of technologies, including CCU, CCS and CDR,
35 to enable transition pathways especially relevant in economies dependent on fossil fuel exports (Lee et
36 al. 2017; Alshammari 2020; Morrow and Thompson 2020; Zakkour et al. 2020). The integration of
37 circular economy and bioeconomy principles (See Cross-Working Group Box 3 in this Chapter on
38 mitigation and adaption via the bioeconomy) is conceptualised in relation to policy development
39 (European Commission 2018) as well as COVID-19 recovery strategies (Palahí et al. 2020) ^{CO2}
40 emphasising the use of renewable energy sources and sustainable management of ecosystems with
41 transformation of biological resources into food, feed, energy and biomaterials.

42 At this stage, however, there is no single globally agreement of how circular economy principles are
43 best to be implemented, and differential government support for circular economy interventions is
44 observed in different jurisdictions.

45 **END BOX 12.4 HERE**

1 **12.6.1.3 Cross-sectoral considerations relating to emerging general purpose technologies**

2 General Purpose Technologies (GPTs) include, but are not limited to, additive manufacturing, artificial
3 intelligence, biotechnology, hydrogen, digitalisation, electrification, nanotechnology and robots (de
4 Coninck et al. 2018). Many of the individual sectoral chapters have identified the roles that such
5 technologies can have in supporting mitigation of GHG emissions. Section 16.2.2.3 presents an
6 overview of the individual technologies and specific applications thereof.

7 In this chapter, which focuses on cross-sectoral implications of mitigation, it is highlighted that certain
8 of these GPTs will find application across the sectors, and there will be synergies and trade-offs when
9 utilising these technologies in more than sector. One example here is the use of hydrogen as an energy
10 carrier, which when coupled with low carbon energy, has potential for driving mitigation in energy,
11 industry, transport, and buildings. The increased uptake of hydrogen across the economy requires
12 establishment of hydrogen production, transport and storage infrastructure which could simultaneously
13 support multiple sectors, although there is the potential to utilise existing infrastructure in some parts
14 of the world (Alanne and Cao 2017).

15 Box 12.5 provides for further details on hydrogen in the context of cross-sectoral mitigation specifically,
16 while further details on the role of hydrogen in individual sectors are provided in Chapters 6, 8, 9, 10
17 and 11. In contrast, the benefits of digitalisation, which could potentially give rise to substantial energy
18 savings across multiple sectors, need to be traded off against demand for electricity to operate consumer
19 devices, data centres, and data networks. Measures are required to increase energy efficiency of these
20 technologies (IEA 2017). Section 5.3.4.1 of this report provides further information on energy and
21 emissions benefits and costs of digitalisation.

22 With respect to co-impacts of GPTs, the other focus of this chapter, it is highlighted that assessment of
23 the environmental, social and economic implications of such technologies is challenging and context
24 specific with multiple potential cross-sectoral linkages (de Coninck et al. 2018). Each GPT would need
25 to be explored in context of what it is being used for, and potentially in the geographical context, in
26 order to understand the co-impacts of its use.

27 **START BOX 12.5 HERE**

28 **Box 12.5: Hydrogen in the context of cross-sectoral mitigation options**

29 The interest in hydrogen as an intermediary energy carrier has grown rapidly in the years since the 5th
30 Assessment Report of WGIII (AR5) was published. This is reflected in this WGIII assessment report,
31 where the term ‘hydrogen’ is used more than five times more often than in AR5. In Chapter 6 of this
32 report, it is shown that hydrogen can be produced with low carbon impact from fossil fuels (Section
33 6.4.2.6), renewable electricity and nuclear energy (Section 6.4.5.1), or biomass (Section 6.4.2.5). In the
34 energy sector, hydrogen is one of the options for storage of energy in low-carbon electricity systems
35 (Sections 6.4.4.1 and 6.6.2.2). But, also importantly, hydrogen can be produced to be used as a fuel for
36 sectors that are hard-to-decarbonise; this is possible directly in the form of hydrogen, but also in the
37 form of ammonia or other energy carriers (Section 6.4.5.1). In the transport sector, fuel cell engines
38 (Section 10.3.3) running on hydrogen can become important, especially for heavy duty vehicles
39 (Section 10.4.3). In the industry sector hydrogen already plays an important role in the chemical sector
40 (for ammonia and methanol production (Box 11.1 in Chapter 11) and in the fuel sector (in oil refinery
41 processes and for biofuel production (IEA 2019b). Beyond the production of ammonia and methanol
42 for both established and novel applications, the largest potential industrial application for low-carbon
43 hydrogen is seen in steelmaking (Section 11.4.1.1). Hydrogen and hydrogen-derivatives can play a
44
45

1 further role as substitute energy carriers (Section 11.3.5) and for the production of intermediate
2 chemical products such as methanol, ethanol and ethylene when combined with CCU (Section 11.3.6).
3 For the building sector, the exploration of the usefulness of hydrogen is at an early stage (Box 9.4 in
4 Chapter 9).

5
6 An overview report (IEA 2019b) already sees opportunities in 2030 for buildings, road freight and
7 passenger vehicles. This report also suggests a high potential application in iron and steel production,
8 aviation and maritime transport, and for electricity storage. Several industry roadmaps have been
9 published that map out a possible role for hydrogen until 2050. The most well-known and ambitious is
10 the roadmap by the Hydrogen Council (2017), which sketches a global scenario leading to 78 EJ
11 hydrogen use in 2050, mainly for transport, industrial feedstock, industrial energy and to a lesser extent
12 for buildings and power generation. Hydrogen makes up 18% of total final energy use in this vision.
13 An analysis by IRENA on hydrogen from renewable sources comes to a substantially lower number: 8
14 EJ (excluding hydrogen use in power production and feedstock uses). On a regional level, most
15 roadmaps and scenarios have been published for the European Union, e.g. by the Fuel Cell and
16 Hydrogen Joint Undertaking (Blanco et al. 2018; EC 2018; FCH 2019; Navigant 2019). All these
17 reports have scenario variants with hydrogen share in final energy use of 10% to over 20% by 2050.

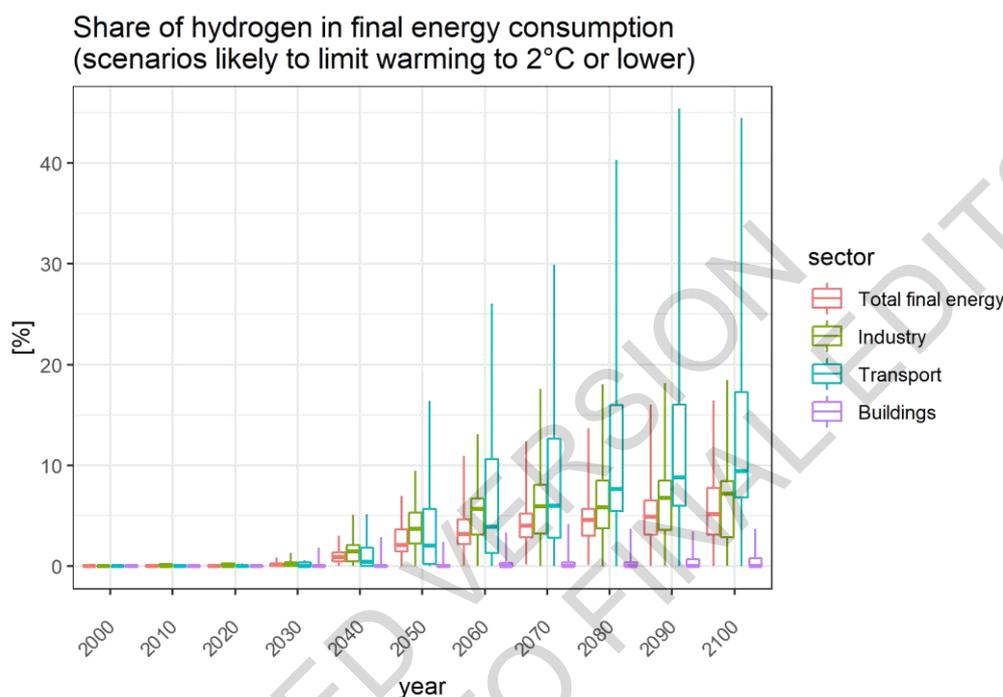

18 When it comes to the production of low-carbon hydrogen, the focus of the attention is on production
19 from electricity from renewable sources via electrolysis, so-called ‘green hydrogen’. However, ‘blue
20 hydrogen’, produced out of natural gas with CCS is also often considered. Since a significantly
21 increasing role for hydrogen would require considerable infrastructure investments and would affect
22 existing trade flows in raw materials, governments have started to set up national hydrogen strategies,
23 both potential exporting (e.g. Australia) and importing (e.g. Japan) countries (METI 2017; COAG
24 Energy Council 2019).

25
26 As already reported in Chapter 6 (Section 6.2.4.1) production costs of green hydrogen are expected to
27 come down from the current levels of above 100 USD MWh⁻¹. Price expectations are: 40–60 € MWh⁻¹
28 for both green and blue hydrogen production in the EU by 2050 (Navigant 2019) with production
29 costs already being lower in North Africa; 42–87 USD MWh⁻¹ for green hydrogen in 2030 and 20 – 41
30 USD MWh⁻¹ in 2050 (BNEF 2020); 75 € MWh⁻¹ in 2030 (Glenk and Reichelstein 2019). For fossil-
31 based technologies combined with CCS, prices may range from 33 – 80 USD MWh⁻¹ (Table 6.8 in
32 Chapter 6). Such prices can make hydrogen competitive for industrial feedstock applications, and
33 probably for several transportation modes in combination with fuel cells, but without further incentives,
34 not necessarily for stationary applications in the coming decades: wholesale natural gas prices are
35 expected to range from 7–31 USD MWh⁻¹ across regions and scenarios, according to the World Energy
36 Outlook (IEA 2020a); coal prices mostly are even lower than natural gas prices (all fossil fuel prices
37 refer to unabated technology and untaxed fuels). The evaluation of macro-economic impacts is
38 relatively rare. A study by (Mayer et al. 2019b) indicated that a shift to hydrogen in iron and steel
39 production would lead to regional GDP losses in the range of 0.4–2.7% in 2050 across EU+3 with some
40 regions making gains under a low-cost electricity scenario.

41
42 The IAM scenarios imply a modest role played by hydrogen, with some scenarios featuring higher
43 levels of penetration. The consumption of hydrogen is projected to increase by 2050 and onwards in
44 scenarios likely limiting global warming to 2°C or below, and the median share of hydrogen in total
45 final energy consumption is 2.1% in 2050 and 5.1% in 2100 (Box 12.4, Figure 1) (Numbers are based
46 on the AR6 scenarios database.) There is large variety in hydrogen shares, but the values of 10% and
47 more of final energy use that occur in many roadmaps are only rarely reached in the scenarios. Hydrogen
48 is predominantly used in the industry and transportation sectors. In the scenarios, hydrogen is produced
49 mostly by electrolysis and by biomass energy conversion with CCS (Box 12.5, Figure 1). Natural gas

1 with CCS is expected to only play a modest role; here a distinct difference between the roadmaps quoted
2 before and the IAM results is observed.

3
4 It is concluded that there is increasing confidence that hydrogen can play a significant role, especially
5 in the transport sector and the industrial sector. However, there is much less agreement on timing and
6 volumes, and there is also a range of perspectives on role of the various production methods of
7 hydrogen.

10

16 12.6.2 Sectoral policy interactions (synergies and trade-offs)

17 A taxonomy of policy types and attributes is provided by Section 13.6. In addition, the sectoral chapters
18 provide an in-depth discussion of important mitigation policy issues such as policy overlaps, policy
19 mixes, and policy interaction as well as policy design considerations and governance. The point of
20 departure for the assessment in this chapter is a focus on cross-sectoral perspectives aiming at
21 maximising policy synergies and minimising policy trade-offs.

22 Synergies and trade-offs resulting from mitigation policies are not clearly discernible from either sector-
23 level studies or global and regional top-down studies. Rather, they would require a cross-sectoral
24 integrated policy framework (von Stechow et al. 2015; Singh et al. 2019; Monier et al. 2018; Pardoe et
25 al. 2018) or multiple-objective-multiple-impact policy assessment framework identifying key co-
26 impacts and avoiding trade-offs (Ürge-Vorsatz et al. 2014) (*robust evidence, high agreement*).

1 Sectoral studies typically cover differentiated response measures while the IAM literature mostly uses
2 uniform efficient market-based measures. This has important implications for understanding the
3 differences in magnitude and distribution of mitigation costs and potentials of Section 12.2 (Rausch and
4 Karplus 2014; Karplus et al. 2013). There is a comprehensive literature on the efficiency of uniform
5 carbon pricing compared to sector-specific mitigation approaches, but relatively less literature on the
6 distributional impacts of carbon taxes and measures to mitigate potential adverse distributional impacts
7 (Åhman et al. 2017; Rausch and Reilly 2015; Mu et al. 2018; Wang et al. 2016b; Rausch and Karplus
8 2014). For example, in terms of cross-sectoral distributional implications, studies find negative
9 competitiveness impacts for the energy intensive industries (Wang et al. 2016b; Åhman et al. 2017;
10 Rausch and Karplus 2014). (*robust evidence, medium agreement*)

11 Strong inter-dependencies and cross-sectoral linkages create both opportunities for synergies and the
12 need to address trade-offs. This calls for coordinated sectoral approaches to climate change mitigation
13 policies that mainstream these interactions (Pardoe et al. 2018). Such an approach is also called for in
14 the context of cross-sectoral interactions of adaptation and mitigation measures, examples are in the
15 agriculture, biodiversity, forests, urban, and water sectors (Di Gregorio et al. 2017; Arent et al. 2014;
16 Berry et al. 2015). Integrated planning and cross-sectoral alignment of climate change policies are
17 particularly evident in developing countries' NDCs pledged under the Paris Agreement, where key
18 priority sectors such as agriculture and energy are closely aligned between the proposed mitigation and
19 adaptation actions in the context of sustainable development and the SDGs. An example is the
20 integration between smart agriculture and low carbon energy (Antwi-Agyei et al. 2018; England et al.
21 2018). Yet, there appear to be significant challenges relating to institutional capacity and resources to
22 coordinate and implement such cross-sectoral policy alignment, particularly in developing country
23 contexts (Antwi-Agyei et al. 2018) (*robust evidence, high agreement*).

24 Another dimension of climate change policy interactions in the literature is related to trade-offs and
25 synergies between climate change mitigation and other societal objectives. For example, in mitigation
26 policies related to energy, trade-offs and synergies between universal electricity access and climate
27 change mitigation would call for complementary policies such as pro-poor tariffs, fuel subsidies, and
28 broadly integrated policy packages (Dagnachew et al. 2018). In agriculture and forestry, research
29 suggests that integrated policy programs enhance mitigation potentials across the land-use-agriculture-
30 forestry nexus and lead to synergies and positive spill-overs (Galik et al. 2019). To maximise synergies
31 and deal with trade-offs in such a cross-sectoral context, evidence-based/informed and holistic policy
32 analysis approaches like nexus approaches and multi-target back-casting approaches that take into
33 account unanticipated outcomes and indirect consequences would be needed (Klausbrückner et al.
34 2016; van der Voorn et al. 2020; Hoff et al. 2019; see Box 12.6) (*robust evidence, high agreement*).

35 The consequences of large-scale land-based mitigation for food security, biodiversity, (Dasgupta 2021)
36 the state of soil, water resources, etc. can be significant depending on many factors, such as economic
37 development (including distributional aspects), international trade patterns, agronomic development,
38 diets, land use governance and policy design, and not least climate change itself (Fujimori et al. 2018;
39 Hasegawa et al. 2018; Van Meijl et al. 2018; Winchester and Reilly 2015). Policies and regulations that
40 address other aspects apart from climate change can indirectly influence the attractiveness of land-
41 based mitigation options. For example, farmers may find it attractive to shift from annual food/feed
42 crops to perennial grasses and short rotation woody crops (suitable for bioenergy) if the previous land
43 uses become increasingly restricted due to impacts on groundwater quality and eutrophication of water
44 bodies (Sections 12.4 and 12.5) (*robust evidence, medium agreement*).

1 Finally, there are knowledge gaps in the literature particularly in relation to policy scalability and in
2 relation to the extent and magnitude of policy interactions when scaling the policy to a level consistent
3 with low GHG emissions pathways such as 2°C and 1.5°C.

4 5 **START BOX 12.6 HERE**

6 7 **Box 12.6: Case Study, Sahara Forest Project in Aqaba, Jordan**

8 9 **Nexus Framing**

10 Shifting to renewable (in particular solar) energy reduces dependency on fossil fuel imports and
11 greenhouse gas emissions, which is crucial for mitigating climate change. Employing renewable energy
12 for desalination of seawater and for cooling of greenhouses in integrated production systems can
13 enhance water availability, increase crop productivity and generate co-products and co-benefits (e.g.,
14 algae, fish, dryland restoration, greening of the desert).

15 16 **Nexus Opportunities**

17 The Sahara Forest project integrated production system uses amply available natural resources, namely
18 solar energy and seawater, for improving water availability and agricultural/biomass production, while
19 simultaneously providing new employment opportunities. Using hydroponic systems and humidity in
20 the air, water needs for food production are 50% lower compared to other greenhouses.

21 22 **Technical and Economic Nexus Solutions**

23 Several major technologies are combined in the Sahara Forest Project, namely electricity production
24 through the use of solar power (PV or CSP), freshwater production through seawater desalination using
25 renewable energy, seawater-cooled greenhouses for food production, and outdoor revegetation using
26 run-off from the greenhouses.

27 28 **Stakeholders Involved**

29 The key stakeholders which benefit from such an integrated production system are from the water sector
30 which urgently requires an augmentation of irrigation (and other) water, as well as from the agricultural
31 sector, which relies on the additional desalinated water to maintain and increase agricultural production.
32 The project also involves public and private sector partners from Jordan and abroad, with little
33 engagement of civil society so far.

34 35 **Framework Conditions**

36 The Sahara Forest Project has been implemented at pilot scale so far, including the first pilot with one
37 hectare and one greenhouse pilot in Qatar and a larger “launch station” with three hectares and two
38 greenhouses in Jordan). These pilots have been funded by international organisations such as the
39 Norwegian Ministry of Climate and Environment, Norwegian Ministry of Foreign Affairs and the
40 European Union. Alignment with national policies, institutions and funding as well as upscaling of the
41 project is underway or planned.

42 43 **Monitoring and Evaluation and Next Steps**

44 The multi-sectoral planning and investments that are needed to up-scale the project require cooperation
45 among the water, agriculture, and energy sectors and an active involvement of local actors, private
46 companies, and investors. These cooperation and involvement mechanisms are currently being
47 established in Jordan. Given the emphasis on the economic value of the project, public-private
48 partnerships are considered as the appropriate business and governance model, when the project is up-
49 scaled. Scenarios for upscaling (seawater use primarily in low lying areas close to the sea, to avoid
50 energy-intensive pumping) include 50MW of CSP, 50 hectares of greenhouses, which would produce
51 34,000 tons of vegetables annually, provide employment for over 800 people, and sequester more than
52 8,000 tons of CO₂ annually.

4

5 **12.6.3 International trade spill-over effects and competitiveness**

6 International spill-overs of mitigation policies are effects that carbon-abatement measures implemented
7 in one country have on sectors in other countries. These effects include 1) carbon leakage in
8 manufacture, 2) the effects on energy trade flows and incomes related to fossil fuel exports from major
9 exporters, 3) technology and knowledge spill-overs; 4) transfer of norms and preferences via various
10 approaches to establish sustainability requirements on traded goods, e.g., EU-RED and environmental
11 labelling systems to guide consumer choices (*robust evidence, medium agreement*). This section focuses
12 on cross-sectoral aspects of international spill-overs related to the first two effects.

13 **12.6.3.1 Cross-sectoral aspects of carbon leakage**

14 Carbon leakage occurs when mitigation measures implemented in one country/sector lead to the rise in
15 emissions in other countries/sectors. Three types of spill-overs are possible: 1) domestic cross-sectoral
16 spill-overs when mitigation policy in one sector leads to the re-allocation of labour and capital towards
17 the other sectors of the same country; 2) international spill-overs within a single sector when mitigation
18 policy leads to substitution of domestic production of carbon-intensive goods with their imports from
19 abroad; 3) international cross-sectoral spill-overs when mitigation policy in one sector in one country
20 leads to the rise in emissions in other sectors in other countries. While the first two are described in
21 Section 13.6, this section focuses on the third. Though some papers address this type of leakage, there
22 is still significant lack of knowledge on this topic.

23 One possible channel of cross-sectoral international carbon leakage is through global value chains.
24 Mitigation policy in one country not only leads to shifts in competitiveness across industries producing
25 final goods but also across those producing raw materials and intermediary goods all over the world.

26 This type of leakage is especially important because the countries that provide basic materials are
27 usually emerging or developing economies, many of which have no or limited regulation of GHG
28 emissions. For this reason, foreign direct investment in developing economies usually leads to an
29 increase in emissions (Bakhsh et al. 2017; Shahbaz et al. 2015; Kiviyiro and Arminen 2014): in case of
30 basic materials the effect of expansion of economic activity on emissions exceeds the effect of
31 technological spill-overs, while for developed countries the effect is opposite (Pazienza 2019; Shahbaz
32 et al. 2015). Meng et al. (2018) calculated that environmental costs for generating one unit of GDP
33 through international trade was 1.4 times higher than that through domestic production in 1995. By
34 2009, this difference increased to 1.8 times. Carbon leakage due to the differences in environmental
35 regulation was the main driver of this increase.

36 In order to address emissions leakage through global value chains, Liu and Fan (2017) propose the
37 value-added-based emissions accounting principle, that makes possible to account for GHG emissions
38 within the context of the economic benefit principle. Davis et al. (2011) notice that the analysis of value
39 chains gives an opportunity to find the point where regulation would be the most efficient and the least
40 vulnerable to leakage. For instance, transaction costs of global climate policy and the risks of leakage
41 may be reduced if emissions are regulated at the extraction stage as there are far fewer agents involved
42 in this process than in burning of fossil fuels or consumption of energy-intensive goods. Li et al. (2020)

1 calls for coordinated efforts to reduce emissions in trade flows in pairs of the economies with the highest
2 leakage such as China and the United States, China and Germany, China and Japan, Russia and
3 Germany.

4 Unfortunately, these proposals either face difficulties in collection and verification of data on emissions
5 along value chains or require a high level of international cooperation which is hardly achievable at the
6 moment. (Neuhoff et al. 2016; Pollitt et al. 2020) focus on the regulation of emissions embodied in
7 global value chains through national policy instruments. They propose implementation of a charge on
8 consumption of imported basic materials into the European emissions trading system. Such a charge,
9 equivalent to around €80 tCO₂⁻¹, could reduce the EU's total CO₂ emissions by up to 10% by 2050
10 (Pollitt et al. 2020) without significant effects on competitiveness. This proposal is very close to border
11 carbon adjustment introduced in the EU and described in more detail in Sections 13.2 and 13.6.

12 Cross-sectoral effects of carbon leakage also occur through the multiplier effect, when the mitigation
13 policy in any sector in country A leads to the increase of relative competitiveness and therefore
14 production of the same sector in country B that automatically leads to the expansion of economic
15 activity in other sectors of country B. This expansion may in turn lead to the rise of production and
16 emissions in country A as a result of feedback effects. These spill-overs should be taken into
17 consideration while designing climate policy, along with potential synergies that may appear due to
18 joint efforts. However, the scale of these effects with regards to leakage shouldn't be overestimated.
19 Even for intrasectoral leakage, many *ex-ante* modelling studies generally suggest limited carbon
20 leakage rates (Chapter 13). Intersectoral leakage should be even less significant. Interregional spill-over
21 and feedback effects are well-studied in China (Zhang 2017; Ning et al. 2019). Even within a single
22 country, interregional spill-over effects are much lower than intraregional effects, and feedback effects
23 are even less intense. Cross-sectoral spill-overs across national borders as a result of mitigation policy
24 should be even smaller, although these are less well-studied. In future, if the differences in carbon price
25 between regions increase, leakage through cross-sectoral multipliers may play a more important role.

26 Another important cross-sectoral aspect of carbon leakage concerns the transport sector. If mitigation
27 policy leads to the substitution of domestic carbon-intensive production with imports, one of the side
28 effects of this substitution is the rise of emissions from transportation of imported goods. International
29 transport is responsible for about a third of worldwide trade-related emissions, and over 75 percent of
30 emissions for major manufacturing categories (Cristea et al. 2013). Carbon leakage would potentially
31 increase the emissions from transportation significantly as the trade of major consuming economies of
32 the EU and US would shift towards distant trading partners in East and South Asia. Meng et al. (2018)
33 consider more distant transportation as one of the major contributors to the rise in emissions embodied
34 in international trade from 1995 to 2009.

35 Emissions leakage due to international trade, investment and value chains is a significant obstacle to
36 more ambitious climate policies in many regions. However, it doesn't mean that disruption of trade
37 would reduce global emissions. Zhang et al. (2020) show that deglobalisation and the drop in
38 international trade may result in emissions reductions in the short term, but in the longer term it will
39 make each country build more complete industrial systems to satisfy their final demand, although they
40 have comparative disadvantages in some production stages. As a result, emissions would increase.
41 According to Zhang et al. (2020) for China, the decrease of the degree of global value chain participation
42 (which ranges from 0 to 1) by 0.1 would lead to an increase in gross carbon intensity of China's exports
43 of 11.7%. On distributional implications, Parrado and De Cian (2014) report that trade-driven spill-
44 overs effects transmitted through imports of materials and equipment result in significant inter-sectoral
45 distributional effects with some sectors witnessing substantial expansion in activity and emissions and
46 others witnessing a decline in activities and emissions.

1 It should also be mentioned that international trade leads to important knowledge and technology spill-
2 overs (Sections 16.3 and 16.5) and is critically important for achieving other Sustainable Development
3 Goals (Section 12.6.1). Any policies imposing additional barriers to international trade should be
4 therefore implemented with great caution and require comprehensive evaluation of various economic,
5 social and environmental effects.

6 **12.6.3.2 The spill-over effects on the energy sector**

7 Cross-sectoral trade-related spill-overs of mitigation policies include their effect on energy prices. Other
8 things being equal, regulation of emissions of industrial producers decreases the demand for fossil fuels
9 that would reduce prices and encourage the rise of fossil fuel consumption in regions with no or weaker
10 climate policies (*robust evidence, medium agreement*).

11 Arroyo-Currás et al. (2015) study the energy channel of carbon leakage with the REMIND IAM of the
12 global economy. They come to the conclusion that the leakage rate through the energy channel is less
13 than 16% of the emission reductions of regions who introduce climate policies first. This result doesn't
14 differ much for different sizes and compositions of the early mover coalition.

15 Bauer et al. (2015) built a multi-model scenario ensemble for the analysis of energy-related spill-overs
16 of mitigation policies and reveal huge uncertainty: energy-related carbon leakage rates vary from
17 negative values to 50%, primarily depending on the trends in inter-fuel substitution.

18 Another kind of spill-over in energy sector concerns the “green paradox”; announcement of future
19 climate policies causes an increase in production and trade in fossil-fuels in the short term (Jensen et al.
20 2015; Kotlikoff et al. 2016). The delayed carbon tax should therefore be higher than an immediately
21 implemented carbon tax in order to achieve the same temperature target (van der Ploeg 2016). Studies
22 also make a distinction between a “weak” and “strong” green paradox (Gerlagh 2011). The former
23 refers to a short-term rise in emissions in response to climate policy, while the latter refers to rising
24 cumulative damage.

25 The green paradox may work in different ways for different kinds of fossil fuels. For instance, Coulomb
26 and Henriot (2018) show that climate policies in the transport and power-generation sectors increase
27 the discounted profits of the owners of conventional oil and gas, compared to the no-regulation baseline,
28 but will decrease these profits for coal and unconventional oil and gas producers.

29 Many studies also distinguish different policy measures by the scale of green paradox they provide. The
30 immediate carbon tax is the first-best instrument from the perspective of the global welfare. Delayed
31 carbon tax leads to some green paradox but it is less than in the case of the support of renewables
32 (Michielsen 2014; van der Ploeg and Rezai 2019). With respect to the latter, support of renewable
33 electricity has a lower green paradox than the support of biofuels (Gronwald et al. 2017; Michielsen
34 2014). The existence of the green paradox is an additional argument in favour of more decisive climate
35 policy now: any postponements will lead to additional consumption of fossil fuels and consequently the
36 need for more ambitious and costly efforts in future.

37 The effect of fossil fuel production expansion as a result of anticipated climate policy may be
38 compensated by the effect of divestment. Delayed climate policy creates incentives for investors to
39 divest from fossil fuels. Bauer et al. (2018) show that this divestment effect is stronger and thus
40 announcing of climate policies leads to the reduction of energy-related emissions.

41 The implication of the effects of mitigation policies through the energy related spill-overs channel is of
42 particular significance to oil-exporting countries (*medium evidence, medium agreement*). Emissions

1 reduction-measures lead to the decreasing demand for fossil fuels and consequently to the decrease in
2 its exports from major oil- and gas- exporting countries. The case of Russia is one of the most
3 illustrative. Makarov et al. (2020) show that the fulfilment of Paris Agreement parties of their NDCs
4 would lead to 25% reduction of Russia's energy exports by 2030 with significant reduction of its
5 economic growth rates. At the same time, the domestic consumption of fossil fuels is anticipated to
6 increase in response to the drop of external demand that would provoke carbon leakage (Orlov and
7 Aaheim 2017). Such spill-overs demonstrate the need for the dialogue between exporters and importers
8 of fossil fuels while implementing the mitigation policies.

10 **12.6.4 Implications of finance for cross-sectoral mitigation synergies and trade-offs**

11 Finance is a principal enabler of GHG mitigation and an essential component of countries' NDC
12 packages submitted under the Paris climate agreement (UNFCCC 2016). The assessment of investment
13 requirements for mitigation along with their financing at sectoral levels are addressed in detail by
14 sectoral chapters while the assessment of financial sources, instruments, and the overall mitigation
15 financing gap is addressed by Chapter 15 (Sections 15.3, 15.4, and 15.5). The focus in this chapter with
16 respect to finance is on the scope and potential for financing integrated solutions that create synergies
17 between and among sectors.

18 Cross-sectoral considerations in mitigation finance are critical for the effectiveness of mitigation action
19 as well as for balancing the often conflicting social, developmental and environmental policy goals at
20 the sectoral level. True measures of mitigation policy impacts and hence plans for resource mobilisation
21 that properly address costs and benefits cannot be developed in isolation of their cross-
22 sectoral implications. Unaddressed cross-sectoral coordination and interdependency issues are
23 identified as major constraints in raising the necessary financial resources for mitigation in a number of
24 countries (Bazilian et al. 2011; Welsch et al. 2014; Hoff et al. 2019a).

25 Integrated financial solutions to leverage synergies between sectors, as opposed to purely sector-based
26 financing at international, national, and local levels are needed to scale up GHG mitigation
27 potentials. At the international level, Finance from Multilateral Development Banks (MDBs) is a major
28 source of GHG mitigation finance in developing countries (World Bank Group 2015; Ha et al. 2016;
29 Bhattacharya et al. 2016, 2018) (*medium evidence, medium agreement*). In 2018, MDBs reported a total
30 of USD 30,165 million in financial commitments to climate change mitigation, with 71% of total
31 mitigation finance being committed through investment loans and the rest in the form of equity,
32 guarantees, and other instruments. GHG reduction activities eligible for MDB finance are limited to
33 those compatible with low-emission pathways recognising the importance of long-term structural
34 changes, such as the shift in energy production to low-carbon energy technologies and the modal shift
35 to low-carbon modes of transport leveraging both greenfield and energy efficiency projects. Sector-
36 wise, the MDBs mitigation finance for 2018 is allocated to renewable energy (29%), transport (18%),
37 energy efficiency (18%), lower-carbon and efficient energy generation (7%), agriculture, forestry and
38 land use (8%), waste and waste-water (8%), and other sectors (12%) (MDB 2019). Unfortunately, due
39 to institutional and incentives issues MDBs finance has mostly focused on sectoral solutions and has
40 not been able to properly leverage cross-sectoral synergies. At the national level, applied research has
41 shown that integrated modelling of land, energy and water resources not only has the potential to
42 identify superior solutions, but also reveals important differences in terms of investment requirements
43 and required financing arrangements compared to the traditional sectoral financing toolkits (Welsch et
44 al. 2014). Agriculture, forestry, nature-based-solutions (NBS) and other forms of land use are promising
45 sectors for leveraging financing solutions to scale up GHG mitigation efforts (Section 15.4). Moving to

1 more productive and resilient forms of land use is a complex task given the crosscutting nature of land-
2 use that necessarily results in apparent trade-offs between mitigation, adaptation, and development
3 objectives. Finance is one area to manage these trade-offs where there may be opportunities to redirect
4 the hundreds of billions spent annually on land use around the world towards green activities, without
5 sacrificing either productivity or economic development (Falconer et al. 2015). Nonetheless, that would
6 require active public support in design of land use mitigation and adaptation strategies, coordination
7 between public and private instruments across land-use sectors, and leveraging of policy and financial
8 instruments to redirect finance toward greener land-use practices (*limited evidence, medium*
9 *agreement*). For example, the Welsch et al. (2014) study on Mauritius shows that the promotion of a
10 local biofuel industry from sugar cane could be economically favourable in the absence of water
11 constraints, leading to a reduction in petroleum imports and GHG emissions while enhancing energy
12 security. Yet, under a water-constrained scenario as a result of climate change, the need for additional
13 energy to expand irrigation to previously rain-fed sugar plantations and to power desalination plants
14 yields the opposite result in terms of GHG emissions and energy costs, making biofuels a sub-optimal
15 option, and negatively affects their economics and the prospects for financing.

16 At the local level, integrated planning and financing are needed to achieve more sustainable
17 outcomes. For example, at a city level integration is needed across sectors such as transport, energy
18 systems, buildings, sewage and solid waste to optimise emissions footprints. How a city is designed
19 will affect transportation demands, which makes it either more or less difficult to implement efficient
20 public transportation, leading in turn to more or less emissions. Under such cases, solutions in terms of
21 public and private investment paths and financing policies based on purely internal sector
22 considerations are bound to cause adverse impacts on other sectors and poor overall
23 outcomes (Gouldson et al. 2016).

24 Availability and access to finance are among the major barriers to GHG emissions mitigation across
25 various sectors and technology options (*robust evidence, high agreement*). Resource maturity
26 mismatches and risk exposure are two main factors limiting ability of commercial banks and other
27 private lenders to contribute to green finance (Mazzucato and Semieniuk 2018). At all levels,
28 mobilising the necessary resources to leverage cross-sectoral mitigation synergies would require the
29 combination of public and private financial sources (Jensen and Dowlatabadi 2018). Traditional public
30 financing would be required to synergise mitigation across sectors where the risk-return and time
31 profiles of investment are not sufficiently attractive for the business sector. Over the years, private
32 development financing through public-private partnerships (PPP) and other related variants has been a
33 growing source of finance to leverage cross-sectoral synergies and manage trade-offs (Ishiwatari et al.
34 2019; Attridge and Engen 2019; Anbumozhi and Timilsina 2018). Promoting such blended approaches
35 to finance along with result-based financing architectures to strengthen delivery institutions are
36 advocated as effective means to mainstream cross-sectoral mitigation finance (Ishiwatari et al. 2019;
37 Attridge and Engen 2019) (*limited evidence, high agreement*). The World Bank group and the
38 International Financial Corporation (IFC) have used the blended finance results-based approach to
39 climate financing that addresses institutional, infrastructure, and service needs across sectors
40 targeting developing countries and marginalised communities (GPRBA 2019; IDA 2019).

41

42 **12.7 Knowledge Gaps**

43 Finally, the literature review and analysis in Chapter 12 has taken account of the post-AR5 literature
44 available and accessible to the chapter authors. Nonetheless, the assessment of the chapter is incomplete

1 without mentioning knowledge gaps encountered during the assessment. These knowledge gaps
2 include:

3 1) Interactions (synergies and trade-offs) between different CDR methods when deployed together are
4 under-researched.

5 • Co-benefits and trade-offs with biodiversity and ecosystem services associated with the
6 implementation of CDR methods.

7 • Constraining technical costs and potentials for CDR methods to define realistically achievable
8 costs and potentials. Such research is useful for improving the representation of CDR methods
9 in IAMs and country-level mitigation pathway modelling.

10 2) More work is required on how framing and communication of mitigation actions in terms of
11 mitigation versus co-benefits potential affects public support in different contexts.

12 3) Additional research work is required to determine the cross-sectoral mitigation potential of emerging
13 General Purpose Technologies.

14 4) Lack of literature on mitigation finance frameworks promoting cross-sectoral mitigation linkages.

15 5) Additional research is needed to better quantify the net GHG emissions and co-benefits and adverse
16 effects of emerging food technologies.

17 • Research in social and behavioural sciences should invest in assessing effectiveness of
18 instrument aiming at shifting food choices in different national contexts.

19 • A better evidence basis is required to understand synergistic effects of policies in food system
20 policy packages.

21 6) Literature on regional/global mitigation potential of biomass production systems that are strategically
22 deployed in agriculture/forestry landscapes, to achieve specific co-benefits.

23 7) Knowledge on land occupation and associated co-benefits and adverse side-effects from large-scale
24 deployment of non-AFOLU mitigation options, and how such options can be integrated with agriculture
25 and forestry to maximise synergies and minimise trade-offs.

26 **Frequently Asked Questions (FAQs)**

27 **FAQ 12.1 How could new technologies to remove carbon dioxide from the atmosphere contribute** 28 **to climate change mitigation?**

29 Limiting the increase in warming to well below 2°C, and achieving net zero CO₂ or GHG emissions,
30 will require anthropogenic CO₂ removal (CDR) from the atmosphere.

31 The CDR methods studied so far have different removal potentials, costs, co-benefits and side effects.
32 Some biological methods for achieving CDR, like A/R or wetland restoration, have long been practiced.
33 If implemented well, these practices can provide a range of co-benefits, but they can also have adverse
34 side effects such as biodiversity loss or food price increases. Other chemical and geochemical
35 approaches to CDR include Direct Air Carbon Capture and Storage (DACCS), Enhanced Weathering
36 or Ocean Alkalinity Enhancement. They are generally less vulnerable to reversal than biological
37 methods.

1 DACCS uses chemicals that bind to CO₂ directly from the air; the CO₂ is then removed from the sorbent
2 and stored underground or mineralised. Enhanced Weathering involves the mining of rocks containing
3 minerals that naturally absorb CO₂ from the atmosphere over geological timescales, which are crushed
4 to increase the surface area and spread on soils (or elsewhere) where they absorb atmospheric CO₂.
5 Ocean Alkalinity Enhancement involves the extraction, processing, and dissolution of minerals and
6 addition to the ocean where they enhance sequestration of CO₂ as bicarbonate and carbonate ions in the
7 ocean.

8 **FAQ 12.2 Why is it important to assess mitigation measures from a systemic perspective, rather**
9 **than only looking at their potential to reduce Greenhouse Gas (GHG) emissions?**

10 Mitigation measures do not only reduce GHGs, but have wider impacts. They can result in decreases or
11 increases in GHG emissions in another sector or part of the value chain to where they are applied. They
12 can have wider environmental (e.g., air and water pollution, biodiversity), social (e.g., employment
13 creation, health) and economic (e.g., growth, investment) co-benefits or adverse side effects. Mitigation
14 and adaptation can also be linked. Taking these considerations into account can help to enhance the
15 benefits of mitigation action, and avoid unintended consequences, as well as provide a stronger case for
16 achieving political and societal support and raising the finances required for implementation.

17 **FAQ 12.3 Why do we need a food systems approach for assessing GHG emissions and mitigation**
18 **opportunities from food systems?**

19 Activities associated with the food system caused about one-third of total anthropogenic GHG
20 emissions in 2015, distributed across all sectors. Agriculture and fisheries produce crops and animal-
21 source food, which are partly processed in the food industry, packed, distributed, retailed, cooked, and
22 finally eaten. Each step is associated with resource use, waste generation, and GHG emissions.

23 A food systems approach helps identify critical areas as well as novel and alternative approaches to
24 mitigation on both supply side and demand side of the food system. But complex co-impacts need to be
25 considered and mitigation measures tailored to the specific context. International cooperation and
26 governance of global food trade can support both mitigation and adaptation.

27 There is large scope for emissions reduction in both cropland and grazing production, and also in food
28 processing, storage and distribution. Emerging options such as plant-based alternatives to animal food
29 products and food from cellular agriculture are receiving increasing attention, but their mitigation
30 potential is still uncertain and depends on the GHG intensity of associated energy systems due to
31 relatively high energy needs. Diet changes can reduce GHG emissions and also improve health in
32 groups with excess consumption of calories and animal food products, which is mainly prevalent in
33 developed countries. Reductions in food loss and waste can help reduce GHG emissions further.

34 Recommendations of buying local food and avoiding packaging can contribute to reducing GHG
35 emissions but should not be generalised as trade-offs exist with food waste, GHG footprint at farm gate,
36 and accessibility to diverse healthy diets.

1 Executive Summary

2 **Long-term deep emission reductions, including the reduction of emissions to net zero, is best achieved**
3 **through institutions and governance that nurture new mitigation policies, while at the same time**
4 **reconsidering existing policies that support continued Greenhouse Gas (GHG) emissions** (*robust*
5 *evidence, high agreement*). To do so effectively, the scope of climate governance should include both direct
6 efforts to target GHG emissions and indirect opportunities to tackle GHG emissions that result from efforts
7 directed towards other policy objectives). {13.2, 13.5, 13.6, 13.7, 13.9}

8 **Institutions and governance underpin mitigation by providing the legal basis for action. This includes**
9 **setting up implementing organisations and the frameworks through which diverse actors interact**
10 (*medium evidence, high agreement*). Institutions can create mitigation and sectoral policy instruments; policy
11 packages for low-carbon system transition; and economy wide measures for systemic restructuring. {13.2,
12 13.7, 13.9}

13 **Policies have had a discernible impact on mitigation for specific countries, sectors, and technologies**
14 (*robust evidence, high agreement*), **avoiding emissions of several GtCO₂-eq yr⁻¹** (*medium evidence,*
15 *medium agreement*). Both market-based and regulatory policies have distinct, but complementary roles. The
16 share of global GHG emissions subject to mitigation policy has increased rapidly in recent years, but big
17 gaps remain in policy coverage, and the stringency of many policies falls short of what is needed to achieve
18 strong mitigation outcomes (*robust evidence, high agreement*). {13.6, Cross-chapter box 10 in Chapter 14}

19 **Climate laws enable mitigation action by signalling the direction of travel, setting targets,**
20 **mainstreaming mitigation into sector policies, enhancing regulatory certainty, creating law-backed**
21 **agencies, creating focal points for social mobilization, and attracting international finance** (*medium*
22 *evidence, high agreement*). By 2020, ‘direct’ climate laws primarily focused on GHG reductions were
23 present in 56 countries covering 53% of global emissions, while more than 690 laws, including ‘indirect’
24 laws, may also have an effect on mitigation. Among direct laws, ‘framework’ laws set an overarching legal
25 basis for mitigation either by pursuing a target and implementation approach, or by seeking to mainstream
26 climate objectives through sectoral plans and integrative institutions. {13.2}

27 **Institutions can enable improved governance by coordinating across sectors, scales and actors,**
28 **building consensus for action, and setting strategies** (*medium evidence, high agreement*). Institutions are
29 more stable and effective when they are congruous with national context, leading to mitigation-focused
30 institutions in some countries and the pursuit of multiple objectives in others. Sub-national institutions play
31 a complementary role to national institutions by developing locally-relevant visions and plans, addressing
32 policy gaps or limits in national institutions, building local administrative structures and convening actors
33 for place-based decarbonisation. {13.2}

34 **Sub-national actors are important for mitigation because municipalities and regional governments**
35 **have jurisdiction over climate-relevant sectors such as land-use, waste and urban policy; are able to**
36 **experiment with climate solutions; and can forge partnerships with the private sector and**
37 **internationally to leverage enhanced climate action** (*robust evidence, high agreement*). More than 10,500
38 cities and nearly 250 regions representing more than 2 billion people have pledged largely voluntary action
39 to reduce emissions. Indirect gains include innovation, establishing norms and developing capacity.
40 However, sub-national actors often lack national support, funding, and capacity to mobilize finance and
41 human resources, and create new institutional competences. {13.5}

42 **Climate governance is constrained and enabled by domestic structural factors, but it is still possible**
43 **for actors to make substantial changes** (*medium evidence, high agreement*). Key structural factors are
44 domestic material endowments (such as fossil fuels and land-based resources); domestic political systems;
45 and prevalent ideas, values and belief systems. Developing countries face additional material constraints in
46 climate governance due to development challenges and scarce economic or natural resources. A broad group

1 of actors influence how climate governance develop over time, including a range of civic organizations,
2 encompassing both pro-and anti-climate action groups. {13.3, 13.4}

3 **Mitigation strategies, instruments and policies that fit with dominant ideas, values and belief systems**
4 **within a country or within a sector are more easily adopted and implemented** (*medium evidence,*
5 *medium agreement*). Ideas, values and beliefs may change over time. Policies that bring perceived direct
6 benefits, such as subsidies, usually receive greater support. The awareness of co-benefits for the public
7 increases support of climate policies (*robust evidence, high agreement*). {13.2, 13.3, 13.4}

8 **Climate litigation is growing and can affect the outcome and ambition of climate governance** (*medium*
9 *evidence, high agreement*). Since 2015, at least 37 systemic cases have been initiated against states that
10 challenge the overall effort of a state to mitigate or adapt to climate change. If successful, such cases can
11 lead to an increase in a country's overall ambition to tackle climate change. Climate litigation has also
12 successfully challenged governments' authorizations of high-emitting projects setting precedents in favour
13 of climate action. Climate litigation against private sector and financial institutions is also on the rise. {13.4}

14 **The media shapes the public discourse about climate mitigation. This can usefully build public support**
15 **to accelerate mitigation action, but may also be used to impede decarbonisation** (*medium evidence, high*
16 *agreement*). Global media coverage (across a study of 59 countries) has been growing, from about 47,000
17 stories in 2016-17 to about 87,000 in 2020-21. Generally the media representation of climate science has
18 increased and become more accurate over time. On occasion, the propagation of scientifically misleading
19 information by organized counter-movements has fuelled polarization, with negative implications for climate
20 policy. {13.4}

21 **Explicit attention to equity and justice is salient to both social acceptance and fair and effective**
22 **policymaking for mitigation** (*robust evidence, high agreement*). Distributional implications of alternative
23 climate policy choices can be usefully evaluated at city, local and national scales as an input to policymaking.
24 Institutions and governance frameworks that enable consideration of justice and just transitions are likely to
25 build broader support for climate policymaking. {13.2, 13.6, 13.8, 13.9}

26 **Carbon pricing is effective in promoting implementation of low-cost emissions reductions** (*robust*
27 *evidence, high agreement*). While the coverage of emissions trading and carbon taxes has risen to over 20
28 percent of global CO₂ emissions, both coverage and price are lower than is needed for deep reductions. The
29 design of market mechanisms should be effective as well as efficient, balance distributional goals and find
30 social acceptance. Practical experience has driven progress in market mechanism design, especially of
31 emissions trading schemes (*robust evidence, high agreement*). Carbon pricing is limited in its effect on
32 adoption of higher-cost mitigation options, and where decisions are often not sensitive to price incentives
33 such as in energy efficiency, urban planning, and infrastructure (*robust evidence, medium agreement*).
34 Subsidies have been used to improve energy efficiency, encourage the uptake of renewable energy and other
35 sector-specific emissions saving options (*robust evidence, high agreement*) {13.6}

36 **Regulatory instruments play an important role in achieving specific mitigation outcomes in sectoral**
37 **applications** (*robust evidence, high agreement*). Regulation is effective in particular applications and often
38 enjoys greater political support, but tends to be more economically costly, than pricing instruments (*robust*
39 *evidence, medium agreement*). Flexible forms of regulation (e.g., performance standards) have achieved
40 aggregate goals for renewable energy generation, vehicle efficiency and fuel standards, and energy efficiency
41 in buildings and industry (*robust evidence, high agreement*). Infrastructure investment decisions are
42 significant for mitigation because they lock in high- or low- emissions trajectories over long periods.
43 Information and voluntary programs can contribute to overall mitigation outcomes (*medium evidence, high*
44 *agreement*). Designing for overlap and interactions among mitigation policies enhances their effectiveness
45 (*robust evidence, high agreement*). {13.6}

46 **Removing fossil fuel subsidies could reduce emissions by 1-10% by 2030 while improving public**
47 **revenue and macroeconomic performance** (*robust evidence, medium agreement*). {13.6}

1 **National mitigation policies interact internationally with effects that both support and hinder**
2 **mitigation action** (*medium evidence, high agreement*). Reductions in demand for fossil fuels tend to
3 negatively affect fossil fuel exporting countries (*medium evidence, high agreement*). Creation of markets for
4 emission reduction credits tends to benefit countries able to supply credits. Policies to support technology
5 development and diffusion tend to have positive spillover effects (*medium evidence, high agreement*). There
6 is no consistent evidence of significant emissions leakage or competitiveness effects between countries,
7 including for emissions-intensive trade-exposed industries covered by emission trading systems (*medium*
8 *evidence, medium agreement*). {13.6}

9 **Policy packages are better able to support socio-technical transitions and shifts in development**
10 **pathways toward low carbon futures than are individual policies** (*robust evidence, high agreement*). For
11 best effect, they need to be harnessed to a clear vision for change and designed with attention to local
12 governance context. Comprehensiveness in coverage, coherence to ensure complementarity, and consistency
13 of policies with the overarching vision and its objectives are important design criteria. Integration across
14 objectives occurs when a policy package is informed by a clear problem framing and identification of the
15 full range relevant policy sub-systems. {13.7}

16 **The co-benefits and trade-offs of integrating adaptation and mitigation are most usefully identified**
17 **and assessed prior to policy making rather than being accidentally discovered** (*robust evidence, high*
18 *agreement*). This requires strengthening relevant national institutions to reduce silos and overlaps, increasing
19 knowledge exchange at the country and regional levels, and supporting engagement with bilateral and
20 multilateral funding partners. Local governments are well placed to develop policies that generate social and
21 environmental co-benefits but to do so require legal backing and adequate capacity and resources. {13.8}

22 **Climate change mitigation is accelerated when attention is given to integrated policy and economy**
23 **wide approaches, and when enabling conditions (governance, institutions, behaviour, innovation,**
24 **policy, and finance), are present** (*robust evidence, medium agreement*). Accelerating climate mitigation
25 includes simultaneously weakening high carbon systems and encouraging low carbon systems; ensuring
26 interaction between adjacent systems (e.g. energy and agriculture); overcoming resistance to policies (e.g.,
27 from incumbents in high carbon emitting industries), including by providing transitional support to the
28 vulnerable and negatively affected by distributional impacts; inducing changes in consumer practices and
29 routines; providing transition support; and addressing coordination challenges in policy and governance.
30 {13.7, 13.9}

31 **Economy wide packages, including economic stimulus packages, can contribute to shifting sustainable**
32 **development pathways and achieving net zero outcomes whilst meeting short term economic goals**
33 (*medium evidence, high agreement*). The 2008-9 Global Recession showed that policies for sustained
34 economic recovery go beyond short-term fiscal stimulus to include long-term commitments of public
35 spending on the low carbon economy; pricing reform; addressing affordability; and minimising distributional
36 impacts. COVID-19 spurred stimulus packages and multi-objective recovery policies that may have the
37 potential to meet short-term economic goals while enabling longer-term sustainability goals. {13.9}

38

1 **13.1 Introduction**

2 This chapter assesses national and sub-national policies and institutions. Given the scale and scope of the
3 climate challenge, an immediate challenge for this assessment is defining its scope. Because a very wide
4 range of institutions and policies at multiple scales carry implications for climate change, the approach
5 followed here is to embrace a broad approach. Consequently, institutions and policies discussed include
6 dedicated climate laws and organisations (Section 13.2) and direct mitigation policies such as carbon taxes
7 (Section 13.6), but also those, such as sectoral ministries and their policies (Sections 13.6 and 13.7) and sub-
8 national entities such as regional bodies, cities, and their policies (Section 13.5), the implications of which
9 are salient to mitigation outcomes. This approach recognises that there are important linkages with
10 international climate governance (Chapter 14), notably the role of internationally mandated Nationally
11 Determined Contributions' in stimulating domestic policy development (Section 13.2), transnational
12 networks in spurring sub-national action (Section 13.5), and international effects of domestic policies
13 (Section 13.6).

14 This encompassing approach to climate governance is also built on a recognition that climate policymaking
15 is routinely formulated in the context of multiple policy objectives such as energy security, energy access,
16 urban development, and mitigation-adaptation linkages. This informs policymaking based on an
17 understanding that to fully maximise direct and indirect climate mitigation potential, maximising co-benefits
18 and minimising trade-offs should be explicitly sought rather than accidentally discovered and policies
19 designed accordingly. This understanding also informs the design of institutions (Section 13.2) and policies
20 (Sections 13.6 and 13.7) as well as the linkage between mitigation and adaptation (Section 13.8).

21 The chapter also engages with several new developments and an expansion of the literature since AR5.

22 A growing literature assesses how national policymaking on climate mitigation is dependent on national
23 politics around, and building consensus on, climate action. This, in turn, is shaped by both nationally specific
24 structural features (Section 13.3) and the role of different actors in the policy making process (Section 13.4).
25 Important new avenues through which climate policy making is shaped, such as climate litigation (Section
26 13.4.2), and channels for public opinion formation, such as the media (Section 13.4.3) are also assessed. The
27 chapter weaves discussions of the role of justice, understood through a discussion of procedural justice
28 (Section 13.2), distributional justice (Section 13.6) and vulnerability (Section 13.8), and its role in creating
29 public support for climate action (Section 13.9).

30 A significant new theme is the focus on the dynamic elements of policymaking, that is, how policy can be
31 designed to accelerate mitigation. This includes through technological transitions, socio-technical transitions,
32 shifts in development pathways and economy wide measures. This literature emphasizes the importance of
33 examining not just individual policies, but packages of policies (Section 13.7) and how these are enabled by
34 the alignment of policy, institutions, finance, behaviour and innovation. (Section 13.9). Also new is attention
35 to the opportunities for economy-wide system change presented by consideration of post-COVID recovery
36 packages, and wider efforts at sustainable economic restructuring (Section 13.9). Consistent with the
37 discussion in Chapter 4, these larger approaches offer opportunities to undertake systemic restructuring and
38 shift development pathways.

39 Finally, the chapter addresses core themes from earlier assessment reports, but seeks to do so in an enhanced
40 manner. The discussion of climate institutions assesses a growing literature on climate law, as well as both
41 purpose-built climate organisations and the layering of climate responsibilities on existing organisations at
42 national and sub-national scales (Section 13.2). The discussion of policies focuses on an ex post assessment
43 of policies, as well as the interaction among them, and learnings on how they can be combined in packages
44 (Sections 13.6 and 13.7). It also lays out a framework for their assessment that encompasses environmental
45 effectiveness, economic effectiveness, distributional outcomes, co-benefits, institutional requirements, as
46 well as a new criterion of transformational potential (Section 13.6).

1 The aim of this chapter is to assess the full range of the multi-stranded and diverse literature on climate
2 institutions and policy, reflecting the richness of real-world climate governance.

3

4 **13.2 National and sub-national institutions and governance**

5 Institutions and governance arrangements can help address ‘policy gaps’ and ‘implementation gaps’ (Cross-
6 Chapter Box 4 in Chapter 4) that hinder climate mitigation. While the need for institutions and governance
7 is universal, individual country approaches vary, based on national approaches and circumstances, as
8 discussed in this section.

9 Since AR5, the understanding of climate governance has become more encompassing and complex,
10 involving multiple actors, decision-making arenas, levels of decision-making and a variety of political goals.
11 Climate governance sometime directly targets GHG emissions; at other times mitigation results from
12 measures that primarily aim to solve other issues, for instance relating to food production, forest
13 management, energy markets, air pollution, transport systems or technology development, but with
14 mitigation or adaptation effects (Karlsson et al. 2020).

15 Consistent with usage in this assessment, institutions are rules, norms and conventions that guide, constrain
16 or enable behaviours and practices, including the organisations through which they operate, while
17 governance is the structure, processes and actions that public and private actors use to address societal goals
18 (See Glossary for complete definitions). Multiple terms are used in the literature to discuss climate
19 governance, often varying across countries. Climate laws, or legislation, is passed by legislatures, and often
20 sets the overarching governance context, but the term is also used to refer to legislation that is salient to
21 climate outcomes even if not centrally focused on climate change. National strategies, often referred to as
22 plans, most often operate through executive action by government, set guidance for action and often are not
23 legally binding, although strategies may also be enshrined in law. Both laws and strategies may elaborate
24 targets, or goals, for emissions outcomes, although these are not necessary components of laws and strategies.
25 While laws typically operate at the national level (states may also make laws in federal nations), strategies,
26 plans and targets may also operate at the sub-national level.

27 This section begins with a discussion of national laws for climate action (Section 13.2.1), followed by a
28 discussion of national strategies (Section 13.2.2). The third section examines institutions (Section 13.2.3),
29 including organisations that are established to govern climate actions, and the final section explores sub-
30 national institutions and their challenges in influencing climate mitigation (Section 13.2.4).

31

32 **13.2.1 Climate laws**

33 National laws that govern climate action often set the legal basis for climate action (Averchenkova et al.
34 2021). This legal basis can serve several functions: establish a platform for transparent target setting and
35 implementation (Bennett 2018); provide a signal to actors by indicating intent to harness state authority
36 behind climate action (Scotford and Minas 2019); promise enhanced regulatory certainty (Scotford et al.
37 2017); create law-backed agencies for coordination, compliance and accountability (Scotford and Minas
38 2019); provide a basis for mainstreaming mitigation into sector action, and create focal points for social
39 mobilisation (Dubash et al. 2013) (*medium evidence, high agreement*). For lower/middle income countries,
40 in particular, the existence of a law may also attract international finance by serving as a signal of credibility
41 (Fisher et al. 2017). The realisation of these potential governance gains depends on local context, legal
42 design, successful implementation, and complementary action at different scales.

43 There are both narrow and broad definitions of what counts as ‘climate laws’. The literature distinguishes
44 direct climate laws that explicitly considers climate change causes or impacts -- for example through mention
45 of greenhouse gas reductions in its objectives or title (Dubash et al. 2013) -- from indirect laws that have ‘the

1 capacity to affect mitigation or adaptation’ through the subjects they regulate, for example, through
2 promotion of co-benefits, or creation of reporting protocols (Scotford and Minas 2019). Closely related is a
3 ‘sectoral approach’ based on the layering of climate considerations into existing laws in the absence of an
4 overarching framework law (Rumble 2019). Many countries also adopt executive climate strategies
5 (discussed in Section 13.2), which may either coexist with or substitute for climate laws, and that may also
6 be related to a country’s NDC process under the Paris Agreement.

7 The prevalence of both direct and indirect climate laws has increased considerably since 2007, although
8 definitional differences across studies complicate a clear assessment of their relative importance (Nachmany
9 and Setzer 2018; Iacobuta et al. 2018) (*medium evidence, high agreement*). Direct climate laws – with
10 greenhouse gas limitation as a direct objective -- had been passed in 56 countries (of 194 studied) covering
11 53% of emissions in 2020, with most of that rise happening between 2010 and 2015 (see Figure 13.1). Both
12 direct and indirect laws - those that have an effect on mitigation even if this is not the primary outcome – is
13 most closely captured by the “Climate Change Laws of the World” database, which illustrates the same trend
14 of growing prevalence, documenting 694 mitigation-related laws by 2020 versus 558 in 2015 and 342 in
15 2010 (Nachmany and Setzer 2018; LSE Grantham Research Institute on Climate Change and the
16 Environment 2021).¹ Among these, the majority are accounted for by sectoral indirect laws. For example, a
17 study of Commonwealth countries finds that a majority of these countries have not taken the route of a single
18 overarching law, but rather have an array of laws across different areas, for example, Indian laws on energy
19 efficiency and Ghana’s laws on renewable energy promotion (Scotford et al. 2017).

20 Some direct climate laws may serve as ‘framework’ laws (Averchenkova et al. 2017; Rumble 2019) that set
21 an overarching legal context within which other legislation and policies operate. Framework laws are
22 intended to provide a coherent legal basis for action, to integrate past legislation in related areas, set clear
23 directions for future policy, and create necessary processes and institutions (Townshend et al. 2013;
24 Fankhauser et al. 2018; Averchenkova et al. 2017; Rumble 2019; Averchenkova et al. 2021) (*medium
25 evidence, medium agreement*). There are a variety of approaches to framework laws. Reviews of climate
26 legislation, many of which draw particularly from the long-standing UK Climate Change Act, suggest the
27 need for statutory targets with a long-term direction, shorter term instruments such as carbon budgets to
28 induce action toward targets, a clear assignment of duties and responsibilities including identification of
29 policies and responsibility for their implementation, annual reporting to Parliament; an independent body to
30 support evidence-based decision making and rules to govern information collection and provision (Barton
31 and Campion 2018; Fankhauser et al. 2018; Averchenkova et al. 2021; Abraham-Dukuma et al. 2020).

32 However, country examples also suggest other, different approaches to framework laws. Korea’s Framework
33 Act on Low Carbon, Green Growth seeks to shift business and society toward green growth through a process
34 of strategy setting and action plans (Jang et al. 2010). Kenya’s framework Climate Change Act creates an
35 institutional structure to mainstream climate considerations into sectoral decisions, one of several examples
36 across Africa of efforts to create framework legislation to promote mainstreaming (Rumble 2019). Mexico’s
37 General Law on Climate Change includes sectoral emission targets, along with the creation of coordinating
38 institutions across ministries and sub-national authorities (Averchenkova and Guzman Luna 2018).
39 Consequently, different countries have placed emphasis on different aspects of framework laws, although
40 the most widely prevalent approach is that exemplified by the UK.

41 Climate laws spread through multiple mechanisms, including the impetus provided by international
42 negotiation events, diffusion by example across countries, and domestic factors such as business cycles
43 (*medium evidence, medium agreement*). Major landmark events under the UNFCCC have been associated
44 with increases in national legislation (Iacobuta et al. 2018), with a stronger effect in countries where
45 international commitments are binding (Fankhauser et al. 2016). Diffusion through example of legislation

FOOTNOTE ¹ Data from climate-laws.org, search for mitigation focused legislation for different time frames. Accessed Oct 31, 2021.

1 from other countries has been documented (Fleig et al. 2017; Torney 2017; Inderberg 2019; Torney 2019;
2 Fankhauser et al. 2016). For example, the UK Climate Change Act was an important influence in pursuing
3 similar acts in Finland and Ireland (Torney 2019) and was also considered in the formulation of Mexico's
4 General Law on Climate Change (Averchenkova and Guzman Luna 2018). The presence of a framework
5 law is positively associated with creation of additional supportive legislation (Fankhauser et al. 2015).
6 Domestic contextual factors can also affect the likelihood of legislation such as a weak business cycle that
7 can impact the political willingness to pass legislation (Fankhauser et al. 2015). In some cases, civil society
8 groups play a role as advocates for legislation, as occurred in the UK (Lockwood 2013; Lorenzoni and
9 Benson 2014; Carter and Childs 2018; Devaney et al. 2020) and in Germany in the build up to passage of
10 their respective Climate Change Act (Flachsland and Levi 2021).

11 The performance of framework laws suggests a mixed picture. While the structure of the UK Act successfully
12 sets a direction of travel and has resulted in a credible independent body, it performs less well in fostering
13 integration across sectoral areas and providing an enforcement mechanism (Averchenkova et al. 2021). A
14 review of seven European climate change acts concludes that overall targets may not be entirely aligned with
15 planning, reporting and evaluation mechanisms, and that sanction mechanisms are lacking across the board
16 (Nash and Steurer 2019), which limit the scope for legislation to perform its integrative task. These
17 observations suggest the need for careful attention to the design of framework laws.

18 There is extremely limited evidence on the aggregate effects of climate laws on climate outcomes, although
19 there is a broader literature assessing climate policies (see Section 13.6 in this Chapter and Cross-Chapter
20 Box 10 in Chapter 14). A single assessment of direct and indirect climate laws as well as relevant executive
21 action across a global database finds a measurable and positive effect: global annual emissions have reduced
22 by about 5.9GtCO₂ compared to an estimation of what they otherwise would have been (Eskander and
23 Fankhauser 2020). Climate laws require further research, including on the quantification of impact,
24 framework versus sectoral approaches, and the various mechanisms through which laws act - target setting,
25 creating institutional structures, mainstreaming and ensuring compliance.

26
27
28

National climate change mitigation legislation

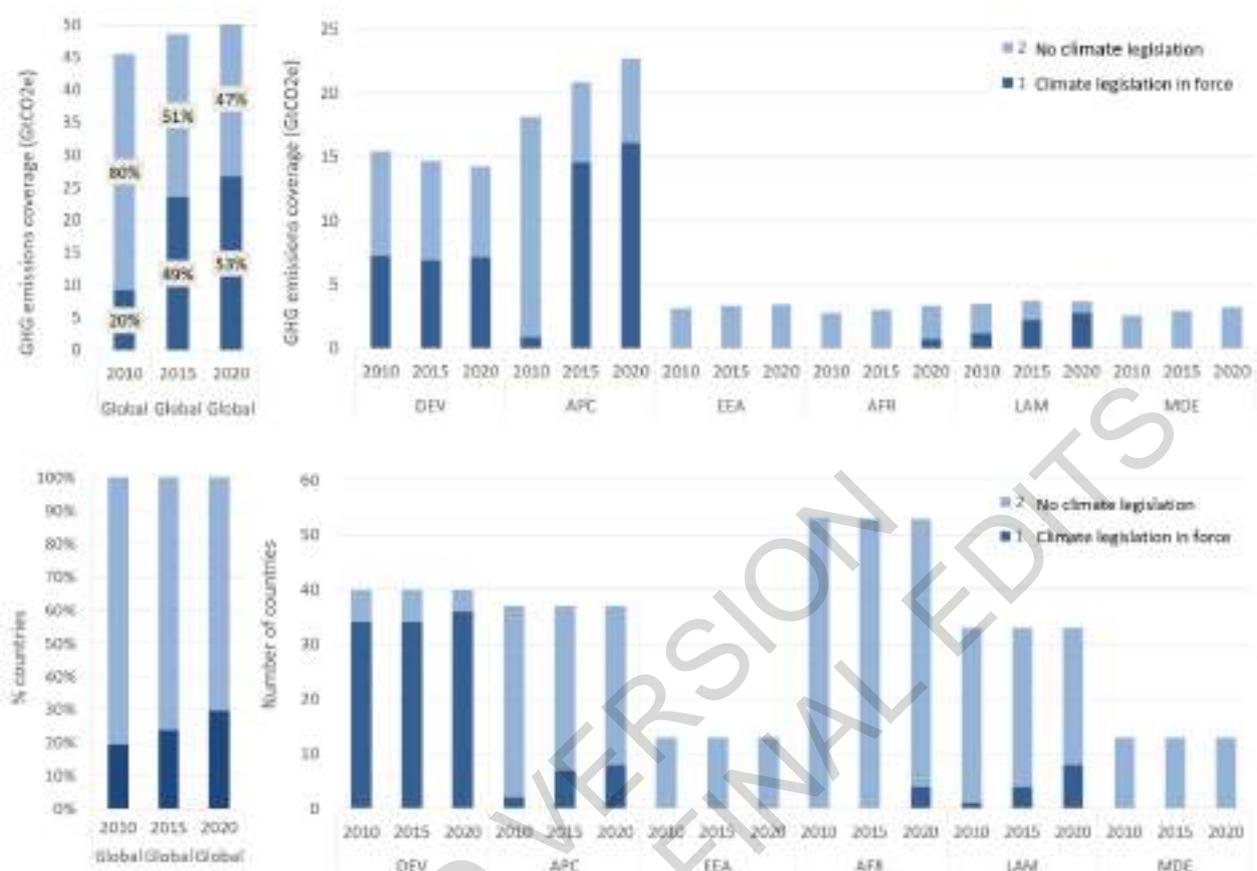

Figure 13.1 Prevalence of legislation by emissions and number of countries across regions

Top: Shares of global GHG emissions under national climate change legislations – in 2010, 2015 and 2020. Emissions data used are for 2019, since emissions shares across regions deviated from past patterns in 2020 due to COVID.

Bottom: Number of countries with national climate legislation - in 2010, 2015, and 2020

Climate legislation is defined as an act passed by a parliament that includes in its title or objectives reductions in GHGs.

AR6 regions: DEV = Developed countries; APC = Asia and developing Pacific; EEA = Eastern Europe and West-Central Asia; AFR = Africa; LAM = Latin America and the Caribbean; MDE = Middle East.

Source: Updated and adapted from (Iacobuta et al. 2018) to reflect AR6 regional aggregation and recent data.

13.2.2 National strategies and Nationally Determined Contributions

National climate strategies, which are often formulated through executive action, contribute to climate governance in several ways. Strategies enable discussion of low-emissions pathways while accounting for uncertainty, national circumstances and socio-economic objectives (Falduto and Rocha 2020).

They frequently set out long term emission goals and possible trajectories over time, with analysis of technological and economic factors (Levin et al. 2018; WRI 2020). This can include quantitative modelling of low-emissions transitions and their economic effects to inform policymakers and stakeholders of potential outcomes (Waisman et al. 2019; Weitzel et al. 2019). Scenario analysis can be used to explore how to make strategies more robust in the face of uncertainty (Sato and Altamirano 2019). Strategies and their regular

1 revision can support long-term structural change by stimulating deliberation and learning (Voß et al. 2009),
2 and to make the link between mitigation and adaptation objectives and actions (Watkiss and Klein 2019;
3 Hans et al. 2020). As part of the Paris Agreement process, several countries have prepared and submitted
4 long-term low-emissions development strategies (Levin et al. 2018), while others have different forms of
5 national climate change strategies independently of the UNFCCC process. Strategies set over time by the
6 European Union are discussed in Box 13.1.

7 Nationally Determined Contributions (NDCs) prepared under the Paris Agreement may be informed by
8 national strategies (Rocha and Falduto 2019). But the process of preparing NDCs can itself raise political
9 awareness, encourage institutional innovation and coordination, and engage stakeholders (Röser et al. 2020).
10 Nationally determined contributions (NDCs) illustrate a diversity of approaches: direct mitigation targets,
11 strategies, plans and actions for low GHG emission development, or the pursuit of mitigation co-benefits
12 resulting from economic diversification plans and/or adaptation actions (UNFCCC Secretariat 2021). Figure
13 13.2 shows that the prevalence of emission targets increased across all regions between 2010 and 2020, the
14 period during which the Paris Agreement was reached.

15 The NDCs vary in their scope, content and time frame, reflecting different national circumstances, and are
16 widely heterogeneous in both stringency and coverage of mitigation efforts (Pauw et al. 2018; Campagnolo
17 and Davide 2019; Pauw et al. 2019; UNFCCC Secretariat 2016, 2021). The mitigation targets in the new or
18 updated NDCs range from economy-wide absolute emission reduction targets to strategies, plans and actions
19 for low-emission development, with specific timeframes or implementation periods specified. Less than 10%
20 of parties' NDCs specify when their emissions are expected to peak and some of these parties express their
21 target as a carbon budget (UNFCCC Secretariat 2021). Many long term strategies submitted by Parties to the
22 UNFCCC refer to net zero emissions or climate neutrality, carbon neutrality, or GHG neutrality with
23 reference to 2050, 2060 or mid-century targets (UNFCCC Secretariat 2021). The growing prevalence and
24 coverage of emission targets is documented in Figure 13.2.

25
26
27
28

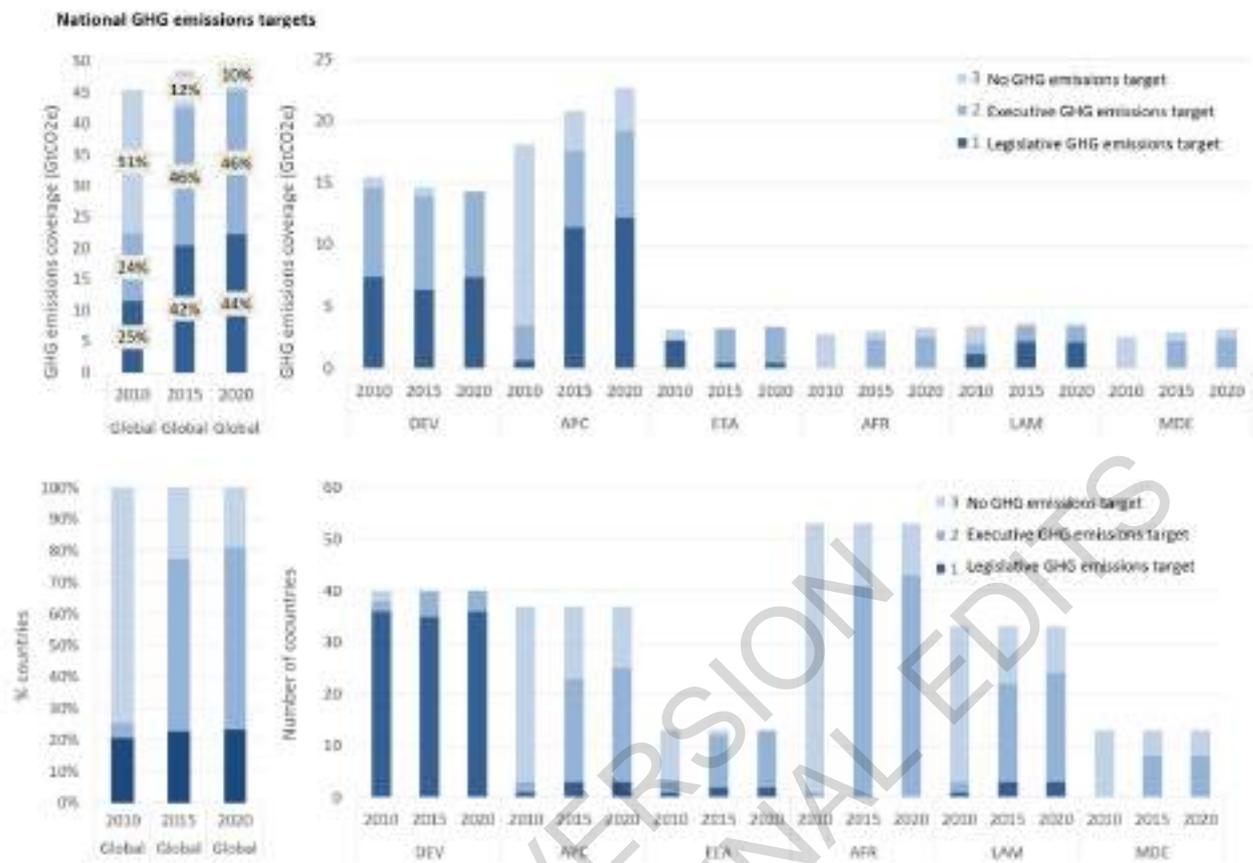

Figure 13.2 Prevalence of targets by emissions and number of countries across region

Top: Shares of global GHG emissions under national climate emission targets – in 2010, 2015 and 2020. Emissions data used are for 2019, since emissions shares across regions deviated from past patterns in 2020 due to COVID.

Bottom: Number of countries with national climate emission targets - in 2010, 2015, and 2020

Emissions reductions targets were taken into account as a legislative target when they were defined in a law or as part of a country's submission under the Kyoto Protocol, or as an executive target when they were included in a national policy or official submissions under the UNFCCC. Targets were included if they were economy wide or included at least the energy sector. The proportion of national emissions covered are scaled to reflect coverage and whether targets are in GHG or CO₂ terms.

AR6 regions: DEV = Developed countries; APC = Asia and developing Pacific; EEA = Eastern Europe and West-Central Asia; AFR = Africa; LAM = Latin America and the Caribbean; MDE = Middle East.

Source: Updated and adapted from (Iacobuta et al. 2018) to reflect AR6 regional aggregation and recent data.

Almost all Parties outlined domestic mitigation measures as key instruments for achieving mitigation targets in specific priority areas such as energy supply (89%), transport (80%), buildings (72%), industry (39%), agriculture (67%), LULUCF (75%) and waste (68%). Renewable energy generation was the most frequently indicated mitigation option (84%), followed by improving energy efficiency of buildings (63%) and multisector energy efficiency improvement (48%); afforestation, reforestation and revegetation (48%); and improving energy efficiency of transport (45%) (UNFCCC Secretariat 2021). Parties often communicated mitigation options related to the circular economy, including reducing waste (29%) and recycling waste (30%) and promoting circular economy (25%). Many Parties highlighted policy coherence and synergies between their mitigation measures and development priorities, which included long-term low-emission

1 development strategy(ies) (LT-LEDS), the sustainable development goals (SDGs) and, for some, green
2 recovery from the COVID-19 pandemic.

3 Some countries approach NDCs as an opportunity to integrate mitigation objectives and broader economic
4 shifts or sectoral transformations (*medium evidence, medium agreement*). For example, Brazil's 2016 NDC
5 focussed on emissions from land use change, including agricultural intensification, to align mitigation with
6 a national development strategy of halting deforestation in the Amazon, and increasing livestock production
7 (De Oliveira Silva et al. 2018). While the forest sector accounts for the bulk of Madagascar's mitigation
8 potential, its NDC promotes GHG mitigation in both AFOLU and energy sectors to maximize co-benefits,
9 and achieve a higher number of sustainable development goals (SDGs) (Nogueira et al. 2020).

10

11 **START BOX 13.1 HERE**

12

Box 13.1 EU climate policy portfolio and the European Green Deal

13 The European Union (EU)² has developed an encompassing climate governance framework (Kulovesi and
14 Oberthür 2020), having ratified the Kyoto Protocol in 2002. In 2003 the EU adopted an Emissions Trading
15 System for sectors with large GHG emitters, which started in 2005. From 2007 to 2009, the EU revised its
16 climate policies, including for vehicle emissions, renewable energy and energy efficiency, and adopted
17 targets for 2020 for GHG emissions reductions, renewable energy shares and energy efficiency
18 improvements. It also adopted in 2009 an Effort Sharing Decision for Member States' emissions reductions
19 for the period 2013 - 2020 in sectors not covered by the ETS (Boasson and Wettestad 2013; Bertoldi 2018).
20 The ETS has been improved multiple times, including through a 2015 Market Stability Reserve to reduce
21 the surplus of emission allowances (Wettestad and Jevnaker 2019; Chaton et al. 2018). In 2010, the European
22 Commission created a directorate-general (equal to a ministry at the domestic level) for Climate Action.
23 Between 2014 and 2018, the EU agreed on emission reduction targets for 2030 of 30% GHG emission
24 reductions compared to 1990, and again revised its climate policy portfolio including new targets for
25 renewable energies and energy efficiency and a new Effort Sharing Regulation (Fitch-Roy et al. 2019a;
26 Oberthür 2019).

27 From 2018, climate planning and reporting has been regulated by the EU Governance Regulation (Regulation
28 (EU) 2018/1999), requiring member states to develop detailed and strategic National Energy and Climate
29 Plans (Knodt et al. 2020). In 2019, the European Commission, backed by the European Council (heads of
30 states and government in the EU) and the European Parliament, launched a new broad climate and
31 environment initiative; the 'European Green Deal', implying the revision of many EU polices and
32 introducing the Climate Pact (European Commission 2019a). This roadmap develops a 'new growth strategy
33 for the EU' aimed at reaching climate neutrality by 2050 and spans multiple sectors. In 2020, the European
34 Commission introduced a new climate law establishing the framework for achieving the climate neutrality
35 by 2050 principle, and upgraded its 2030 GHG emission reduction target to at least net 55% reduction, which
36 was adopted in June 2021 (European Commission 2020a). In June 2021, the new policy package "Fit for 55"
37 was adopted by the Commission; the packages included a proposal for the revision of the ETS, including its
38 extension to shipping and a separate emission trading system for road transport and buildings, a revision of
39 the effort sharing regulation, an amendment of the regulation setting CO₂ emission standards for cars and
40 vans, a revision of the energy tax directive, a new carbon border adjustment mechanism, a revision of
41 renewable energy and energy efficiency targets and directives, and a new social climate funds to make the
42 transition to climate neutrality fair.

FOOTNOTE ² The European Union is an international organization that is discussed here because it plays a large role in shaping climate obligations and policies of its Member States.

1 **END BOX 13.1 HERE**

2
3 **13.2.3 Approaches to national institutions and governance**

4 **13.2.3.1 The forms of climate institutions**

5 Universal ‘best-practice’ formulations of organisations may not be applicable across country contexts, but
6 institutions that are suited to national context can be ratcheted up over time in their scope and effectiveness
7 (*medium evidence, medium agreement*). National climate institutions take diverse forms because they emerge
8 out of country specific interactions between national climate politics and existing institutional structures.
9 Certain institutional forms tend to be common across countries, such as expert climate change commissions;
10 a review finds eleven such institutions in existence as of mid-2020. Although this institutional form may be
11 common, these commissions vary in terms of expertise, independence and focus (Abraham-Dukuma et al.
12 2020), reinforcing the important shaping role of national context.

13 A review of institutions in eight countries suggests three broad processes through which institutions emerge:
14 ‘purpose-built’ dedicated institutions focused explicitly on mitigation; ‘layering’ of mitigation objectives on
15 existing institutions; and ‘latent’ institutions created for other purposes that nonetheless have implications
16 for mitigation outcomes (Dubash 2021). In relatively few countries do new, purpose-built, legally-mandated
17 bodies created specifically for climate mitigation exist although this number is growing; examples include
18 the UK (Averchenkova et al. 2018), China (Teng and Wang 2021), Australia (Keenan et al. 2012) and New
19 Zealand (Timperley 2020). These cases indicate that dedicated and lasting institutions with a strategic long-
20 term focus on mitigation emerge only under conditions of broad national political agreement around climate
21 mitigation as a national priority (Dubash 2021). However, the specific forms of those institutions differ, as
22 illustrated by the case of the UK’s Climate Change Committee established as an independent agency (see
23 Box 13.2) and China, which is built around a top-down planning structure (See Box 13.3).

24
25 **START BOX 13.2 HERE**

26 **Box 13.2 Climate change institutions in the UK**

27 The central institutional arrangements of climate governance in the UK were established by the 2008 Climate
28 Change Act (CCA): statutory five-year carbon budgets; an independent advisory body, the Committee on
29 Climate Change (CCC); mandatory progress monitoring and reporting to Parliament; and continuous
30 adaptive planning following a five-yearly cycle. The CCC is noteworthy as an innovative institution that has
31 also been emulated by other countries.

32 The design of the CCC was influenced by the concept of independent central banking (Helm et al. 2003). It
33 has established a reputation for independent high quality analysis and information dissemination, is
34 frequently referred to in Parliament and widely used by other actors in policy debates, all of which suggest
35 a high degree of legitimacy (Averchenkova et al. 2018). However, since the CCC only recommends rather
36 than sets budgets (McGregor et al. 2012), accountability for meeting the carbon budgets works primarily
37 through reputational and political effects rather than legal enforcement.

38 **END BOX 13.2 HERE**

39
40 **START BOX 13.3 HERE**

41 **Box 13.3 China’s climate change institutions**

1 Climate governance in China features a combination of top-down planning and vertical accountability (Sims
2 Gallagher and Xuan 2019; Teng and Wang 2021). An overarching coordination role is performed by the
3 Leading Group on Carbon Peaking and Carbon Neutrality, appointed by and reporting to the Central
4 Committee of the Chinese Communist Party, and the National Leading Group on Climate Change Response,
5 Energy Conservation, and Emissions Reduction (NLGCCR), headed by the Premier and consisting of more
6 than 30 ministers (Wang et al. 2018a). The Department of Climate Change (DCC) under the Ministry of
7 Ecology and Environment (MEE) is the primary agency in charge of climate issues, with a corresponding
8 local Bureau of Ecology and Environment in each province or city. While MEE is the leading agency for
9 climate policy, the National Development and Reform Commission (NDRC) is the leading agency for setting
10 overall and industry-specific targets in five-year plans, and thus has a key role in coordinating carbon
11 emissions targets with energy and industrial development targets (Wang et al. 2019; Yu 2021). Involvements
12 of ministries related to foreign affairs, public finance, science and technology, as well as sector ministries
13 such as transportation, construction, and manufacturing industries are also needed to push forward sector-
14 specific climate initiatives. At subsidiary levels of government carbon intensity targets are enforced through
15 a “targets and responsibilities” system that is directly linked to the evaluation of governments’
16 performances (Lin 2012a; Li et al. 2016).

17 **END BOX 13.3 HERE**

18
19 Where economy-wide institutions do not exist, new institutions may still address sub-sets of the challenge.
20 In Australia, while political conditions resulted in the repeal of an overarching Clean Energy Act in 2014,
21 although a Climate Change Authority continued, other institutions primarily focused on the energy sector
22 such as the Clean Energy Regulator, the Clean Energy Finance Corporation, and the Australia Renewable
23 Agency continued to shape energy outcomes (MacNeil 2021).

24 Where new dedicated organisations have not emerged, countries may layer climate responsibilities on
25 existing institutions; the addition of mitigation to the responsibilities of the US Environmental Protection
26 Agency is an example (Mildenberger 2021). Layering is also a common approach when climate change is
27 embedded within consideration of multiple objectives of policy. In these cases, climate institutions tend to
28 be layered on sectoral institutions for the pursuit of co-benefits or broader development concerns. Examples
29 include India, where energy security was an important objective of renewable energy promotion policy (Pillai
30 and Dubash 2021), Brazil’s mitigation approach focused on sectoral forest policy (Hochstetler 2021) and
31 South Africa’s emphasis on job creation as a necessary factor in mitigation policy (Chandrashekeran et al.
32 2017; Rennkamp 2019). Prior to this process of layering, sectoral institutions, such as in forest and energy
33 sectors, may play an important latent role in shaping climate outcomes, before climate considerations are
34 part of their formal mandate.

35 New rules and organisations are not only created, they are also dismantled or allowed to wither away. Cases
36 of institutional dismantling or neglect include the Australian Clean Energy Act (Crowley 2017; MacNeil
37 2021), the Indian Prime Minister’s Council on Climate Change, which, while formally functional, effectively
38 does not meet (Pillai and Dubash 2021), and the weakening of climate units inside sectoral ministries in
39 Brazil (Hochstetler 2021). While there is limited literature on the robustness of climate institutions, case
40 studies suggest institutions are more likely to emerge, persist and be effective when institutions map to a
41 framing of climate change that has broad political support (*medium evidence, medium agreement*). Thus
42 while mitigation focused framings and institutions may win political support in some countries, in other cases
43 sectorally focused or multiple objectives oriented institutions may be most useful and resilient (Dubash
44 2021).

45 **13.2.3.2 Addressing climate governance challenges**

46 Climate governance challenges include ensuring coordination, building consensus by mediating conflict, and
47 setting strategy (*medium evidence, high agreement*). Coordination is important because climate change is an

1 all-of-economy and society problem that requires cross-sectoral and cross-scale action; building consensus
2 is needed because large scale transformations can unsettle established interests; and strategy setting is
3 required due to the transformative and time-bound nature of climate mitigation (Dubash et al. 2021). Yet,
4 climate institutions have a mixed record in addressing these challenges.

5 Institutions that provide coordination, integration across policy areas and mainstreaming are particularly
6 important given the scope and scale of climate change (See Section 13.7) (Candel and Biesbroek 2016; Tosun
7 and Lang 2017). Ministries of environment are often appointed as *de facto* agents of coordination, but have
8 been hampered by their limited regulative authority and ability to engage in intra-governmental bargaining
9 with ministries with larger budgets and political heft (Aamodt 2018).

10 Creation of a high-level coordinating body to coordinate across departments and mainstream climate into
11 sectoral actions is another common approach (Oulu 2015). For example, Kenya has created a National
12 Climate Change Council, which operates through a climate change directorate in the environment ministry
13 to mainstream climate change at the county level (Guey and Bilich 2019). Zhou and Mori (2011) suggest
14 that well-functioning inter-agency coordination mechanisms require support from heads of government,
15 involvement by industry and environment agencies; and engagement by multiple sectoral agencies.
16 However, coordination mechanisms without a clear authority and basis for setting directions run the risk of
17 ‘negative coordination’, a process through which ministries comment on each other’s proposals, removing
18 any ideas that run counter to the interests of their own ministry, leading to even weaker decisions (Flachsland
19 and Levi 2021). Countries with dedicated, new climate institutions tend to have a more explicit and
20 authorised body for climate coordination, such as China’s National Leading Group’ (See Box 13.3).

21 Without explicit coordination with finance ministries, there is a risk of parallel and non-complementary
22 approaches. For example, the South African Treasury pursued a carbon tax without clear indication of how
23 it interfaced with a quantitative sectoral budget approach espoused by the environment ministry (Tyler and
24 Hochstetler 2021). Skovgaard (2012) suggests that there is an important distinction between finance
25 ministries that bring a limiting ‘budget frame’ to climate action, versus a ‘market failure frame’ that
26 encourages broader engagement by relevant ministries.

27 Coordination within federal systems poses additional complexities, such as overlapping authority across
28 jurisdictions, multiple norms in place, and approaches to coordination across scales (Brown 2012). Multilevel
29 governance systems such as the EU can influence the design and functioning of climate policies and
30 institutions in member states, such as Germany (Skjærseth 2017; Jänicke and Wurzel 2019; Flachsland and
31 Levi 2021) and the UK (Lockwood 2021a). In some cases, this can result in distinct European modes of
32 governance as has been suggested occurred in the case of wind energy (Fitch-Roy 2016).

33 Within countries, institutional platforms allow federal and subnational governments to negotiate and agree
34 on policy trajectories (Gordon 2015). In Germany, cooperation is channelled through periodic meetings of
35 environment ministers and centre-state working groups (Weidner and Mez 2008; Brown 2012), and in
36 Canada through bilateral negotiations and side-payments between scales of government (Rabe 2007; Gordon
37 2015). Federal systems might allow for sub-national climate action despite constraints at the federal level,
38 as has occurred in Australia (Gordon 2015; MacNeil 2021) and the United States (Rabe 2011; Jordaan et al.
39 2019; Bromley-Trujillo and Holman 2020; Thompson et al. 2020). Where agenda-setting rests with the
40 central government, coordination may operate through targets, as with China (Qi and Wu 2013), or
41 frameworks for policy action, as in India (Vihma 2011; Jogesh and Dubash 2015).

42 Because transition to a low-carbon future is likely to create winners and losers over different time scales;
43 institutions are needed to mediate these interests and build consensus on future pathways (Kuzemko et al.
44 2016; Lockwood et al. 2017; Finnegan 2019; Mildenerger 2020). Institutions that provide credible
45 knowledge can help support ambition. For example, analysis by the UK Climate Change committee has been
46 harnessed, including by non-state actors, to prevent backsliding on decisions (Lockwood 2021a). Institutions
47 can also help create positive feedback by providing spaces in decision making for low carbon interests

1 (Aklin and Urpelainen 2013; Roberts et al. 2018; Lockwood et al. 2017; Finnegan 2019). For example, a
2 renewable energy policy community emerged in China through key agenda setting meetings (Shen 2017),
3 and in India, a National Solar Mission provided a platform for the renewable energy industry (Pillai and
4 Dubash 2021). Conversely, institutions can also exert a drag on change through ‘regulatory inertia,’ as in the
5 case of the UK energy regulator Ofgem, which has exercised veto powers in ways that may limit a low
6 carbon transition (Lockwood et al. 2017).

7 Institutions can also create spaces to accommodate concerns of other actors (Upadhyaya et al. 2021).
8 Deliberative bodies, such as Germany’s Enquete Commission (Weidner and Mez 2008; Flachsland and Levi
9 2021) or the Brazilian Forum on Climate Change (Tyler and Hochstetler 2021) provide a space for
10 reconciling competing visions and approaches to climate change. Many countries are creating deliberative
11 bodies to forge ‘Just Transition’ strategies (Section 13.9). A recent innovation is the creation of Citizens’
12 Assemblies that bring together representative samples of citizens to deliberate on policy questions with the
13 intent of informing them (Sandover et al. 2021; Devaney et al. 2020). The ability of institutions to forge
14 agreement also rests on attention to procedural justice (See Box 13.4).

16 **START BOX 13.4 HERE**

17 **Box 13.4 Procedural justice**

18 Decision making consistent with energy and climate justice requires attention to procedural justice
19 (McCauley and Heffron 2018), which includes how decisions are made, and who is involved and has
20 influence on decisions (Sovacool and Dworkin 2015). Procedural justice emphasizes the importance of
21 equitable access to decision-making processes and non-discriminatory engagement with all stakeholders
22 (Jenkins et al. 2016), attention to the capability, particularly of marginalised groups, to shape decisions
23 (Holland 2017) and recognition of their specific vulnerabilities in collective political processes (Schlosberg
24 2012). Consensus-building institutions should avoid reducing normative questions to technical ones,
25 recognising that values, interests and behaviours are all shaped by ongoing climate governance (Schwanen
26 2021; Ryder 2018). Additionally, communities affected by low-carbon transition may face challenges in
27 articulating their understandings and experiences, which needs to be addressed in the design of climate
28 institutions (Schwanen 2021; Ryder 2018).

29 Spatially localized alternative discourses of justice are often more recognised socially than national and
30 universal framings of climate justice (Bailey 2017). Participatory forms of governance such as climate
31 assemblies and citizen juries (Ney and Verweij 2015) can help enhance the legitimacy of institutional
32 decisions, even while empirical assessments suggest that these approaches continue to face practical
33 challenges (Sandover et al. 2021; Creasy et al. 2021; Devaney et al. 2020).

34 **END BOX 13.4 HERE**

36 Since addressing climate change requires transformative intent and shifting development pathways (Section
37 13.9 in this Chapter, Section 1.6 in Chapter 1, Section 3.6 in Chapter 3, Sections 4.3 and 4.4 in Chapter 4,
38 Section 17.3.2 in Chapter 17, and Cross-Chapter Box 5 in Chapter 4), institutions that can devise strategies
39 and set trajectories are useful enablers of transformation. Strategy setting often requires an overarching
40 framework such as through framework laws that set targets (Averchenkova et al. 2017), or identify key
41 sectors and opportunities for low-carbon transition (Hochstetler and Kostka 2015) and innovation (UNEP
42 2018). Few countries have built deliberate and lasting institutions that provide strategic intent, and those that
43 have, have pursued different approaches. The UK’s approach rests on five-yearly targets (Box 13.2);
44 Germany requires sectoral budgets enforced through the Bundestag (Flachsland and Levi 2021); and China
45 uses an apex decision-body to set targets (Box 13.3) (Teng and Wang 2021).

1 Addressing all of these governance concerns – coordination, mediating interests, and strategy setting –
2 require attention to institutional capacity. These include the capacity to address ‘upstream’ policy issues of
3 agenda setting, framing, analysis and policy design; pursue goals even while mediating interests (Upadhyaya
4 et al. 2021); identify and manage synergies and trade-offs across climate and development objectives (Ürge-
5 Vorsatz et al. 2014; von Stechow et al. 2015; McCollum et al. 2018); identify and choose amongst possible
6 policy options (Howlett and Oliphant 2010); identify areas for transformation and the means to induce
7 innovation (Patt 2017; UNEP 2018); and developing the ability to monitor and evaluate outcomes
8 (Upadhyaya et al. 2021) (See Box 13.5). Domorenok et al. (2021) highlight different aspects of the capacity
9 challenge particularly necessary for integrated policy making including: the capacity for horizontal and
10 vertical coordination; implementation capacity including the independence of the state from interests; and
11 administrative capacity required to address compound problems. At a basic level, questions of governmental
12 capacity – the numbers and training of personnel – can shape the choices available for climate institutions
13 and their ability to be strategic (Richerzhagen and Scholz 2008; Harrison and Kostka 2014; Kim 2016). Box
14 13.5 describes South Africa’s approach to building monitoring and evaluation capacity.

15 The perceived need for attention to institutional capacity is highlighted by the fact that the NDCs of 113
16 developing countries out of 169 countries studied list capacity building as a condition of NDC
17 implementation (Pauw et al. 2020). While international support for capacity is widely articulated as essential
18 for many countries (Khan et al. 2020), ensuring the form of capacity is appropriate, effective and led
19 domestically remains a challenge (Nago and Krott 2020; Sokona 2021).

20

21 **START BOX 13.5 HERE**

22

Box 13.5 South Africa’s monitoring and evaluation system

23 South Africa’s national monitoring and evaluation system provides high-level guidance on information
24 requirements and assessment methodologies (DEA 2015). The country is developing a comprehensive,
25 integrated National Climate Change Information System, to enable tracking, analysis and enhancement of
26 South Africa’s progress towards the country’s transition to a low-carbon economy and climate-resilient
27 society (DFFE Republic of South Africa 2021). It includes information on GHG emission reductions
28 achieved, observed and projected climate change, impacts and vulnerabilities, the impact of adaptation and
29 mitigation actions, financial flows and technology transfer activities. South Africa’s approach is premised
30 upon continuous learning and improvement through a phased implementation approach (DEA 2019).

31 **END BOX 13.5 HERE**

32

33 **13.2.4 Institution building at the sub-national level**

34 Jurisdiction over significant mitigation-related arenas like planning, housing and community development
35 reside at the subnational level. To address linkages between mitigation and local concerns, subnational actors
36 engage in institution building within a broader socio-economic and political context, with actors and
37 institutions at a multitude of scales shaping the effectiveness of subnational-scale interventions (Romero-
38 Lankao et al. 2018a). Mitigation policies may demand coordination between sectoral and jurisdictional units
39 that historically have not collaborated; they may require subnational actors to confront politically sensitive
40 issues such as carbon taxes or increases in utility rates; and they may demand a redistribution of resources
41 to protect endangered ecosystems or vulnerable populations (Hughes and Romero-Lankao 2014).

42 Subnational actors have built climate institutions by creating new visions and narratives, by setting new
43 entities or committing existing offices, providing them with funds, staff and legal authority, or by
44 experimenting with innovative solutions that could be transferred to other local governments or scaled
45 nationally (Hoffmann 2011; Hoornweg et al. 2011; Aylett 2015; Hughes 2019b; Hughes and Romero-Lankao

1 2014; Romero-Lankao et al. 2015). These actors have also created task forces, referendums, coordination of
2 financial and human resources, technical assistance, awareness campaigns and funding (Castán Broto 2017;
3 Romero-Lankao et al. 2018a; Hughes 2019b). National governments can play a key role supporting planning
4 for climate change at the regional and national level, for example, through the articulation of climate change
5 action in national urban politics (Cobbinah et al. 2019; Van Den Berg et al. 2018).

6 **13.2.4.1 Significance of subnational networks**

7 Multi-jurisdictional and multi-sectoral sub-national networks in dozens of countries globally have helped
8 build climate institutions. They have also facilitated social and institutional learning, and addressed gaps in
9 national policy (Holden and Larsen 2015; Jordan et al. 2015; Setzer 2015; Haarstad 2016; Hermwille 2018;
10 Kammerer and Namhata 2018; Rashidi and Patt 2018; Westman and Castan Broto 2018; Lee 2019; Schwartz
11 2019; Lee and Jung 2018).

12 Transnational networks have opened opportunities for subnational actors to play a crucial mitigation role in
13 political stalemates (Jones 2014; Schwartz 2019). The C40, the Global Covenant of Mayors for Climate and
14 Energy, and ICLEI have disseminated information on best practices and promoted knowledge sharing
15 between subnational governments (Lee 2013; Hakelberg 2014; Heidrich et al. 2016; Kona et al. 2016; Di
16 Gregorio et al. 2020) (see Section 14.5.5 in Chapter 14). Organizations such as the US Carbon Cycle Working
17 Group of the United States Global Change Research Program, the Australian Climate Action Network, and
18 the Mexican Metropolitan Environmental Commission have helped facilitate coordination and learning
19 across multiple jurisdictions and sectors, and connected ambiguous spaces between public, private and civil
20 society actors (Horne and Moloney 2019; Romero-Lankao et al. 2015; Hughes 2019b).

21 Transnational networks have limited influence on climate policies where national governments exert top-
22 down control (e.g., in the city of Rizhao, China) (Westman et al. 2019); where subnational actors face
23 political fragmentation, lack regulations, and financial and human resources; or where vertically-integrated
24 governance exists, as in State of São Paulo, Santiago de Chile, and Mexico City (Setzer 2017; Romero-
25 Lankao et al. 2015).

26 Public support for sub-national climate institutions increases when climate policies are linked to local issues
27 such as travel congestion alleviation or air pollution control (Puppim de Oliveira 2013; Romero-Lankao et
28 al. 2013; Simon Rosenthal et al. 2015; Romero-Lankao et al. 2015; Ryan 2015), or when embedded in
29 development priorities that receive support from the national government or citizens (Jørgensen et al. 2015b;
30 Floater et al. 2016; Dubash et al. 2018). For example, Indian cities have engaged in international climate
31 cooperation seeking innovative solutions to address energy, water and infrastructure problems (Beermann et
32 al. 2016).

33 **13.2.4.2 Factors influencing institution building at the subnational level**

34 Availability of federal funding is a fundamental pillar of city actors' capacity to develop mitigation policies.
35 Administrative structures, such as the presence of a professional city manager and staff assigned specifically
36 to climate efforts (Simon Rosenthal et al. 2015). Cooperation between administrative departments, and the
37 creation of knowledge and data on energy use and emissions are also essential for mitigation planning
38 (Hughes and Romero-Lankao 2014; Ryan 2015). For example, the high technical competency of Tokyo's
39 bureaucracy combined with availability of historical and current data enabled the city's unique cap-and-trade
40 system on large building facilities (Roppongi et al. 2017).

41 Visions and narratives about the future benefits or risks of climate change are often effectively advanced at
42 the subnational level, drawing on local governmental abilities to bring together actors involved in place-
43 based decarbonisation across sectors. (Hodson and Marvin 2009; Bush et al. 2016; Huang et al. 2018;
44 Prendeville et al. 2018; Levenda et al. 2019). For example, in the plans of 43 C40 Cities, climate action is
45 framed as part of a vision for vibrant, economically prosperous, and socially just cities, that are habitable,

1 secure, resource-efficient, socially and economically inclusive, and competitive internationally (Romero-
2 Lankao and Gnatz 2019).

3 However, institution building is often constrained by a lack of national support, funding, human resources,
4 coalitions, coordination across old and new organizations, and the ability to create new institutional
5 competences (Valenzuela 2014; Jörgensen et al. 2015a; Anderton and Setzer 2018; Cointe 2019; Di Gregorio
6 et al. 2019; Jaccard et al. 2019; Ryan 2015; Dubash et al. 2018; Romero-Lankao et al. 2018a; Hughes 2019b).
7 Climate mitigation can also be limited by cultural norms and values of policy actors with varying levels of
8 power, and shifting alliances (Lachapelle et al. 2012; Damsø et al. 2016; Giampieri et al. 2019; Romero-
9 Lankao et al. 2018a).

10 Institution building is constrained by inequities; resources, legal remit, knowledge, and political clout vary
11 widely within and among subnational governments globally (Genus and Theobald 2016; Joffe and Smith
12 2016; Klinsky 2018; Markkanen and Anger-Kraavi 2019; Jörgensen et al. 2015b; Reckien et al. 2018).
13 Dominant discourses tend to prioritize scientific and technical expertise and, thus, they focus on
14 infrastructural and economic concerns over the concerns and needs of disadvantaged populations (Heikkinen
15 et al. 2019; Romero-Lankao and Gnatz 2019).

16 In addition, expert driven, technical solutions such as infrastructural interventions can undermine the
17 knowledge of lower income countries, communities or indigenous knowledge holders, yet are often used by
18 subnational governments (Ford et al. 2016; Brattland and Mustonen 2018; Nagorny-Koring 2019; Whyte
19 2017, 2020). Technical solutions, such as electric vehicles or smart grids rarely address the needs and
20 capabilities of disadvantaged communities that may not be able to afford these technologies (Mistry 2014;
21 Romero-Lankao and Nobler 2021). However, mitigation strategies in sectors such as transport and buildings
22 have often focused on technical and market outcomes, the benefits of which are limited to some, while others
23 experience negative externalities or face health risks (Carley and Konisky 2020; Markard 2018; Williams
24 and Doyon 2019). Delivering climate justice requires community-driven approaches to understanding the
25 problem addressing structural inequities and fostering justice, while reducing carbon emissions (Romero-
26 Lankao et al. 2018b; Carley and Konisky 2020; Lewis et al. 2020).

27 To address this situation requires procedural justice that involves all communities, particularly
28 disadvantaged, in climate mitigation decisions and policies (Box 13.4). Also essential is recognition justice,
29 that addresses past inequities through tools such as subsidies, tariffs, rebates, and other policies (Agyeman
30 2013; Rydin 2013; UN Habitat 2016). Both tenets are key to ensure the fair distribution of benefits or
31 negative impacts from mitigation policies (distributional justice) (McCauley and Heffron 2018; Lewis et al.
32 2020). However, the benefits of inclusive approaches are often overlooked in favour of growth oriented
33 mitigation and planning (Rydin 2013; Altenburg 2011; Smith 2019; Lennon 2020). Box 13.6 discusses how
34 the city of Durban has internalized climate change with attention to considerations of justice.

35 Moreover, deep mitigation requires moving beyond existing technological responses (Mulugetta and Castán
36 Broto 2018) to policies that correspond to the realities of developing countries (Bouteligier 2013). However,
37 best practice approaches tend to be fragmented due to the requirements of different contexts, and often
38 executed as pilot projects that rarely lead to structural change (Nagorny-Koring 2019). Instead, context-
39 specific approaches that include consideration of values, cultures and governance better enable successful
40 translation of best practices (Affolderbach and Schulz 2016; Urpelainen 2018).

41

42 **START BOX 13.6 HERE**

43

Box 13.6 Institutionalising climate change within Durban's local government

1 Durban has effectively linked climate change agendas with ongoing sustainability actions and goals. To do
2 so, adaptation has been broadened to include a just transition to a low carbon future to address development,
3 energy security and GHG reduction (Roberts et al. 2016).

4 Durban has mainstreamed climate and justice concerns within local government through strong local
5 leadership by key individuals and departments; included climate concerns within various municipal short-
6 term and long-term planning processes; mobilised civil society; enhanced local and international networking;
7 explored funding opportunities; and restructured institutions (Roberts et al. 2016).

8 Durban shows that embedding responses to climate change within local government activities requires that
9 climate change is made relevant locally and framed within a broader environmental justice framework
10 (Roberts 2010). Civil society has been key in balancing the influence of the private sector on Durban's
11 dynamic political process (Aylett 2013).

12 **END BOX 13.6 HERE**

13 **13.3 Structural factors that shape condition climate governance**

15 A growing literature suggests that ambitious climate policy emerges out of strong domestic political support
16 (Colgan et al. 2021; Aklin and Mildenerger 2020; Lamb and Minx 2020) (*medium evidence, medium*
17 *agreement*). Such support is the outcome of political interest constellations and struggles that vary from
18 country to country. Structural factors (such as economic wealth and natural resources, the character of the
19 national political system, and the dominant ideas, values and beliefs) shape how climate change is governed
20 (Hochstetler 2020; Boasson 2015) (*medium evidence, high agreement*). This section assesses the ways these
21 structural factors affect political dynamics and decision making, and ultimately constrain, sustain or enable
22 development of domestic climate governance.

23 While these structural factors are crucial, they do not determine the outlook of given countries' climate
24 governance, as civic, corporate and/or political groups or individuals can be mobilized and seek to counteract
25 these structural effects, as indicated in the following Section 13.4 that examines the role of various actors
26 and agencies in shaping governance processes. Taken together, Sections 13.3 and 13.4 show that domestic
27 climate governance is not fully constrained by structural factors, but rather that diverse actors can and do
28 achieve substantial changes.

30 **13.3.1 Material endowments**

31 Material endowments are natural and economic resources, such as fossil fuels and renewable energy, forests
32 and land, and economic or financial resources, which tend to shape developments of domestic climate
33 governance (Friedrichs and Inderwildi 2013; Lachapelle and Paterson 2013; Bang et al. 2015; Lamb and
34 Minx 2020) (*medium evidence, high agreement*). Most countries' social and economic systems are largely
35 developed on the basis of their material endowment, and thus they contribute to shape the distribution of
36 political power in that country (Hall and Soskice 2001). Material endowments are by no means the only
37 influencing factor, and actors may succeed to either circumvent or exploit material endowments to impact
38 climate governance (Boasson 2015; Green and Hale 2017; Aklin and Mildenerger 2020) (*limited evidence,*
39 *medium agreement*).

40 Since countries are not bound by their material endowment, countries with similar material endowments may
41 differ in climate governance, whereas those with notable differences in material endowments may have
42 similar policies. For instance, countries with rich fossil fuel endowments are found either adopting rather
43 ambitious emission reduction targets and measures, or remaining weak in developing domestic climate
44 policies (Eckersley 2013; Farstad 2019). Further, countries with radically different electricity systems and

1 energy resource potentials are found developing rather similar renewables support schemes such as feed-in-
2 tariff subsidies and competitive tendering programmes (Vanegas Cantarero 2020; Dobrotkova et al. 2018;
3 Boasson et al. 2021). Some policy instruments are widely applied in both developed and developing
4 countries with similar or different material endowment. For example, renewable energy auctions have been
5 experimented by over 100 countries by the end of 2018 (IRENA 2019).

6 Rich carbon-intensive resources and well developed infrastructure can make low-carbon activities relatively
7 less economically profitable, and negatively influence some perceptions of climate mitigation potential
8 (Bertram et al. 2015a; Erickson et al. 2015). If effective climate policies are introduced despite this, they can
9 alter the importance of country's material endowments in a way that underpin more forceful climate
10 governance over time. For instance, policy interventions to limit fossil fuel exploitation or support renewable
11 energy deployment may change the value of these energy resources over time (Schmitz et al. 2015; Ürgen-
12 Vorsatz et al. 2018; Chailleux 2020; Colgan et al. 2021).

13 Developing countries face additional material constraints in climate governance due to challenges associated
14 with underdevelopment and scarce economic or natural resources (*medium evidence, high agreement*).
15 Hence, many developing countries design domestic climate mitigation policies in combination with policy
16 goals that address various developmental challenges (von Stechow et al. 2016; Deng et al. 2017; Thornton
17 and Comberti 2017; Campagnolo and Davide 2019), such as air quality, urban transportation, energy access,
18 and poverty alleviation (Geall et al. 2018; Klausbrückner et al. 2016; Li et al. 2016; Melamed et al. 2016;
19 Slovic et al. 2016; Xie et al. 2018; Khreis et al. 2017). Combining climate and developmental policies for
20 beneficial synergies should not overlook potential trade-offs and challenges (Dagnachew et al. 2018; Ellis
21 and Tschakert 2019; Peñasco et al. 2021) (see Section 13.7.2 for wider discussion).

22

23 **13.3.2 Political systems**

24 The effectiveness of domestic climate governance will significantly rely on how well it fits with the features
25 of the countries' specific political systems (Schmitz 2017; Lamb and Minx 2020) (*limited evidence, high*
26 *agreement*). Political systems have developed over generations and constitute a set of formal institutions,
27 such as laws and regulations, bureaucratic structures, political executives, legislative assemblies and political
28 parties (Pierson 2004; Egeberg 1999). Different political systems create differing conditions for climate
29 governance to emerge and evolve, but because political systems are so politically and historically entrenched
30 they are not likely to change quickly even though this could facilitate domestic climate mitigation efforts
31 (Duit and Galaz 2008; Boasson et al. 2021) (*medium evidence, high agreement*). In addition, variations in
32 governance capacities also affect climate policy making and implementation (Meckling and Nahm 2018).

33 Broader public participation and more open contestation spaces tend to nurture more encompassing climate
34 policies, facilitate stronger commitments to international agreements (Bättig and Bernauer 2009; Böhmelt et
35 al. 2016), achieve more success in decoupling economic growth from CO₂ emissions (Lægreid and Povitkina
36 2018), reduce more CO₂ emissions (Clulow 2019; von Stein 2020), and maintain lower deforestation rates
37 (Buitenzorgy and Mol 2011) (*medium evidence, medium agreement*). States with less public participation
38 and contestation space can also develop ambitious climate emission reduction targets and institutions
39 (Eckersley 2016; Zimmer et al. 2015; Han 2017; Engels 2018), but the drivers and effects of climate policies
40 within less open and liberal political contexts has not yet been sufficiently investigated.

41 Election systems based on proportional representation tend to have lower emissions, higher energy
42 efficiency, higher renewable energy deployment, and more climate friendly investment than systems where
43 leadership candidates have to secure a majority of the votes to be elected (Fredriksson and Millimet 2004;
44 Finnegan 2019; Lachapelle and Paterson 2013) (*medium evidence, high agreement*). Such systems better
45 enable voters supporting ambitious climate positions to influence policymaking (Harrison and Sundstrom
46 2010; Willis 2018), place less political risks on legislators from additional costs incurred from climate
47 actions on voters (Finnegan 2018, 2019), and strengthen credible commitments to climate policy (Lockwood

1 2021b). Similarly, rules that govern the relationship between governments and civic societies in decision-
2 making have also been shown to matter in climate governance. Corporatist societies, where economic groups
3 are formally involved in public policy making, have better climate-related outcomes (lower CO₂ emissions
4 and higher low-carbon investments) than liberal-pluralist countries, where a larger array of non-
5 governmental organizations compete for informal influence, often through lobbying (Jahn 2016; Liefferink
6 et al. 2009; Finnegan 2018) (*medium evidence, medium agreement*).

7 Political parties with similar ideological roots in different countries (for instance social democratic or
8 conservative parties) may have different positions on climate governance across countries (Boasson et al.
9 2021). Nevertheless, on average, a higher share of green parties in a parliament is associated with lower
10 greenhouse gas emissions (Neumayer 2003; Jensen and Spoon 2011; Mourao 2019), and left-wing parties
11 tend to adopt more pro-climate policy positions (Carter 2013; Tobin 2017; Farstad 2018; Ladrech and Little
12 2019) (*medium evidence, high agreement*). There is also evidence, however, that conservative parties in some
13 countries support climate measures (Båtstrand 2015) and consensus can be achieved on climate actions
14 across the political spectrum (Thonig et al. 2021). At the same time, it seems harder to get support for new
15 climate governance initiatives in systems where many political groups can block decision due to many veto
16 points, for instance in systems with bicameralism (the legislature is divided into two separate assemblies)
17 and/or in federalist governments (where regions have national political representation, e.g. US and Brazil)
18 (Madden 2014; von Stein 2020) (*medium evidence, high agreement*) although federal systems hold out the
19 possibility of sub-national action when federal agreement is limited (Section 13.2). There remains a limited
20 literature on the role of green parties and veto points in developing countries (Haynes 1999; Kernecker and
21 Wagner 2019).

22 In any political system, climate policy adoption and implementation may be obstructed by corrupt practices
23 (Rafaty 2018; Fredriksson and Neumayer 2016) that entail an abuse of entrusted power for private gain
24 (Treisman 2000) (*medium evidence, high agreement*). Evidence shows that CO₂ emissions increase with
25 corruption, either through the direct negative effect of corruption on law enforcement, including in the
26 forestry sector (Sundström 2016), or through the negative effect of corruption on countries' income (Welsch
27 2004). These early findings are reinforced by studies of a global sample of countries (Cole 2007) and from
28 across the developing world (Bae et al. 2017; Wang et al. 2018b; Sahli and Rejeb 2015; Habib et al. 2020;
29 Ridzuan et al. 2019). Corruption also disrupts public support of climate policies by affecting the levels of
30 trust (Harring 2013; Davidovic and Harring 2020; Fairbrother et al. 2019) (*medium evidence, high
31 agreement*), which then impact on the compliance of climate policies. More research is required to further
32 understand the causal mechanisms between corrupt practices and emissions.

34 13.3.3 Ideas, values and belief systems

35 Ideas, values and beliefs affect climate governance by shaping people's perceptions, attitude, and preferences
36 on specific policy and governance issues (Schifeling and Hoffman 2019; McCright et al. 2016b; Boasson
37 2015; Boasson et al. 2021; Leipold et al. 2019) (*medium evidence, high agreement*). While these are often
38 entrenched, they can also change, for instance when facing growing exposures to climate risks, stronger
39 scientific evidence, and dominant public or political discourse (Mayer et al. 2017; Diehl et al. 2021). While
40 change tend to be incremental, the pace of change may vary substantially across countries and specific
41 climate issue areas.

42 However, new norms sometimes only influence political discussion and not actual governance. For instance,
43 more ambitious climate emission reduction targets may not lead to more effective mitigation actions or policy
44 instruments. Put another way, words do not replace actions (Geden 2016).

45 Different sets of beliefs can shape climate related policies, targets, and instruments (Boasson et al. 2021;
46 Boasson and Wettstad 2013; Boasson 2015). First, beliefs link climate governance with social justice
47 concerns; policies, targets and instruments may therefore reflect justice issues (Fuller and McCauley 2016;

1 Reckien et al. 2017; McCauley and Heffron 2018; Routledge et al. 2018; Bäckstrand and Lövbrand 2006,
2 2019). Second, climate mitigation may be seen as primarily a market correction issue and mitigation
3 compatible with economic growth, as exemplified by ecological modernization (Bäckstrand and Lövbrand
4 2006, 2019; Mol et al. 2009), climate capitalism (Newell and Paterson 2010), market logics (Boasson et al.
5 2021; Boasson 2015) or a global commons approach (Bernstein and Hoffmann 2019). Third, climate
6 governance may be understood relative to policies on technological innovation and progress, often
7 conceptualised as social-technical transformations (Geels et al. 2017a).

8 Significant variation in ideas, values and beliefs related to climate governance are detected across and within
9 regions, countries, societies, organisations, and individuals (Shwom et al. 2015; Boasson et al. 2021; Knox-
10 Hayes 2016; Wettestad and Gulbrandsen 2018) (*medium evidence, medium agreement*). These factors
11 provide the context for climate policymaking and include differences in countries' histories (Aamodt 2018;
12 Aamodt and Boasson 2020); the political culture and regulatory traditions in governing environmental and
13 energy issues (Tosun 2018; Aamodt 2018; Boasson et al. 2021); and even bureaucrats' educational
14 background (Rickards et al. 2014). Structural factors in a country, such as deeply held value systems, are not
15 changed rapidly, just as political systems or natural endowments, are not changed rapidly. Consequently
16 climate policy and governance is more effective if it takes into account these deep-rooted values and beliefs.

17 Differences in dominant individual preferences may also be important. The factors that shape individual
18 ideas, values and beliefs about climate governance include trust in politicians, the state and other people in
19 general (Drews and van den Bergh 2016; Harring et al. 2019; Huber et al. 2020), fairness beliefs, variation
20 in political orientation (left leaning more concerned), and class (Schmitz et al. 2018; Inglehart and Norris
21 2017) (*medium evidence, medium agreement*).

22 Levels of climate change concern on the individual level have increased in most countries (Shwom et al.
23 2015), and vary with gender (females are more concerned), and place of residence (urban residents are more
24 concerned) (McCright et al. 2016a; Shwom et al. 2015; Ziegler 2017). The higher educated in developing
25 countries tend to be more concerned (Lee et al. 2015) while individuals working in polluting industries tend
26 to oppose forceful climate governance (Bechtel et al. 2019; Mildemberger 2020).

27 Shifts in mainstream ideas, values and beliefs can underpin changes in climate policy choices and policy
28 outcomes (Mildemberger and Tingley 2019; Schleich et al. 2018) (*limited evidence, medium agreement*). For
29 example, emission trading schemes are welcomed as a new regulatory instrument in China in the context of
30 its market-oriented reforms and ideological shift in the past decades (Lo 2013). Based on the study of 167
31 nation-states and 95 subnational jurisdictions with carbon pricing, researchers find that that high public belief
32 in climate science underpin adoption of systems that produce a rather high carbon price (Levi et al. 2020).
33 These public opinions need to be identified and leveraged in supporting specific policy choices or changes
34 (Mildemberger and Tingley 2019). Policy support tends to be greater if people believe effective measures are
35 being taken by other actors, including other households (Bostrom et al. 2018; Marlon et al. 2019), and other
36 countries and at the international level (Schleich et al. 2018).

37 On the other hand, anti-climate ideas or beliefs may arise due to the introduction of more constraining or
38 ambitious climate policies, for example protests in reaction to toll roads in Norway, which increase the cost
39 of driving, or protests in France against increasing carbon taxes (Grossman 2019; Wanvik and Haarstad
40 2021). The policy implication is that vulnerable or effected groups should be considered when introducing
41 policy change, and that participation, transparency, and good communication all helps to reduce climate
42 related discontent.

43 Survey based studies of public perceptions on hypothetical policy instruments or activities, such as carbon
44 taxes or energy infrastructure, suggest that linking climate policy to other economic and social reforms can
45 increase public support for climate governance (Carattini et al. 2019; Bergquist et al. 2020). People and
46 politicians tend to underestimate other peoples' and politicians' willingness to support mitigation policies
47 (Mildemberger and Tingley 2019; Hurlstone et al. 2014), but if actors are informed about other actors actual

1 perceptions and behaviours this may reduce the tendency to underestimate climate governance support
2 (Mildenberger and Tingley 2019).

3

4 **13.4 Actors shaping climate governance**

5 While Section 13.3 shows that structural factors condition climate governance, their ultimate importance
6 also depends on whether and how various actors are mobilised (Hochstetler 2020; Boasson 2015). A wide
7 range of regional and local governments as well as non-governmental actors have become increasingly
8 engaged in climate governance, for instance through public-private partnerships and transnational networks
9 (Jordan et al. 2018b; Dorsch and Flachsland 2017; Jordan et al. 2015) and through the media and litigation,
10 as discussed here.

11 Climate governance processes result from both slow-moving incremental changes to policy and more rapid
12 bursts of change due to, for example, responses to dramatic weather-events, general elections or global
13 climate summits (Aamodt and Stensdal 2017; Jordan and Moore 2020; Boasson et al. 2021) (*medium*
14 *evidence, high agreement*). While Section 13.3 assessed how entrenched structural factors conditions climate
15 governance developments, this section examines how actors are able to alter climate governance by engaging
16 the climate policy process, undertaking litigation and interacting with media.

17

18 **13.4.1 Actors and agency in the public process**

19 A broad array of actors are engaged in shaping mitigation policy processes, including politicians and political
20 parties, corporate actors, citizen groups, indigenous peoples organizations, labour unions and international
21 organizations. Actors aiming to influence the climate-related policymaking process are studied together to
22 understand climate policy dynamics and outcomes (Bulkeley 2000; Fisher 2004; Fisher and Leifeld 2019;
23 Jasny et al. 2015; Jasny and Fisher 2019; Jost and Jacob 2004) and collaboration and influence within climate
24 policy networks (Ingold and Fischer 2014; Kammerer et al. 2021; McAllister et al. 2014; Wagner and Ylä-
25 Anttila 2018). Most research, however, focuses on one particular type of actor.

26 Political actors are decision-makers, and also influence whether climate governance is perceived as urgent
27 and appropriate (Okereke et al. 2019; Ferrante and Fearnside 2019; Boasson et al. 2021). They include
28 political parties, legislative assemblies and committees, governmental executives and the political leaders of
29 governmental ministries (Boasson 2015). They are more likely to pay attention to climate issues when
30 polling indicates high political salience with the public (Carter 2006, 2014), or when it becomes a contested
31 issue among differing political parties (Boasson et al. 2021). Fluctuations in the public's interest and attention
32 may underpin a disjointed approach in politicians' engagement (Willis 2017, 2018). Policy implementation
33 can be hampered if political actors propose frequent policy changes (Boasson et al. 2021).

34 Corporate actors often influence policies and their adoption (Pulver and Benney 2013; Mildenberger 2020;
35 Goldberg et al. 2020). Corporate actors acting individually or through industry associations, have worked to
36 sway climate policy in different countries (Meckling 2011; Falkner 2008; Bernhagen 2008; Newell and
37 Paterson 2010; Mildenberger 2020). Their ability varies by country and issue (Skjørseth and Skodvin 2010;
38 Boasson and Wettestad 2013; Boasson 2015; Boasson et al. 2021) (*medium evidence, medium agreement*)
39 and depends on material endowments (Moe Singh 2012), access to the political system (Dillon et al. 2018;
40 Mildenberger 2020), and the ability to shape ideas, values and belief systems (Boasson 2015). Corporate
41 actors tend to change their climate policy preferences over time, as indicated by longitudinal studies of some
42 European countries (Boasson and Wettestad 2013; Boasson 2015; Boasson et al. 2021).

43 Corporate actors are crucial to policy implementation because they are prominent emitters of the greenhouse
44 gases and owners of carbon-intensive technologies and potential providers of solutions as developers, owners
45 and adopters of low emission practices and technologies (Perrow and Pulver 2015; Falkner 2008). Many

1 climate policies and measures rely on businesses' willingness to exploit newly created economic
2 opportunities, such as support schemes for renewable energy and energy efficiency sector or carbon pricing
3 (Shen 2015; Olsen 2007; Newell and Paterson 2010; World Bank 2019). Some corporate actors provide
4 climate solutions, such as renewable energy deployment, and have successfully influenced climate policy
5 development related to feed-in tariffs, taxations, quotas, or emission trading schemes, in the EU (Boasson
6 2019), Germany (Leiren and Reimer 2018), the US (Stokes and Breetz 2018), the Nordic countries (Kooij et
7 al. 2018), China (Shen 2017) and Japan (Li et al. 2019).

8 Fossil fuel industries have been important agenda-setters in many countries, including the USA (Dunlap and
9 McCright 2015; Supran and Oreskes 2017; Downie 2018), the EU (Skjærseth and Skodvin 2010; Boasson
10 and Wettestad 2013), Australia (Ayling 2017), China (Shen and Xie 2018; Tan et al. 2021), India (Blondeel
11 and Van de Graaf 2018; Shen 2017; Schmitz 2017), and Mexico (Pulver 2007), with differing positions and
12 impacts across countries (Kim et al. 2016; Nasiritousi 2017). In the US, the oil industry has underpinned
13 emergence of climate scepticism (Farrell 2016a; Dunlap and McCright 2015; Supran and Oreskes 2017),
14 and its spread abroad (Dunlap and Jacques 2013; Engels et al. 2013; Painter and Gavin 2016). Corporate
15 opposition to climate policies is often facilitated by a broad coalition of firms (Cory et al. 2021).

16 Conservative foundations, sometimes financed by business revenues, have funded a diversity of types of
17 groups, including think-tanks, philanthropic foundations, or activist networks to oppose climate policy
18 (Brulle 2014, 2019). However, there is limited knowledge about the conditions under which actors opposed
19 to climate action succeed in shaping climate governance (Kinniburgh 2019; Martin and Islar 2021).

20 Some labour unions have developed positions and programmes on climate change (Snell and Fairbrother
21 2010; Stevins 2013; Rätzzel et al. 2018), formed alliances with other actors in the field of climate policy
22 (Stevins 2018) and participated in domestic policy networks on climate change (Jost and Jacob 2004), but we
23 know little about their relative importance or success. In countries with significant fossil fuel resources such
24 as Australia, Norway, and the United States, labour unions, particularly industrial unions, tend to contribute
25 to reducing the ambition of domestic climate policies mainly due to the concern of job losses (Mildenberger
26 2020). Other studies find that the role of labour unions varies across countries (Glynn et al. 2017).

27 Civil society actors can involve citizens working collectively to change individual behaviours that have
28 climate implications. For example, environmental movements that involve various forms of collective efforts
29 encourage their members to make personal lifestyle changes that reduce their individual carbon footprints
30 (Ergas 2010; Middlemiss 2011; Haenfler et al. 2012; Cronin et al. 2014; Saunders et al. 2014; Büchs et al.
31 2015; Wynes et al. 2018). These efforts seek to change individual members' consumer behaviours by
32 reducing car-use and flying, shifting to non-fossil fuel sources for individual sources of electricity, and eating
33 less dairy or meat (Cherry 2006; Salt and Layzell 1985; Stuart et al. 2013; Thøgersen et al. 2021; Wynes and
34 Nicholas 2017; Büchs et al. 2015; Cronin et al. 2014; Ergas 2010; Haenfler et al. 2012; Middlemiss 2011;
35 Saunders et al. 2014; Wynes et al. 2018). Consumer/citizen engagement is sometimes encouraged through
36 governmental directives, such as the "renewable energy communities" granted by the EU renewable energy
37 directive 2018/2001 (The European Parliament and the Council of the European Union 2018). To date, there
38 are only a limited number of case studies that measure the direct effect of participation in these types of
39 movements as it relates to climate outcomes (Vestergren et al. 2018, 2019; Saunders et al. 2014).

40 Citizens with less access to resources and power also participate by challenging nodes of power—
41 policymakers, regulators, and businesses—to change their behaviours and/or accelerate their efforts. Tactics
42 include lobbying, legal challenges, shareholder activism, coop board stewardship, and voting (Bratton and
43 McCahery 2015; Clemens 1997; Gillan and Starks 2007; Olzak et al. 2016; Schlozman et al. 2012; Viardot
44 2013; Yildiz et al. 2015). Citizens provide the labour and political will needed to pressure political and
45 economic actors to enact emission-reducing policies, as well as providing resistance to them (McAdam 2017;
46 Oreskes and Conway 2012; Fox and Brown 1998; Boli and Thomas 1999).

1 Other citizen engagement involves a range of more confrontational tactics, such as boycotting, striking,
2 protesting, and direct action targeting politicians, policymakers, and businesses (Chamorel 2019; Cock 2019;
3 Eilstrup-Sangiovanni and Bondaroff 2014; Fisher 2010, 2019b; Fisher et al. 2005; Hadden 2014, 2015;
4 Hadden and Jasny 2019; Meyer and Tarrow 1997; O'Brien et al. 2018; Saunders et al. 2012; Swim et al.
5 2019; Tarrow 2005; Wahlström et al. 2013; Walgrave et al. 2012). Climate strikes and other more
6 confrontational forms of climate activism have become increasingly common (Boulianne et al. 2020; de
7 Moor et al. 2021; Evensen 2019; Fisher and Nasrin 2021a; Martiskainen et al. 2020; Fisher 2019b; O'Brien
8 et al. 2018). Very few studies look specifically at the effect of these tactics on actual climate-related outcomes
9 and more research is needed to understand the climate effects of citizen engagement and activism (Fisher
10 and Nasrin 2021b).

11 Citizen engagement has also become common among indigenous groups who tend to have limited structural
12 power but often aim to shape the formation and effects of projects that have implications to climate change.
13 These include opposing extraction and transportation of fossil fuels on their traditional lands (especially in
14 the Americas) (Bebbington and Bury 2013; Hindery 2013; Coryat 2015; Claeys and Delgado Pugley 2017;
15 Wood and Rossiter 2017); large-scale climate mitigation projects that may affect traditional rights
16 (Brannstrom et al. 2017; Moreira et al. 2019; Zárata-Toledo et al. 2019); supporting deployment of small-
17 scale renewable energy initiatives (Thornton and Comberti 2017); seeking to influence the development of
18 REDD+ policies through opposition (Reed 2011); and participation in consultation processes and multi-
19 stakeholder bodies (Bushley 2014; Gebara et al. 2014; Astuti and McGregor 2015; Kashwan 2015; Jodoin
20 2017). Indigenous groups have been reported to have had some influence on some climate discussions,
21 particularly forest management and siting of renewable energy (Claeys and Delgado Pugley 2017; Jodoin
22 2017; Thornton and Comberti 2017). Further, more scientific assessments are required on the role of
23 indigenous groups in climate activism and policy (Jodoin 2017; Claeys and Delgado Pugley 2017; Thornton
24 and Comberti 2017).

25 Activism, including litigation, as well as the tactics of protest and strikes, have played a substantial role in
26 pressuring governments to create environmental laws and environmental agencies tasked with enforcing
27 environmental laws that aimed to maintain clean air and water in countries around the world (McCloskey
28 1991; Schreurs 1997; Rucht 1999; Brulle 2000; Steinhardt and Wu 2016; Wong 2018; Longhofer et al. 2016)
29 (*medium evidence, high agreement*). Several studies find environmental NGOs have a positive effect on
30 reductions in carbon emissions, whether through effects that operate across countries or (Schofer and
31 Hironaka 2005; Jorgenson et al. 2011; Longhofer and Jorgenson 2017; Grant et al. 2018; Frank et al. 2000;
32 Baxter et al. 2013) through impact of NGOs within nations (Dietz et al. 2015; Grant and Vasi 2017; Shwom
33 2011)

34 At the same time, other research has documented various forms of backlash against climate policies, both in
35 terms of voting behaviour, as well as other collective efforts (Boudet et al. 2016; Fast et al. 2016; Hill et al.
36 2010; Krause et al. 2016; Lyon 2016; Mayer 2016; McAdam and Boudet 2012; Muradian and Pascual 2020;
37 Stokes 2016; Stokes and Warshaw 2017; Stokes 2020; Walker et al. 2014; Williamson et al. 2011; Wright
38 and Boudet 2012). In a systematic analysis that includes movements against fossil fuel investments along
39 with those against low-carbon emitting projects around the world, research finds that a quarter of all projects
40 (no matter their targets) were cancelled after facing resistance (Temper et al. 2020).

41

42 **START BOX 13.7 HERE**

43

Box 13.7 Civic engagement: The school strike movement

44 On Friday August 20th 2018, Greta Thunberg participated in the first climate school strike. Since then,
45 Fridays for Future—the name of the group coordinating this tactic of skipping school on Fridays to protest
46 inaction on climate change—has spread around the world.

1 In March 2019, the first *global* climate strike took place, turning out more than 1 million people around the
2 world (Carrington 2019). Six months later in September 2019, young people and adults responded to a call
3 to participate in climate strikes as part of the ‘Global Week for Future’ surrounding the UN Climate Action
4 Summit (Thunberg 2019), and the number of participants globally jumped to an estimated 6 million people
5 (Taylor et al. 2019). Although a handful of studies have reported on who was involved in these strikes, how
6 they were connected, and their messaging (Marris 2019; Wahlström et al. 2019; Bevan et al. 2020; Han and
7 Ahn 2020; Holmberg and Alvinus 2020; Jung et al. 2020; Martiskainen et al. 2020; de Moor et al. 2021;
8 Thackeray et al. 2020; Trihartono et al. 2020; Evensen 2019; Fisher 2019a; Boulianne et al. 2020; Fisher and
9 Nasrin 2021b), its consequences in terms of political outcomes and emissions reductions have yet to be fully
10 understood (Fisher and Nasrin 2021b).

11 Although digital activism makes it easier to connect globally, it is unclear how digital technology will affect
12 the youth climate movement, and its effects on carbon emissions. Research suggests that online activism is
13 likely to involve a more limited range of participants and perspectives (Bennett 2013; Elliott and Earl 2018).
14 Digital tactics could also mean that groups are less embedded in communities and less successful at creating
15 durable social ties, factors that have been found to lead to longer term engagement (Rohlinger and Bunnage
16 2018; Tufekci 2017; Shirky 2010).

17 **END BOX 13.7 HERE**

18
19 A range of international organizations can be important, particularly in developing countries, for instance by
20 assisting in framing of national climate governance and supporting the design of climate policies through
21 technical assistance projects (Talaei et al. 2014; Ortega Díaz and Gutiérrez 2018; Bhamidipati et al. 2019;
22 Charlery and Trærup 2019; Kukkonen et al. 2018). Yet for these climate aid initiatives to work effectively
23 requires improved institutional architecture, better appreciation of local contexts, and more inclusive and
24 transparent governance, based on evidence from many multilateral mechanisms like REDD+, CDM, GEF
25 and GCF (Gomez 2013; Arndt and Tarp 2017), and bilateral programmes on energy, agriculture and land
26 use sectors (Rogner and Leung 2018; Moss and Bazilian 2018; Arndt and Tarp 2017).

27 28 **13.4.2. Shaping climate governance through litigation**

29 Outside the formal climate policy processes, climate litigation is another important arena for various actors
30 to confront and interact over how climate change should be governed (Calzadilla 2019; Peel and Osofsky
31 2015, 2018; Setzer and Vanhala 2019; Paiement 2020; Wegener 2020; Wilensky 2015; Bouwer 2018; Setzer
32 and Byrnes 2019) (*robust evidence, high agreement*). Climate litigation is an attempt to control, order or
33 influence the behaviour of others in relation to climate governance, and it has been used by a wide variety of
34 litigants (governments, private actors, civil society and individuals) at multiple scales (local, regional,
35 national and international) (Osofsky 2007; Lin 2012b; Keele 2017; McCormick et al. 2018; Peel and Osofsky
36 2018; Setzer and Vanhala 2019). Climate litigation has become increasingly common (United Nations
37 Environment Programme 2020), but its prevalence varies across countries (Peel and Osofsky 2015; Wilensky
38 2015; Bouwer 2018; Setzer and Higham 2021; Lin and Kysar 2020) (*medium evidence, high agreement*).
39 This is not surprising, given that courts play differing roles across varying political systems and law traditions
40 (La Porta et al. 1998).

41 This sub-section focuses on relevant climate litigation for policies and institutions. Climate litigation is
42 further discussed in Sections 14.5.1.2 (linkages between mitigation and human rights) and 14.5.3 (cross-
43 country implications and international courts/tribunals).

44 The vast majority of climate cases have emerged in United States, Australia and Europe, and more recently
45 in developing countries (Humby 2018; Kotze and du Plessis 2019; Peel and Lin 2019; Setzer and Benjamin
46 2019; Zhao et al. 2019; Rodríguez-Garavito 2020). As of 31 May 2021, 1,841 cases of climate change
47 litigation from around the world had been identified. Of these, 1,387 were filed before courts in the United

1 States, while the remaining 454 were filed in 39 other countries and 13 international or regional courts and
2 tribunals (including the courts of the European Union). Outside the US, Australia (115), the UK (73) and the
3 EU (58) remain the jurisdictions with the highest volume of cases. The majority of cases, 1,006, have been
4 filed since 2015 (Setzer and Higham 2021). The number of climate litigation cases in developing countries
5 is also growing. There are at least 58 cases in 18 Global South jurisdictions (Setzer and Higham 2021; Humby
6 2018; Kotze and du Plessis 2019; Peel and Lin 2019; Setzer and Benjamin 2019; Zhao et al. 2019; Rodríguez-
7 Garavito 2020) (*robust evidence, high agreement*).

8 Overall, courts have also played a more active role for climate governance in democratic political systems
9 (Peel and Osofsky 2015; Eskander et al. 2021), but recently legal reforms have also developed in other
10 countries, such as the environmental public interest law in China that allows individuals and groups to initiate
11 environmental litigation (Xie and Xu 2021; Zhao et al. 2019). Whether and to what extent differing law
12 traditions and political systems influence the role and importance of climate litigation has, however, not been
13 examined enough scientifically (Peel and Osofsky 2020; Setzer and Vanhala 2019).

14 The majority of climate change litigation cases are brought against governments, by civic and non-
15 governmental organisations and corporations (Eisenstat 2011; Markell and Ruhl 2012; Fisher et al. 2017;
16 Wilensky 2015; Setzer and Higham 2021). Many, although not all of these cases, seek to ensure that
17 governmental action on climate change is more ambitious, and better aligned with the need to avert or
18 respond to climate impacts identified and predicted by the scientific community (Setzer and Higham 2021;
19 Markell and Ruhl 2012). Climate aligned cases against governments can be divided into two distinct
20 categories: claims challenging the overall effort of a State or its organs to mitigate or adapt to climate change
21 (sometimes referred to as ‘systemic climate litigation’) (Jackson 2020) and claims regarding authorisation
22 of third-party activity (Bouwer 2018; Gerrard 2021; Ghaleigh 2021).

23 Systemic climate litigation that seeks an increase in a country’s ambition to tackle climate change has been
24 a growing trend since the first court victories in the Urgenda case in the Netherlands (see Box 13.8 below)
25 and the Leghari case in Pakistan in 2015. These cases motivated a wave of similar climate change litigation
26 across the world (Sindico et al. 2021; Roy and Woerdman 2016; Mayer 2019; Ferreira 2016; Peeters 2016;
27 Paiement 2020; Barritt 2020). Between 2015 and 2021, individuals and communities initiated at least 37
28 cases (including Urgenda and Leghari) against states (Setzer and Higham 2021), challenging the
29 effectiveness of legislation and policy goals (Setzer and Higham 2021; Jackson 2020). Some cases also seek
30 to shape new legal concepts such as ‘rights of nature’ recognized in the Future Generations case in Colombia
31 (Savaresi and Auz 2019; Rodríguez-Garavito 2020) and ‘ecological damage’ in the case of Notre Affaire à
32 Tous and others v. France (Torre-Schaub 2021).

34 **START BOX 13.8 HERE**

35 **Box 13.8 An example of systemic climate litigation: Urgenda v State of the Netherlands**

36 The judgment in *Urgenda v. State of the Netherlands* established the linkage between a state’s international
37 duty, domestic actions, and human rights commitments as to the recommendations of IPCC’s AR5 (Burgers
38 and Staal 2019; Antonopoulos 2020). It was the first to impose a specific emissions reduction target on a
39 state (de Graaf and Jans 2015; Cox 2016; Loth 2016). The District Court of The Hague ordered the Dutch
40 Government to reduce emissions by at least 25% by the end of 2020. Following the decision of the district
41 court of The Hague in 2015 the Dutch government announced that it would adopt additional measures to
42 achieve the 25% emissions reduction target by 2020 (Mayer 2019). The decision was upheld by the Court of
43 Appeal in 2018 and the Supreme Court in 2019. Since the first judgment in 2015 significant changes in the
44 climate policy environment have been reported, the results of which have included the introduction of a
45 Climate Act and the decision to close all remaining coal fired power plants by 2030 (Verschuuren 2019;
46 Wonneberger and Vliegthart 2021).

1 END BOX 13.8 HERE

2

3 Moreover, there are a number of regulatory challenges to state authorisation of high-emitting projects, which
4 differs from systemic cases against states (Bouwer 2018; Hughes 2019a). For instance, the High Court in
5 Pretoria, South Africa, concluded that climate change is a relevant consideration for approving coal-fired
6 power plants (Humby 2018). Similarly, the Federal Court of Australia concluded that the Minister for the
7 Environment owed a duty of care to Australian children in respect to climate impacts when exercising a
8 statutory power to decide whether to authorise a major extension to an existing coal mine (Peel and Markey-
9 Towler 2021)

10 Climate change litigation has also been brought against corporations by regional or local governments and
11 non-governmental organisations (Ganguly et al. 2018; Wilensky 2015; Foerster 2019). One type of private
12 climate change litigation alleges climate change-related damage and seeks compensation from major carbon
13 polluters (Ganguly et al. 2018; Wewerinke-Singh and Salili 2020). The litigators claim that major oil
14 producers are historically responsible for a significant portion of global greenhouse gas emissions (Heede
15 2014; Frumhoff et al. 2015; Ekwurzel et al. 2017; Stuart-Smith et al. 2021). These cases rely on
16 advancements in climate science, specifically climate attribution (Marjanac et al. 2017; Marjanac and Patton
17 2018; McCormick et al. 2018; Minnerop and Otto 2020; Burger et al. 2020b; Stuart-Smith et al. 2021). It is
18 alleged that major carbon emitters had knowledge and awareness of climate change and yet took actions to
19 confound or mislead the public about climate science (Supran and Oreskes 2017). Strategic climate change
20 litigation has also been used to hold corporations to specific human rights responsibilities (Savaresi and Auz
21 2019; Savaresi and Setzer 2021) (see further Box 13.8).

22 In addition to direct cases targeting high emitters, litigation is also now being used to argue against financial
23 investments in the fossil fuel industry (Franta 2017; Colombo 2021). In May 2021, the Hague District Court
24 of the Netherlands issued a ground-breaking judgment holding energy company Royal Dutch Shell (RDS)
25 legally responsible for greenhouse gas emissions from its entire value chain (Macchi and Zeben 2021).
26 Claims have also been brought against banks, pension funds and investment funds for failing to incorporate
27 climate risk into their decision-making, and to disclose climate risk to their beneficiaries (Solana 2020;
28 Wasim 2019; Bowman and Wiseman 2020). These litigation cases also impact on the financial market
29 without directly involving specific financial institutions into the case (Solana 2020) but somehow aim to
30 change their risk perceptions and attitude on high carbon activities (Griffin 2020).

31 The outcomes of climate litigation can affect the stringency and ambitiousness of climate governance
32 (McCormick et al. 2018; Eskander et al. 2021). In the United States, pro-regulation litigants more commonly
33 win in relation to renewable energy and energy efficiency cases, and more frequently lose in relations to
34 coal-fired power plant cases (McCormick et al. 2018). Outside the US, more than half (58%) of litigation
35 have outcomes that are aligned with climate action (Setzer and Higham 2021). But these cases can also have
36 impacts outside of the legal proceedings before, during and after the case has been brought and decided
37 (Setzer and Vanhala 2019). These impacts include changes in the behaviour of the parties (Peel and Osofsky
38 2015; Pals 2021), public opinion (Hilson 2019; Burgers 2020), financial and reputational consequences for
39 involved actors (Solana 2020), and impact on further litigation (Barritt 2020). Individual cases have also
40 attracted considerable media attention, which in turn can influence how climate policy is perceived (Nosek
41 2018; Barritt and Sediti 2019; Paiement 2020; Hilson 2019). While there is evidence to show the influence
42 of some key cases on climate agenda-setting (Wonneberger and Vliegthart 2021), it is still unclear the
43 extent to which climate litigation actually results in new climate rules and policies (Peel and Osofsky 2018;
44 Setzer and Vanhala 2019; Peel and Osofsky 2020) and to what degree this holds true for all cases (Jodoin et
45 al. 2020). However, there is now increasing academic agreement that climate litigation has become a
46 powerful force in climate governance (Bouwer 2018; Peel and Osofsky 2020; United Nations Environment
47 Programme 2020; Burgers 2020). In general, litigations can be applied to constrain both public and private

1 entities, and to shape structural factors mentioned in Section 13.3, such as the beliefs and institutions around
2 climate governance.

4 **13.4.3 Media as communicative platforms for shaping climate governance**

5 Media is another platform for various actors to present, interpret and shape debates around climate change
6 and its governance (Tindall et al. 2018). The media coverage of climate change has grown steadily since
7 1980's (O'Neill et al. 2015; Boykoff et al. 2019), but the level and type of coverage differs over time and
8 from country to country (Boykoff 2011; Schmidt et al. 2013; Schäfer and Schlichting 2014) (*robust evidence,*
9 *high agreement*). Media can be a useful conduit to build public support to accelerate mitigation action, but
10 may also be utilized to impede decarbonisation endeavours (Farrell 2016b; Carmichael et al. 2017;
11 Carmichael and Brulle 2018; Boykoff 2011; O'Neill et al. 2015). Different media systems in different regions
12 and countries and with unique cultural and political traditions also affect how climate change is
13 communicated (Eskjær 2013).

14 A broad variety of media platforms cover climate change issues, including traditional news media, such as
15 newspapers and broadcasting, digital social media (Walter et al. 2018), creative narratives such as climate
16 fiction and films (Svoboda 2016); humour and entertainment media (Brewer and McKnight 2015; Skurka et
17 al. 2018; Boykoff and Osnes 2019); and strategic communications campaigns (Hansen and Machin 2008;
18 Hoewe and Ahern 2017). Media coverage can have far-reaching consequences on policy processes, but we
19 know less about its relative importance compared to other policy shaping factors (Liu et al. 2011;
20 Hmielowski et al. 2014; Boykoff 2011) (*medium evidence, medium agreement*).

21 Popular culture images, science fictions and films of ecological catastrophe can dramatically and emotively
22 convey the dangers of climate change (Bulfin 2017). The overall accuracy of the media coverage on climate
23 change has improved from 2005 to 2019 in the United Kingdom (UK), Australia, New Zealand, Canada, and
24 the US (McAllister et al. 2021). Moreover, coverage of climate science is increasing. One study (MeCCO)
25 has tracked media coverage of climate change from over 127 sources from 59 countries in North and Latin
26 America, Europe, Middle East, Africa, Asia and Oceania (Boykoff et al. 2021). It shows the number of media
27 science stories in those sources grew steadily from 47376 per annum to 86587 per annum between 2017 and
28 2021 across print, broadcast, digital media and entertainment (Boykoff et al. 2021).

29 However, increasing media coverage does not always lead to more accurate coverage of climate change
30 mitigation, as it can also spur diffusion of misinformation (Boykoff and Yulsman 2013; van der Linden et
31 al. 2015; Whitmarsh and Corner 2017; Fahy 2018; Painter 2019). In addition, media professionals have at
32 times drawn on the norm of representing both sides of a controversy, bearing the risk of the disproportionate
33 representation of scepticism of anthropogenic climate change despite the convergent agreement in climate
34 science that humans contribute to climate change. (Freudenburg and Muselli 2010; Boykoff 2013; McAllister
35 et al. 2021; Tindall et al. 2018; Painter and Gavin 2016) (*robust evidence, high agreement*). This occurs
36 despite increasing consensus among journalists regarding the basic scientific understanding of climate
37 change (Brüggemann and Engesser 2017).

38 Accurate transference of the climate science has been undermined significantly by climate change counter-
39 movements, particularly in the US (McCright and Dunlap 2000, 2003; Jacques et al. 2008; Brulle et al. 2012;
40 Boussalis and Coan 2016; Boykoff and Farrell 2019; Farrell 2016a; Carmichael et al. 2017; Carmichael and
41 Brulle 2018; Almiron and Xifra 2019) in both legacy and new/social media environments through
42 misinformation (van der Linden et al. 2017) (*robust evidence, high agreement*), including about the causes
43 and consequences of climate change (Brulle 2014; Farrell 2016b; Supran and Oreskes 2017; Farrell 2016a).
44 Misinformation can rapidly spread through social media (Walter et al. 2018). Together with the proliferation
45 of suspicions of 'fake news' and 'post-truth', some traditional and social media contents have fuelled
46 polarization and partisan divides on climate change in many countries (Feldman et al. 2017; Hornsey et al.
47 2018), which can further deter development of new and ambitious climate policy (Tindall et al. 2018).

1 Further, the ideological stance of media also influences the intensity and content of media coverage, in
2 developed and developing countries alike (Dotson et al. 2012; Stoddart and Tindall 2015).

3 Who dominates the debate on media, and how open the debate can be varies significantly across countries
4 (Takahashi 2011; Poberezhskaya 2015) based on participants' material and technological power. Fossil fuel
5 industries have unique access to mainstream media (Geels 2014) via advertisements, shaping narratives of
6 media reports, and exerting political influence in countries like Australia and the US (Holmes and Star 2018;
7 Karceski et al. 2020). For social media, novel technical tools, such as automated bots, are emerging to shape
8 climate change discussion on major online platforms such as Twitter (Marlow et al. 2021). Open debates can
9 underpin the adoption of more ambitious climate policy (Lyytimäki 2011). Media coverage on energy saving,
10 patriotism, and social justice in the countries like US and the UK have helped connect mitigation of climate
11 change with other concerns, thereby raising support to climate action (Leiserowitz 2006; Trope et al. 2007;
12 Doyle 2016; Corner and Clarke 2017; Markowitz and Guckian 2018; Whitmarsh and Corner 2017). Further,
13 media coverage of climate change mitigation has influenced public opinions through discussions on political,
14 economic, scientific and cultural themes about climate change (Irwin and Wynne 1996; Smith 2000; Boykoff
15 2011; O'Neill et al. 2015) (*medium evidence, high agreement*).

16 Common challenges in reporting climate change exist around the world (Schäfer and Painter 2021; Schmidt
17 et al. 2013), but particularly so in the developing countries, due to lower capacities, lack of journalists'
18 training in complex climate subjects, and lack of access to clear, timely and understandable climate-related
19 resources and images in newsrooms (Harbinson 2006; Shanahan 2009; Broadbent et al. 2016; Lück et al.
20 2018) (*robust evidence, high agreement*). Ugandan journalist Patrick Luganda has said, "Those most at risk
21 from the impacts of climate change typically have had access to the least information about it through mass
22 media." (Boykoff, 2011), indicating that information availability and capacity is a manifestation of global
23 climate (in)justice.

24

25 **13.5 Subnational actors, networks, and partnerships**

26 In many countries, subnational actors and networks are a crucial component of climate mitigation as they
27 have remit over land use planning, waste management, infrastructure, housing and community development,
28 and their jurisdictions are often where the impacts of climate change are felt (*robust evidence, high
29 agreement*). Depending on the legal framework and other institutional constraints, subnational actors play
30 crucial roles in developing, delivering and contesting decarbonisation visions and pathways (Schroeder et al.
31 2013; Ryan 2015; Amundsen et al. 2018; Fuhr et al. 2018; Bäckstrand et al. 2017; Abbott et al. 2016) (Section
32 13.3.3).

33 Sub-national actors include organizations, jurisdictions, and networks (e.g., a coalition of cities or state
34 authorities). These are either formal or informal, profit or non-profit and public or private (Avelino and
35 Wittmayer 2016). For example, corporations are formal, private, and for-profit, the state and labour
36 organizations are formal, public, and non-profit, and communities are private, informal, and non-profit. An
37 intermediary sector, crossing the boundaries between private and public, for profit and non-profit, includes
38 energy cooperatives, not-for-profit energy enterprises, and the scientific community (Avelino and Wittmayer
39 2016).

40 To address the challenge of climate mitigation, a range of actors across sectors and jurisdictions have created
41 coalitions for climate governance, operating as actor-networks. For example, mitigation policies are
42 particularly effective when they are integrated with co-benefits such as health, biodiversity, and poverty
43 reduction (Romero-Lankao et al. 2018a). Transnational business and public-private partnerships and
44 initiatives, as well as international co-operation at the sub-national and city levels are discussed in Chapter
45 14.

46

1 **13.5.1 Actor-networks, and policies**

2 The decision adopting the Paris Agreement welcomed contributions of subnational actors to mobilizing and
3 scaling up ambitious climate action (see also Chapter 14). They engage in climate relevant mechanisms, such
4 as the Sustainable Development Goals and the New Urban Agenda. Subnational actors fill a gap in national
5 policies, participate in transnational and subnational climate governance networks and facilitate learning and
6 exchange among governmental, community, and private organizations at multiple levels, gathering
7 knowledge and best practices such as emission inventories and risk management tools that can be applied in
8 multiple contexts (Kona et al. 2016; Sharifi and Yamagata 2016; Michaelowa and Michaelowa 2017;
9 Warbroek and Hoppe 2017; Bai et al. 2018; Busch et al. 2018; Hsu et al. 2018; Lee and Jung 2018; Marvin
10 et al. 2018; Romero-Lankao et al. 2018b; Ürge-Vorsatz and Seto 2018; Heikkinen et al. 2019; Amundsen et
11 al. 2018; Hultman et al. 2020).

12 Subnational climate change policies exist in more than 142 countries and exemplify the increasing
13 significance of mitigation policy at the subnational level (Hsu et al. 2018). However, estimations of the
14 number of subnational actors pledging voluntary climate action are challenging and underreporting is a
15 concern (Chan and Morrow 2019; Hsu et al. 2018). As can be seen in Figure 13.3 more than 10,500 cities
16 and nearly 250 regions representing more than 2 billion people, factoring for overlaps in population between
17 these jurisdictions, have pledged climate action as of December 2020 (Hsu et al. 2020a). More jurisdictions
18 in Europe and North America have pledged action, but in terms of population almost all regions are
19 substantially engaged in subnational action.

20 Many of these efforts are organised around transnational or regional networks. For example, a coalition of
21 130 subnational (i.e., state, and regional) governments, representing 21% of the global economy and 672
22 million people, has pledged about 9% emissions reduction compared to a base year (CDP 2020). More than
23 10,000 cities, representing more than 10 percent of the global population, participate in the Global Covenant
24 of Mayors, C40 Cities (Global Covenant of Mayors for Climate and Energy 2018), and ICLEI's - Local
25 Governments for Sustainability carbon registry (Hsu et al. 2018). In Europe alone, more than 6,000 cities
26 have adopted their own climate action plans (Palermo et al. 2020a) and nearly 300 U.S. subnational actors –
27 cities and states - were committed to maintaining momentum for climate action as part of 'We Are Still In
28 coalition' (We Are Still In coalition 2020) in the absence of national U.S. climate legislation. Further, as of
29 October 2020, more than 826 cities and 103 regional governments had made specific pledges to decarbonize,
30 whether in a specific sector (e.g., buildings, electricity, or transport) or through their entire economies,
31 pledging to reduce their overall emissions by at least 80 percent or greater (NewClimate Institute and Data
32 Driven EnviroLab 2020). Cities such as Barcelona, Spain and Seattle, Washington have adopted net zero
33 goals for 2050 in policy legislation, while many more cities throughout the world, including the Global South
34 such as Addis Ababa in Ethiopia, have net zero targets under consideration (Energy & Climate Intelligence
35 Unit 2019, 2021).

36

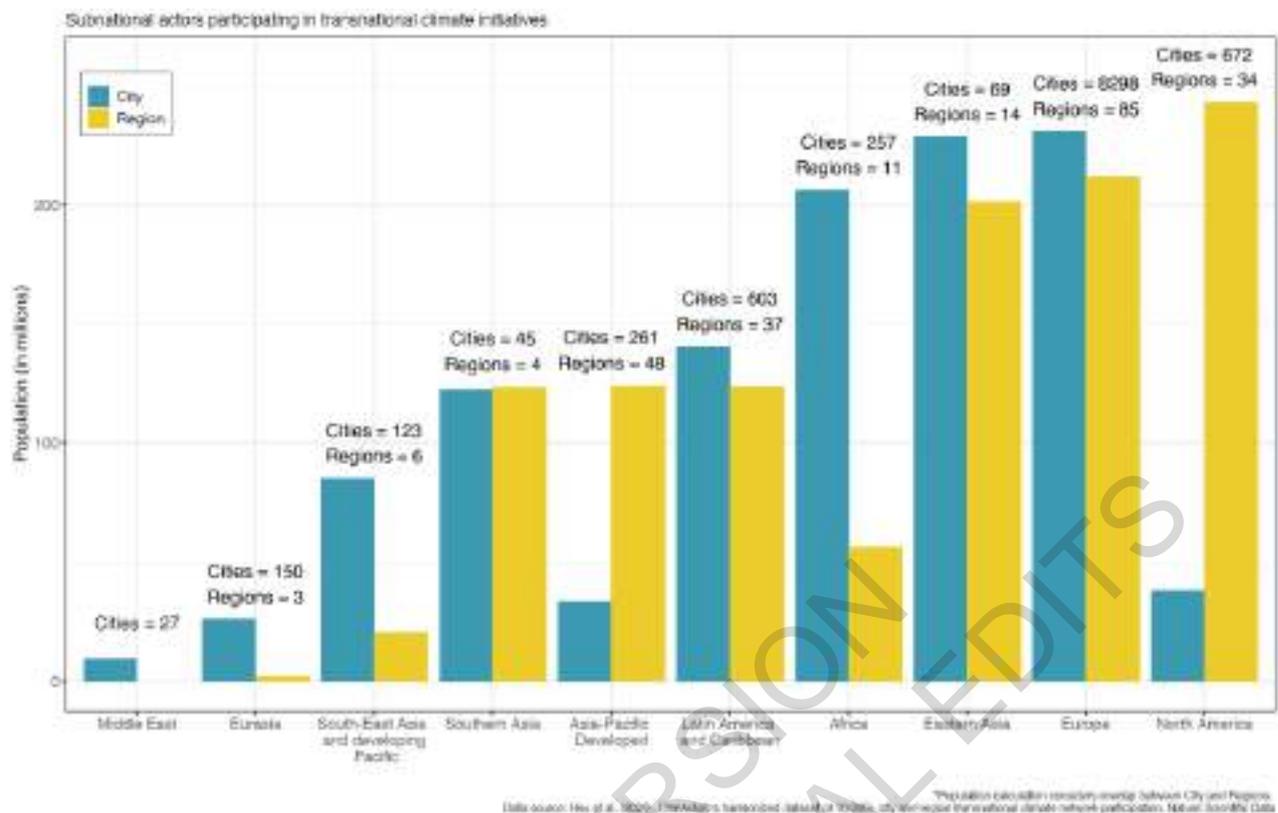

Figure 13.3 Sub-national GHG mitigation commitments: Total population by IPCC region

Population of subnational actors (cities and regions) recording climate action commitments as captured in the ClimActor dataset. Population calculation considers overlap between City and Regions by only accounting for population once for Cities and Regions that are nested jurisdictions

Source: Adapted from (Hsu et al. 2020a) to reflect IPCC AR6 aggregation. Compiled in 2020 from multiple sources based on most recent year of data available.

Sub-national mitigation policies are highlighted below, based on the taxonomy of policies in 13.6.1:

- a) Economic instruments: As of 2020, there were carbon pricing initiatives (ETS, carbon tax or both) in 24 subnational jurisdictions (World Bank 2021a). Examples include emission trading systems within the U.S. the Regional Greenhouse Gas Initiative (RGGI) and Western Climate Initiative, tax rebates for the purchase of EVs, a carbon tax in British Columbia, and a cap-and-trade scheme in Metropolitan Tokyo (Houle et al. 2015; Murray and Rivers 2015; Hibbard et al. 2018; Bernard and Kichian 2019; Raymond 2019; Xiang and Lawley 2019; Chan and Morrow 2019).
- b) Regulatory instruments: Policies such as land use and transportation planning, performance standards for buildings, utilities, transport electrification, and energy use by public utilities, buildings and fleets are widely prevalent (Bulkeley 2013; Jones 2013; C40 and ARUP 2015; Martinez et al. 2015; Hewitt and Coakley 2019; Palermo et al. 2020b). Policies such as regulatory restrictions, low emission zones, parking controls, delivery planning and freight routes, focus on traffic management and reduction of local air pollution but also have a mitigation impact (Slovic et al. 2016; Khreis et al. 2017; Letnik et al. 2018). For instance, in coordination with national governments, subnational actors in China, Europe and US have introduced access to priority lanes, free parking and other strategies fostering the roll-out of EVs (Creutzig 2016; Zhang and Bai 2017; Teske et al. 2018; Zhang and Qin 2018; Romero-Lankao et al. 2021).

- 1 c) Land-use planning addresses building form, density, energy, and transport, which are relevant for
2 decarbonisation (Creutzig et al. 2015; Torabi Moghadam et al. 2017; Teske et al. 2018). Its
3 effectiveness is limited by absent or fragmented jurisdiction, financial resources and powers,
4 competition between authorities and policy domains, and national policies that restrict local
5 governments' ability to enact more ambitious policies (Fudge et al. 2016; Gouldson et al. 2016;
6 Petersen 2016). Most rapidly growing smaller cities in Latin America, Asia and Africa lack capacity
7 for urban planning and enforcement (Romero-Lankao et al. 2015; Creutzig 2016).
- 8 d) Other policies: These include information and capacity building, such as carbon labelling aimed at
9 providing carbon footprint information to consumers (Liu et al. 2016); disclosure and benchmarking
10 policies in buildings to increase awareness of energy issues and track mitigation progress (Hsu et al.
11 2017; Papadopoulos et al. 2018); and procurement guidelines developed by associations (Sustainable
12 Purchasing Leadership Council 2021). For instance, a building retrofit program was initiated in New
13 York and Melbourne to foster energy efficiency improvements through knowledge provision,
14 training, and consultation (Trencher et al. 2016; Trencher and van der Heijden 2019).
15 Also significant is government provision of public good, services, and infrastructure (Romero
16 Lankao et al. 2019), which includes provision of electric buses or buses on renewable fuels for public
17 transportation (Kamiya and Teter 2019) and zero emission urban freight transport (Quak et al. 2019),
18 sustainable food procurement for public organizations in cities (Smith et al. 2016), decentralized
19 energy resources (Marquardt 2014; Hirt et al. 2021; Kahsar 2021), and green electricity purchase via
20 community choice aggregation programs and franchise agreements (Armstrong 2019).

21 22 **13.5.2 Partnerships and experiments**

23 Partnerships, such as those among private and public, or transnational and subnational entities, have been
24 found to enable better mitigation results in areas outside direct government control such as residential energy
25 use, emissions from local businesses, or private vehicles (Fenwick et al. 2012; Castán Broto and Bulkeley
26 2013; Aylett 2014; Hamilton et al. 2014; Bulkeley et al. 2016; Wakabayashi and Arimura 2016; Grandin
27 et al. 2018). Partnerships take advantage of investments that match available grants or enable a local energy
28 project, or enhance the scope or impact of mitigation (Burch et al. 2013).

29 Subnational actors have also been associated with experiments and laboratories, which promise to achieve
30 the deep change required to address the climate mitigation gap (Smeds and Acuto 2018; Marvin et al. 2018).
31 Experiments span smart technologies (e.g., in Malmö, Sweden (Parks 2019), Eco-Art, Transformation-Labs
32 and other approaches that question the cultural basis of current energy regimes and seek reimaged or
33 reinvented futures (Guy et al. 2015; Voytenko et al. 2016; Hodson et al. 2018; Peng and Bai 2018; Culwick
34 et al. 2019; Pereira et al. 2019; Sengers et al. 2019; Castán Broto and Bulkeley 2013; Smeds and Acuto
35 2018). They may include governance experiments, from formally defined policy experiments to informal
36 initiatives that mobilise new governance concepts (Kivimaa et al. 2017a; Turnheim et al. 2018), and co-
37 design initiatives and grassroots innovations (Martiskainen 2017; Sheikh and Bhaduri 2021). These
38 initiatives often expand the scope for citizen participation. For example, Urban Living Labs foster
39 innovation, coproducing responses to existing problems of energy use, energy poverty and mobility that
40 integrate scientific and expert knowledge with local knowledge and common values (Voytenko et al. 2016;
41 Marvin et al. 2018). The European Network of Living Labs- with a global outreach- has established a model
42 of open and citizen-centric innovation for policy making. The proliferation of Climate Assemblies at the
43 national and sub-national level further emphasises the increasing role that citizens can play in both innovating
44 and planning for carbon mitigation (Sandover et al. 2021).

45 State and local authorities are often central to initiating and implementing experiments and use an
46 incremental, 'learning by doing' governing approach (Bai et al. 2010; Nevens et al. 2013; Mcguirk et al.
47 2015; Nagorny-Koring and Nocht 2018; Castán Broto and Bulkeley 2013; Hodson et al. 2018; Peng and

1 Bai 2018; Smeds and Acuto 2018; Culwick et al. 2019; Sengers et al. 2019). Experiments relate to
2 technological learning and changes in policies, practices, services, user behaviour, business models,
3 institutions, and governance (Wieczorek et al. 2015; Kivimaa et al. 2017a; Laurent and Pontille 2018;
4 Torrens et al. 2019; Castán Broto and Bulkeley 2013).

5 Experimentation has contributed to learning, changes in outcomes when implemented, and shifts in the
6 political landscape (Turnheim et al. 2018). Experiments, however, are often isolated and do not always result
7 in longer-term, more widespread changes. The transformative potential (understood as changes in the
8 fundamental attributes of natural and human systems, see Glossary) of experiments is constrained by
9 uncertainty about locally relevant climate change solutions and effects; a lack of comprehensive, and
10 sectorally inclusive national policy frameworks for decarbonisation; budgetary and staffing limitations; and
11 a lack of institutional and political capacity to deliver integrated and planned approaches (Evans and
12 Karvonen 2014; Wittmayer et al. 2016; Webb et al. 2017; Hölscher et al. 2018; Mcguirk et al. 2015; Bulkeley
13 et al. 2016; Grandin et al. 2018; Nagorny-Koring 2019; Sengers et al. 2019; Voytenko et al. 2016).

14

15 **13.5.3 Performance and global mitigation impact**

16 The performance of subnational actors' mitigation policies have been measured using criteria such as
17 existence of mitigation targets, incentives for mitigation, definition of a baseline, and existence of a
18 monitoring, reporting, and verification procedure (Hsu et al. 2019). Existing evaluations range from small-
19 scale studies assessing the mitigation potential of commitments by subnational regions, cities and companies
20 in the U.S. or in ten high-emitting economies (Roelfsema 2017; Hsu et al. 2019), to larger studies finding
21 that over 9,149 cities worldwide could mitigate 1,400 MtCO₂-eq in 2030 (Global Covenant of Mayors for
22 Climate and Energy 2018; Hsu et al. 2018, 2019). These subnational mitigation potential estimates vary since
23 a range of approaches exists for accounting for overlaps between subnational governments and their nested
24 jurisdictions (e.g., states, provinces, and national governments) (Roelfsema et al. 2018; Hsu et al. 2019). One
25 analysis found that the cities of New York, Berlin, London, Greater Toronto, Boston, and Seattle have
26 achieved on average a 0.27 tCO₂-eq per capita per year reduction (Kennedy et al. 2012). Hsu et al. (Hsu et
27 al. 2020c) found that 60 percent of more than 1,000 European cities, representing 6 percent of the EU's total
28 emissions, are on track to achieving their targets, reducing more than 51 million tons MtCO₂-eq. While
29 evidence is limited, there are concerns that implementation challenges persist with city level plans,
30 particularly tied to management of initiatives and engagement of the population (Messori et al. 2020).

31 Whether participation in transnational climate initiatives impacts subnational governments' achievement on
32 climate mitigation goals is uncertain. Some find that higher ambition in climate mitigation commitments did
33 not translate into greater mitigation (Kona et al. 2016; Hsu et al. 2019). Other studies associate participation
34 in networks with increased solar PV investment (Khan and Sovacool 2016; Steffen et al. 2019), and with
35 potential to achieve carbon emissions reductions per capita in line with a global 2 °C scenario (Kona et al.
36 2016).

37 Reporting networks may attract high-performing actors, suggesting an artificially high level of cities
38 interested in taking climate action or piloting solutions (self-selection bias) that may not be effective
39 elsewhere (van der Heijden 2018). Many studies present a conservative view of potential mitigation impact
40 because they draw upon publicly reported mitigation actions and exclude subnational actions that are not
41 reported (Kuramochi et al. 2020)

42 In addition to direct mitigation contributions, climate action partnerships may deliver indirect effects that,
43 while difficult to quantify, ensure long-term change (Chan et al. 2015). Experimentation and policy
44 innovation helps to establish best practices (Hoffmann 2011); set new norms for ambitious climate action
45 that help build coalitions (Bernstein and Hoffmann 2018; Chan et al. 2015); and translate into knowledge
46 sharing or capacity building (Lee and Koski 2012; Purdon 2015; Acuto and Rayner 2016; Hakelberg 2014).

1 Emergent research explores whether, in addition to realising outcomes, mitigation initiatives also provide
 2 the resources, skills and networks that governments and other stakeholders currently use to target other
 3 development goals (Shaw et al. 2014; Wolfram 2016; Wiedenhofer et al. 2018; Amundsen et al. 2018;
 4 Heikkinen et al. 2019).

6 **13.6 Policy instruments and evaluation**

7 Institutions and governance processes described in previous section result in specific policies, that
 8 governments then implement and that shape actions of many stakeholders. This section assesses the empirical
 9 experience with the range of policy instruments available to governments with which to shape mitigation
 10 outcomes. Section 13.7 that follows deals with how these instruments are combined into packages, and
 11 Section 13.9 addresses economy-wide measures and issues.

12 Many different policy instruments for GHG reduction are in use. They fall into a few major categories that
 13 share key characteristics. This section provides one possible taxonomy of these major types of policy
 14 instruments, presents a set of criteria for policy evaluation, and synthesizes the literature on the most common
 15 mitigation policies. The emphasis is on recent empirical evidence on the performance of different policy
 16 instruments and lessons that can be drawn from these experiences. This builds on and enhances the AR5
 17 Chapter 15, which provided a more theoretical treatment of policy instruments for mitigation.

19 **13.6.1 Taxonomy and overview of mitigation policies**

20 *13.6.1.1 Taxonomy of mitigation policies*

21 A large number of policies and policy instruments can affect GHG emissions and/or sequestration, whether
 22 their primary purpose is climate change mitigation or not. Consequently, consistent with the approach in this
 23 chapter, this section adopts a broad interpretation to what is considered mitigation policy. Also, the section
 24 recognizes the multiplicity of policies that overlap and interact.

25 Environmental policy instruments, including for climate change mitigation, have long been grouped into
 26 three main categories – (1) economic instruments, (2) regulatory instruments, and (3) other instruments –
 27 although the specific terms differ across disciplines and additional categories are common (Kneese and
 28 Schultze 1975; Jaffe and Stavins 1995; Nordhaus 2013; Wurzel et al. 2013). Examples of common policies
 29 in each category are shown in Table 13.1, but this is not a comprehensive list. Principles of and empirical
 30 experience with the various instruments are synthesized in Sections 13.6.3 to 13.6.5, international
 31 interactions are covered in 13.6.6.

33 **Table 13.1 Classification of mitigation policies**

Category	Examples of common types of mitigation policy instruments
Economic instruments	Carbon taxes, GHG emissions trading, fossil fuel taxes, tax credits, grants, renewable energy subsidies, fossil fuel subsidy reductions, offsets, R&D subsidies, loan guarantees
Regulatory instruments	Energy efficiency standards, renewable portfolio standards, vehicle emission standards, ban on SF ₆ uses, biofuel content mandates, emission performance standards, methane regulations, land-use controls
Other instruments	Information programs, voluntary agreements, infrastructure, government technology procurement policies, corporate carbon reporting

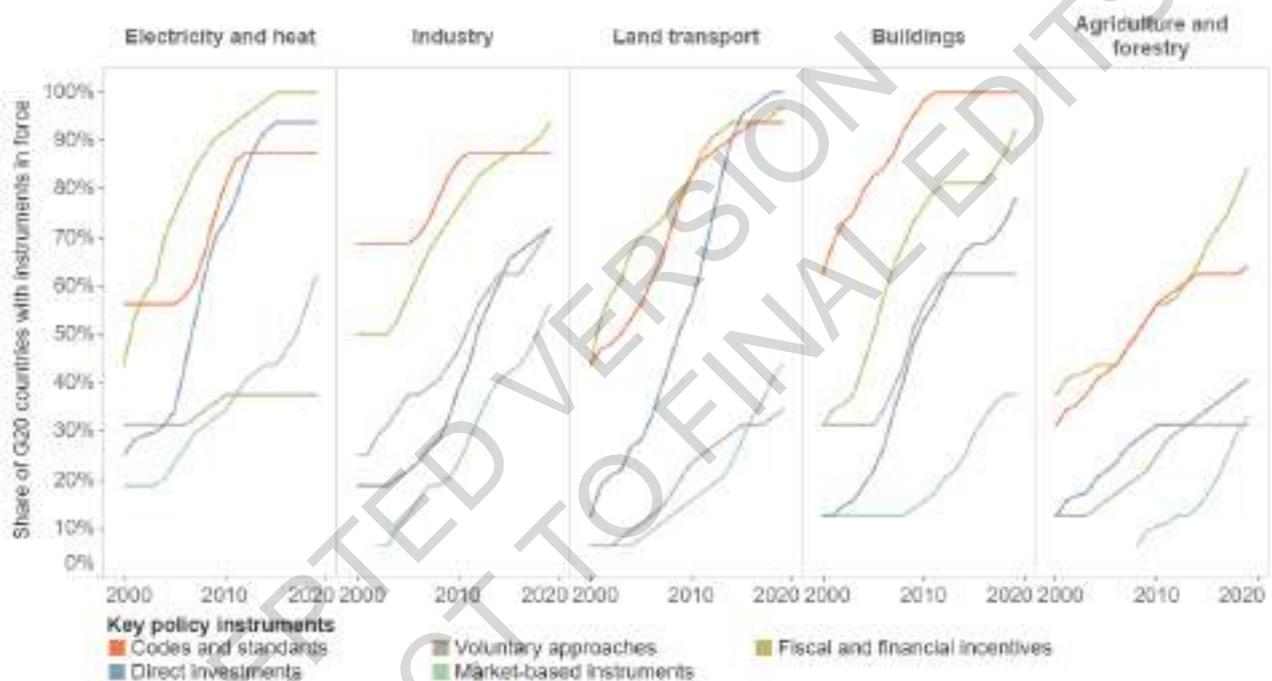

1 13.6.1.2 Coverage of mitigation policies

2 An increasing share of global emissions sources is subject to mitigation policies, though coverage is still
3 incomplete (Nascimento et al. 2021; Eskander and Fankhauser 2020).

4 While consistent information on global prevalence of policies is not available, in G20 countries the use of
5 various policy instruments has increased steadily over the past two decades (Nascimento et al. 2021). The
6 share of countries that had mitigation policy instruments in place rose across all sectoral categories, albeit to
7 different extents in different sectors and for different policy instruments (Figure 13.4). Among G-20
8 countries the electricity and heat generation has the greatest number of policies in place, and the agriculture
9 and forestry sector the fewest (Nascimento et al. 2021).

10 The mix of policies has shifted towards more regulatory instruments and carbon pricing relative to
11 information policies and voluntary action (Schmidt and Fleig 2018; Eskander and Fankhauser 2020).

12

13

14 **Figure 13.4 Share of countries that adopted different policy instruments in different sectors, 2000-2020 (three**
15 **year moving average).**

16 Source: Reproduced from (Nascimento et al. 2021).

17 The IEA database, which tracks renewable energy and energy efficiency policies at the national and sub-
18 national levels for about 160 countries, indicates an average of about 225 new renewable energy and energy
19 efficiency policies annually from 2010 through 2019 with a peak in the number of new renewable energy
20 policies in 2011 (IEA 2021).

21 While an increasing share of CO₂ emissions from fossil fuel combustion is subject to mitigation policies,
22 there remain many countries and sectors where no dedicated mitigation policies apply to fuel combustion.
23 Fossil fuel use is subject to energy taxes in the majority but not all jurisdictions, and in some instances, it is
24 subsidised.

25 The main gaps in current mitigation policy coverage are non-CO₂ emissions and CO₂ emissions associated
26 with production of industrial materials and chemical feedstocks, which are connected to broader questions
27 of shifting to cleaner production systems (Bataille et al. 2018a; Davis et al. 2018). Sequestration policies

1 focus mainly on forestry and CCS with limited support for other carbon dioxide removal and use options
2 (Geden et al. 2019; Vonhedemann et al. 2020).

3 **13.6.1.3 Stringency and overall effectiveness of mitigation policies**

4 The stringency of mitigation policies varies greatly by country, sector and policy (see Box 13.9). Stringency
5 can be increased through sequential changes to policies (Pahle et al. 2018).

6 Estimates of the effective carbon price (as an estimate of overall stringency across policy instruments) differ
7 greatly between countries and sectors (World Bank 2021a). Countries with higher overall effective carbon
8 prices tend to have lower carbon intensity of energy supply and lower emissions intensity of the economy,
9 as shown in an analysis of 42 G20 and OECD countries (OECD 2018). The carbon price that prevails under
10 a carbon tax or ETS is not directly a measure of policy stringency across an economy, as the carbon prices
11 typically only cover a share of total emissions, and rebates or free allowance allocations can limit
12 effectiveness (OECD 2018). At low emissions prices, mitigation incentives are small; as of April 2021,
13 seventeen jurisdictions with a carbon pricing policy had a tax rate or allowance price less than USD5 per
14 tCO₂ (World Bank 2021a).

15

16 **START BOX 13.9 HERE**

17

Box 13.9 Comparing the stringency of mitigation policies

18 Comparing the stringency of policies over time or across jurisdictions is very challenging and there is no
19 single widely accepted metric or methodology (Tosun and Schnepf 2020; Fekete et al. 2021; Compston and
20 Bailey 2016; Burck et al. 2019). Policies are also assessed for their estimated effect on emissions, however
21 this requires estimation of a counterfactual baseline and isolation of other effects (see Cross-Chapter Box 10
22 in Chapter 14). Economic instruments can be compared on the basis of their price or cost per tCO₂-eq. Even
23 that is fraught with complexity in the context of different definitions and estimations for fossil fuel taxes and
24 subsidies. For non-price policies an implicit or equivalent carbon price can be estimated. Factors such as the
25 tax treatment of compliance costs can increase complexity. Accounting for the combined effect of
26 overlapping policies presents additional challenges and such estimates are subject to numerous limitations.

27 **END BOX 13.9 HERE**

28

29 Other policies, such as fossil fuel subsidies, may provide incentives to increase emissions thus limiting the
30 effectiveness of the mitigation policy (Section 13.6.3.6). Those effects may be complex and difficult to
31 identify. In most countries trade policy provides an implicit subsidy to CO₂ emissions (Shapiro 2020). The
32 analysis of emissions from energy use in buildings in Chapter 9 illustrates the factors that support and
33 counteract mitigation policies.

34 Furthermore, emissions pricing policies encourage reduction of emissions whose marginal abatement cost is
35 lower than the tax/allowance price, so they have limited impact on emissions with higher abatement costs
36 such as industrial process emissions (Bataille et al. 2018a; Davis et al. 2018). EU ETS emission reductions
37 have been achieved mainly through implementation of low cost measures such as energy efficiency and fuel
38 switching rather than more costly industrial process emissions.

39 Estimating the overall effectiveness of mitigation policies is difficult because of the need to identify which
40 observed changes in emissions and their drivers are attributable to policy effort and which to other factors.
41 Cross-Chapter Box 10 in Chapter 14 brings together several lines of evidence to indicate that mitigation
42 policies have had a discernible impact on mitigation for specific countries, sectors and technologies and led
43 to avoided global emissions to date by several billion tonnes CO₂-eq annually (*medium evidence, medium
44 agreement*).

1

2 **13.6.2 Evaluation criteria**

3 Policy evaluation is a “careful, retrospective assessment of merit, worth and value of the administration,
4 output and outcomes of government interventions” (Vedung 2005). The inherent complexity of climate
5 mitigation policies calls for the application of multiple criteria, and reflexiveness of analysis with regard to
6 governments’ and societies’ objectives for policies (Huitema et al. 2011).

7 Evaluation of climate mitigation policy tends to focus on the environmental effectiveness and economic
8 efficiency or cost-effectiveness of GHG mitigation policies, with distributional equity sometimes as an
9 additional criterion. In policy design and implementation there is rising interest in co-benefits and side-
10 effects of climate policies, as well as institutional requirements for implementation and the potential of
11 policies to have transformative effect on systems. Table 13.2 elaborates.

12 Not all criteria are applicable to all instruments or in all circumstances and the relative importance of different
13 criteria depend on the objectives in the specific the context. A given policy instrument may score highly on
14 only some assessment criteria. In practice, the empirical evidence seldom exists for assessment of a policy
15 instrument across all criteria.

16

17

Table 13.2 Criteria for evaluation and assessment of policy instruments and packages

Criterion	Description
Environmental effectiveness	Reducing GHG emissions is the primary goal of mitigation policies and therefore a fundamental criterion in evaluation. Environmental effectiveness has temporal and spatial dimensions.
Economic effectiveness	Climate change mitigation policies usually carry economic costs, and/or bring economic benefits other than through avoided future climate change. Economic effectiveness requires minimizing costs and maximizing benefits.
Distributional effects	The costs and benefits of policies are usually distributed unequally among different groups within a society (Zachmann et al. 2018), for example between industry, consumers, taxpayers; poor and rich households; different industries; different regions and countries. Policy design affects distributional effects, and equity can be taken into account in policy design in order to achieve political support for climate policies (Baranzini et al. 2017).
Co-benefits, negative side-effects	Climate change mitigation policies can have effects on other objectives, either positive co-benefits (Mayrhofer and Gupta 2016; Karlsson et al. 2020) or negative side-effects. Conversely, impacts on emissions can arise as side-effects of other policies. There can be various interactions between climate change mitigation and the Sustainable Development Goals (Liu et al. 2019).
Institutional requirements	Effective implementation of policies requires that specific institutional prerequisites are met. These include effective monitoring of activities or emissions and enforcement, and institutional structures for the design, oversight and revision and updating of policies. Requirements differ between policy instruments. A

separate consideration is the overall feasibility of a policy within a jurisdiction, including political feasibility (Jewell and Cherp 2020).

Transformative potential

Transformational change is a process that involves profound change resulting in fundamentally different structures (Nalau and Handmer 2015), or a substantial shift in a system's underlying structure (Hermwille et al. 2015). Climate change mitigation policies can be seen as having transformative potential if they can fundamentally change emissions trajectories, or facilitate technologies, practices or products with far lower emissions.

1

2 13.6.3 Economic instruments

3 Economic instruments, including carbon taxes, emissions trading systems (ETS), purchases of emission
4 reduction credits, subsidies for energy efficiency, renewables and research and development and fossil fuel
5 subsidy removal, provide a financial incentive to reduce emissions. Pricing instruments, especially ETS and
6 carbon taxes, have become more prevalent in recent years (Section 13.6.1). They have proven effective in
7 promoting implementation of the low-cost emissions reductions, and practical experience has driven progress
8 in market mechanism design (*robust evidence, high agreement*).

9 13.6.3.1 Carbon taxes

10 A carbon tax is a charge on carbon dioxide or other greenhouse gases imposed on specified emitters or
11 products. In practice features such as exemptions and multiple rates can lead to debate as to whether a specific
12 tax is a carbon tax (Haites 2018). While other taxes can also reduce emissions by increasing the price of
13 GHG emitting products, the result may be inefficient unless the tax rate is proportional to the emissions
14 intensity. A tax on value of fossil fuels, for example, could raise the price on natural gas more than the price
15 of coal, and hence increase emissions if the resulting substitution towards coal were to outweigh reductions
16 in energy use.

17 As of April 2021, 27 carbon taxes had been implemented by national governments, mostly in Europe (World
18 Bank 2021a). Most of the taxes apply to fossil fuels used for transportation and heating and cover between
19 3% and 79% of the jurisdiction's emissions. Several countries also tax F-gases. Tax rates vary widely from
20 less than USD1 to over USD137 per tCO₂-eq. A few jurisdictions lowered existing fuel taxes when they
21 implemented the carbon tax, thus reducing the effective tax rate (OECD 2021a). How the tax revenue is used
22 varies widely by jurisdiction.

23 Carbon taxes tend to garner the least public support among possible mitigation policy options (Rhodes et al.
24 2017; Rabe 2018; Maestre-Andrés et al. 2019; Criqui et al. 2019) although some regulations also meet with
25 opposition (Attari et al. 2009). Policymakers sometimes use the revenue to build support for the tax,
26 allocating some to address regressivity, to address competitiveness claims by industry, to reduce the
27 economic cost by lowering existing taxes, and to fund environmental projects (Gavard et al. 2018; Klenert
28 et al. 2018; Levi et al. 2020).

29 Carbon tax rates can be adjusted for inflation, increases in income, the effects of technological change,
30 changing policy ambition, or the addition or subtraction of other policies. In practice numerous jurisdictions
31 have not increased their tax rates annually and some scheduled tax increases have not been implemented
32 (Haites et al. 2018). Predictability of future tax rates helps improve economic performance (Bosetti and
33 Victor 2011; Brunner et al. 2012). Uncertainty about the future existence of a carbon price can hinder
34 investment (Jotzo et al. 2012) and uncertainty about future price levels can increase the resource costs of
35 carbon pricing (Aldy and Armitage 2020).

1 **13.6.3.2 Emission trading systems**

2 The most common ETS design – cap-and-trade – sets a limit on aggregate GHG emissions by specified
3 sources, distributes tradable allowances approximately equal to the limit, and requires regulated emitters to
4 submit allowances equal to their verified emissions. The price of allowances is determined by the market,
5 except in cases where government determined price floors or ceilings apply.

6 ETSs for GHGs were in place in 38 countries as of April 2021 (World Bank 2021a). The EU ETS, which
7 covers 30 countries, was recently displaced by China’s national ETS as the largest. ETSs tend to cover
8 emissions by large industrial and electricity generating facilities.³ Allowance prices as of April 1, 2021
9 ranged from just over USD1 to USD50, and coverage between 9 and 80% of the jurisdiction’s emissions.

10 Multiple regional pilot ETSs with different designs have been implemented in China since 2013 to provide
11 input to the design of a national system that is to become the world’s largest ETS (Jotzo et al. 2018; Qian et
12 al. 2018; Stoerk et al. 2019). Assessments have identified potential improvements to emissions reporting
13 procedures (Zhang et al. 2019) and the pilot ETS designs (Deng et al. 2018). China’s national ETS covering
14 over 2,200 heat and power plants with annual emissions of about 4 billion tCO₂ took effect in 2021 (World
15 Bank 2021a).

16 All of the ETSs for which data are available have accumulated surplus allowances which reduces their
17 effectiveness (Haites 2018). Surplus allowances indicate that the caps set earlier were not stringent relative
18 to emissions trends. Most of those ETSs have implemented measures to reduce the surplus including
19 removal/cancellation of allowances and more rapid reduction of the cap. Several ETSs have adopted
20 mechanisms to remove excess allowances from the market when supply is abundant and release additional
21 allowances into the market when the supply is limited, such as the EU “market stability reserve” (Hepburn
22 et al. 2016; Bruninx et al. 2020). Initial indications are that this mechanism is at least partially successful in
23 stabilizing prices in response to short term disruptions such as the COVID-19 economic shock (Gerlagh et
24 al. 2020; Bocklet et al. 2019).

25 Some ETS also include provisions to limit the range of market prices, making them ‘hybrids’ (Pizer 2002).
26 A price floor assures a minimum level of policy effect if demand for allowances is low relative to the ETS
27 emissions cap. It is usually implemented through a minimum price at auction, as for example in California’s
28 ETS (Borenstein et al. 2019). A price ceiling allows the government to issue unlimited additional allowances
29 at a pre-determined price to limit the maximum cost of mitigation. Price ceilings have not been activated to
30 date.

31 **13.6.3.3 Evaluation of carbon pricing experience**

32 A carbon tax or GHG ETS increases the prices of emissions intensive goods thus creating incentives to
33 reduce emissions (see (Stavins 2019) for a comparison of a tax and ETS). The principal advantage of a
34 pricing policy is that it promotes implementation of low cost reductions; for a carbon tax, reductions whose
35 cost per tCO₂-eq reduced is lower than the tax and for an ETS the lowest cost (per tCO₂-eq) reductions
36 sufficient to meet the cap. Both a tax and an ETS can be designed to limit adverse economic impacts on
37 regulated sources and emissions leakage.

38 The corresponding limitations of pricing policies are that they have limited impact on adoption of mitigation
39 measures when decisions are not sensitive to prices and do not encourage adoption of higher cost mitigation
40 measures. Their effectiveness in influencing long-term investments depends on the expectation that the
41 policy will continue and expectations related to future tax rates or allowance prices (Brunner et al. 2012).
42 Other policies can be used in combination with carbon pricing to address these limitations.

FOOTNOTE ³ The UK was a member of the EU ETS until December 31, 2020. A UK Emissions Trading Scheme (UK ETS) came into effect on January 1, 2021.

1 The number of pricing policies has increased steadily and covered 21.5% of global GHG emissions in 2020
2 (World Bank 2021a). Effective coverage is lower because virtually all jurisdictions with a pricing policy
3 have other policies that affect some of the same emissions. For example, a few jurisdictions reduced existing
4 fuel taxes when they introduced their carbon tax thus reducing the effective tax rate, and many jurisdictions
5 have two or more pricing policies

6 *Environmental effectiveness and co-benefits*

7 There is abundant evidence that carbon pricing policies reduce emissions. Statistical studies of emissions
8 trends in jurisdictions with and without carbon pricing find a significant impact after controlling for other
9 policies and structural factors (Best et al. 2020; Rafaty et al. 2020). Numerous assessments of specific
10 policies, especially the EU ETS and the British Columbia carbon tax, conclude that most have reduced
11 emissions (Narassimhan et al. 2018; FSR Climate 2019; Haites et al. 2018; Metcalf and Stock 2020; Rafaty
12 et al. 2020; Green 2021; Aydin and Esen 2018; Pretis 2019; Andersson 2019; Arimura and Abe 2021; Bayer
13 and Aklin 2020; Diaz et al. 2020) (*robust evidence, high agreement*).

14 Estimating the emission reductions due to a specific policy is difficult due to the effects of overlapping
15 policies and exogenous factors such as fossil fuel price changes and economic conditions. Studies that
16 attempt to attribute a share of the reductions achieved to the EU ETS place its contribution at 3-25% (FSR
17 Climate 2019; Bayer and Aklin 2020; Chèze et al. 2020). The relationship between a carbon tax and the
18 resulting emission reductions is complex and is influenced by changes in fossil fuel prices, changes in fossil
19 fuel taxes, and other mitigation policies (Aydin and Esen 2018). But the effectiveness of a carbon tax
20 generally is higher in countries where it constitutes a large part of the fossil fuel price (Andersson 2019).

21 Few of the world's carbon prices are at a level consistent with various estimates of the carbon price needed
22 to meet the Paris Agreement goals. In modelling of mitigation pathways likely to limit warming to 2°C
23 (Chapter 3, 3.6.1) marginal abatement costs of carbon in 2030 are about 60 to 120 USD₂₀₁₅/tCO₂, and about
24 170 to 290 USD₂₀₁₅/tCO₂ in pathways that limit warming to 1.5°C with no or limited overshoot (3.6). One
25 synthesis study estimates necessary prices at USD40–80 per tCO₂ by 2020 (High-Level Commission on
26 Carbon Prices 2017). Only a small minority of carbon pricing schemes in 2021 had prices above USD40 per
27 tCO₂, and all of these were in European jurisdictions (World Bank 2021a). Most carbon pricing systems
28 apply only to some share of the total emissions in a jurisdiction, so the headline carbon price is higher than
29 the average carbon price that applies across an economy (World Bank 2021a).

30 Where ETS or carbon taxes exist, they apply to different proportions of the jurisdiction's greenhouse gas
31 emissions. The share of emissions covered by ETSS in 2020 varied widely, ranged from 9% (Canada) to 80%
32 (California) while the share of emissions covered by carbon taxes ranged from 3% (Latvia and Spain) to
33 80% (South Africa) (World Bank 2021a). Where carbon pricing policies are effective in reducing GHG
34 emissions, they usually also generate co-benefits including better air quality. For example, a Chinese study
35 of air quality benefits from lower fossil fuel use under carbon pricing suggests that prospective health co-
36 benefits would partially or fully offset the cost of the carbon policy (Li et al. 2018). Depending upon the
37 jurisdiction (for example, if there are fossil fuel subsidies) carbon pricing could also reduce the economic
38 distortions of fossil fuel subsidies, improve energy security through greater reliance on local energy sources
39 and reduce exposure to fossil fuel market volatility. Substantial carbon prices would be in the domestic self-
40 interest of many countries if co-benefits were fully factored in (Parry et al. 2015).

41 *Economic effectiveness*

42 Economic theory suggests that carbon pricing policies are on the whole more cost effective than regulations
43 or subsidies at reducing emissions (Gugler et al. 2021). Any mitigation policy imposes costs on the regulated
44 entities. In some cases entities may be able to recover some or all of the costs through higher prices (Neuhoff
45 and Ritz 2019; Cludius et al. 2020). International competition from less stringently regulated firms limits the
46 ability of emissions-intensive, trade-exposed (EITE) firms to raise their prices. Thus a unilateral mitigation

1 policy creates a risk of adverse economic impacts, including loss of sales, employment, profits, for such
2 firms and associated emissions leakage (see Section 13.6.6.1).

3 Pricing policies can be designed to minimize these risks; free allowances can be issued to EITE participants
4 in an ETS and taxes can provide exemptions or rebates. An extensive ex post literature finds no statistically
5 significant adverse impacts on competitiveness or leakage (13.6.6.1).

6 An ex post analysis of European carbon taxes finds no robust evidence of a negative effect on employment
7 or GDP growth (Metcalfe and Stock 2020). The British Columbia carbon tax led to a small net increase in
8 employment (Yamazaki 2017) with no significant negative impacts on GDP possibly due to full recycling
9 of the tax revenue (Bernard and Kichian 2021). Few carbon taxes apply to EITE sources (Timilsina 2018),
10 so competitiveness impacts usually are not a particular concern.

11 Government revenue generated by carbon pricing policies globally was approximately USD53 billion in
12 2020 split almost evenly between carbon taxes and ETS allowance sales (World Bank 2021). Revenue raised
13 though carbon pricing is generally considered a relatively efficient form of taxation and a large share of
14 revenue enters general government budgets (Postic and Fetet 2020). Some of the revenue is returned to
15 emitters or earmarked for environmental purposes. Allowance allocation and revenue spending measures
16 have been used to create public support for many carbon pricing policies including at every major reform
17 stage of the EU ETS (Dorsch et al. 2020; Klenert et al. 2018; see also Box 5.11).

18 *Distributional effects*

19 The most commonly studied distributional impact is the direct impact of a carbon tax on household income.
20 Typically it is regressive; the tax induced increase in energy expenditures represents a larger share of
21 household income for lower income households (Grainger and Kolstad 2010; Timilsina 2018; Dorband et al.
22 2019; Ohlendorf et al. 2021). Governments can rebate part or all of the revenue to low income households,
23 or implement other changes to taxation and transfer systems to achieve desired distributional outcomes
24 (Jacobs and van der Ploeg 2019; Saelim 2019; Sallee 2019) (see also Box 5.11). The full impact of the tax –
25 after any distribution of tax revenue to households and typically adverse effects on investors – generally is
26 less regressive or progressive (Williams III et al. 2015; Goulder et al. 2019). Where the tax revenue is treated
27 as general revenue the government relies on existing income redistribution policies (such as income taxes)
28 and social safety net programs to address the distributional impacts.

29 Carbon taxes on fossil fuels have effects similar to the removal of fossil fuel subsidies (Ohlendorf et al. 2021)
30 (see also Section 13.6.3.6). Even if a carbon tax is progressive it increases prices for fuels, electricity,
31 transport, food and other goods and services that adversely affect the most economically vulnerable.
32 Redistribution of tax revenue is critical to address the adverse impacts on low income groups (Dorband et al.
33 2019) (see also Box 5.11). In countries with a limited capacity to collect taxes and distribute revenues to low
34 income households, such as some developing countries, carbon taxes may have greater distributional
35 consequences.

36 Distributional effects have generally not been a significant issue for ETSs. Equity for industrial participants
37 typically is addressed through free allocation of allowances. Impacts on household incomes, with the
38 exception of electricity prices, are too small or indirect to be a concern. Some systems are designed to limit
39 electricity price increases (Petek 2020) or use some revenue for bill assistance to low-income households
40 (RGGI 2019).

41 *Technological change*

42 Carbon pricing, especially an ETS that covers industrial sources, stimulates technological change by
43 participants and others (Calel and Dechezleprêtre 2016; FSR Climate 2019; van den Bergh and Savin 2021)
44 (see also Section 13.6.6.3 and Chapter 16). The purpose of pricing policies is to encourage implementation
45 of the lowest cost mitigation measures. Pricing policies therefore are more likely to stimulate quick, low cost
46 innovation such as fuel switching and energy efficiency, rather than long-term, costly technology

1 development such as renewable energy or industrial process technologies (Calel 2020; Lilliestam et al. 2021).
2 To encourage long-term technology development carbon pricing policies need to be complemented by other
3 mitigation and R&D policies.

4 **13.6.3.4 Offset credits**

5 Offset credits are voluntary GHG emission reductions for which tradable credits are issued by a supervisory
6 body (Michaelowa et al. 2019b). A buyer can use purchased credits to offset an equal quantity of its
7 emissions. In a voluntary market governments, firms and individuals purchase credits to offset emissions
8 generated by their actions, such as air travel. A compliance market allows specified offset credits to be used
9 for compliance with mitigation policies, especially ETSs, carbon taxes and low carbon fuel standards.
10 (Newell et al. 2013; Bento et al. 2016; Michaelowa et al. 2019a).

11 When used for compliance, governments typically specify a maximum quantity of offset credits that can be
12 used, as well as the types of emission reduction actions, the project start dates and the geographic regions
13 eligible credits. Initially, the EU ETS, Swiss ETS and New Zealand ETS accepted credits issued under the
14 Kyoto Protocol (Chapter 14), but they terminated or severely constrained the quantity of international credits
15 allowed for compliance use after 2014 (Shishlov et al. 2016)(see 13.6.6).

16 A key question for any offset credit is whether the emission reductions are ‘additional’: reductions that only
17 happen because of the offset credit payment (Millard-Ball and Ortolano 2010; van Benthem and Kerr 2013;
18 Burke 2016; Bento et al. 2016; Greiner and Michaelowa 2003). To assess additionality and to determine the
19 quantity of credits to be issued, regulators develop methodologies to estimate baseline (business-as-usual)
20 emissions in the absence of offset payments (Newell et al. 2013; Bento et al. 2016). Credits are issued for
21 the difference between the baseline and actual emissions with adjustments for possible emissions increases
22 outside the project boundary (Rosendahl and Strand 2011). Some research suggests that procedural and
23 measurement advances can significantly reduce the risk of severe non-additionality (Mason and Plantinga
24 2013; Bento et al. 2016; Michaelowa et al. 2019a).

25 **13.6.3.5 Subsidies for mitigation**

26 Subsidies for mitigation encourage individuals and firms to invest in assets that reduce emissions, changes
27 in processes or innovation. Subsidies have been used to improve energy efficiency, encourage the uptake of
28 renewable energy and other sector-specific emissions saving options (Chapters 6 to 11), and to promote
29 innovation. Targeted subsidies can achieve specific mitigation goals yet have intrinsically narrower coverage
30 than more broad-based pricing instruments. Subsidies are often used not only to achieve emissions reductions
31 but to address market imperfections or to achieve distributional or strategic objectives. Subsidies are often
32 used alongside or in combination with other policy instruments, and are provided at widely differing cost per
33 unit of emissions reduced.

34 Governments routinely provide direct funding for basic research, subsidies for R&D to private companies,
35 and co-funding of research and deployment with industry (Dzongzi-Undi and Li 2016). Research subsidies
36 have been found to be positively correlated with green product innovation in a study in Germany, Switzerland
37 and Austria (Stucki et al. 2018). Government subsidies for R&D have been found to greatly increase the
38 green innovation performance of energy intensive firms in China (Bai et al. 2019). For more detail see
39 Chapter 16.

40 Subsidies of different forms are often provided for emissions savings investments to businesses and for the
41 retrofit of buildings for energy efficiency. Emissions reductions from energy efficiencies can often be
42 achieved at low cost, but evidence for some schemes suggests lower effectiveness in emissions reductions
43 than expected ex ante (Fowlie et al. 2018; Valentová et al. 2019). Tax credits can be used to encourage firms
44 to produce or invest in low-carbon emission energy and low-emission equipment. Investment subsidies have
45 been found to be more effective in reducing costs and uncertainties in solar energy technologies than
46 production subsidies (Flowers et al. 2016).

1 Subsidies have been provided extensively and in many countries for the deployment of household rooftop
2 solar systems, and increasingly also for commercial scale renewable energy projects, typically using ‘feed-
3 in tariffs’ that provide a payment for electricity generated above the market price (Pyrgou et al. 2016). Such
4 schemes have proven effective in deploying renewable energy, but lock in subsidies for long periods of time.
5 In some cases they provide subsidies at higher levels than would be required to motivate deployment (del
6 Río and Linares 2014). High levels of net subsidies have been shown to diminish incentives for optimal
7 siting of renewable energy installations (Penasco et al. 2019).

8 A variant of subsidies for deployment of renewable energy are auctioned feed-in tariffs or auctioned
9 contracts-for-difference, where commercial providers bid in a competitive process. Auctions typically lead
10 to lower price premiums (Eberhard and Kåberger 2016; Roberts 2020) but efficient outcomes depend on
11 auction design and market structure (Grashof et al. 2020), although an emergent literature also questions
12 whether spread of auctions is due to performance or the dynamics of the policy formulation process (Fitch-
13 Roy et al. 2019b; Grashof et al. 2020; Grashof 2021). The prequalification requirements or the assessment
14 criteria in the auctions sometimes also include local co-benefits such as local economic diversification
15 (Buckman et al. 2019; White et al. 2021).

16 Support for rollout clean technologies at high prices can be economically beneficial in the long run if costs
17 are reduced greatly as a function of deployment (Newbery 2018). Deployment support, much of it in the
18 form of feed-in tariffs in Germany, enabled the scaling up of the global solar photovoltaic industry and
19 attendant large reductions in production costs that by 2020 made solar power cost competitive with fossil
20 fuels (Buchholz et al. 2019). There is also evidence for increased innovation activity as a result of solar feed-
21 in tariffs (Böhringer et al. 2017b).

22 Many governments have also provided subsidies for the purchase of electric vehicles, including with strong
23 effect in China (Ma et al. 2017), Norway (Baldursson et al. 2021) and other countries, and sometimes at
24 relatively high rates (Kong and Hardman 2019).

25 **13.6.3.6 Removal of fossil fuel subsidies**

26 Many governments subsidize fossil fuel consumption and/or production through a variety of mechanisms
27 (Burniaux and Chateau 2014) (see Figure 13.5). Different approaches exist to defining the scope and
28 estimating the magnitude of fossil fuel subsidies (Koplow 2018), and all involve estimates, so the magnitudes
29 are uncertain. Rationalizing inefficient fossil fuel subsidies is one of the indicators to measure progress
30 toward Sustainable Development Goal 12 -- Ensure sustainable consumption and production patterns (UNEP
31 2019a).

32 Consumption subsidies represent approximately 70% of the total. Most of the subsidies go to petroleum,
33 which accounts for roughly 50% of the consumption subsidies and 75% of the production subsidies (IEA
34 2020; OECD 2020). Much of the variation in the consumption subsidies is due to fluctuations in the world
35 price of oil which is used as the reference price.

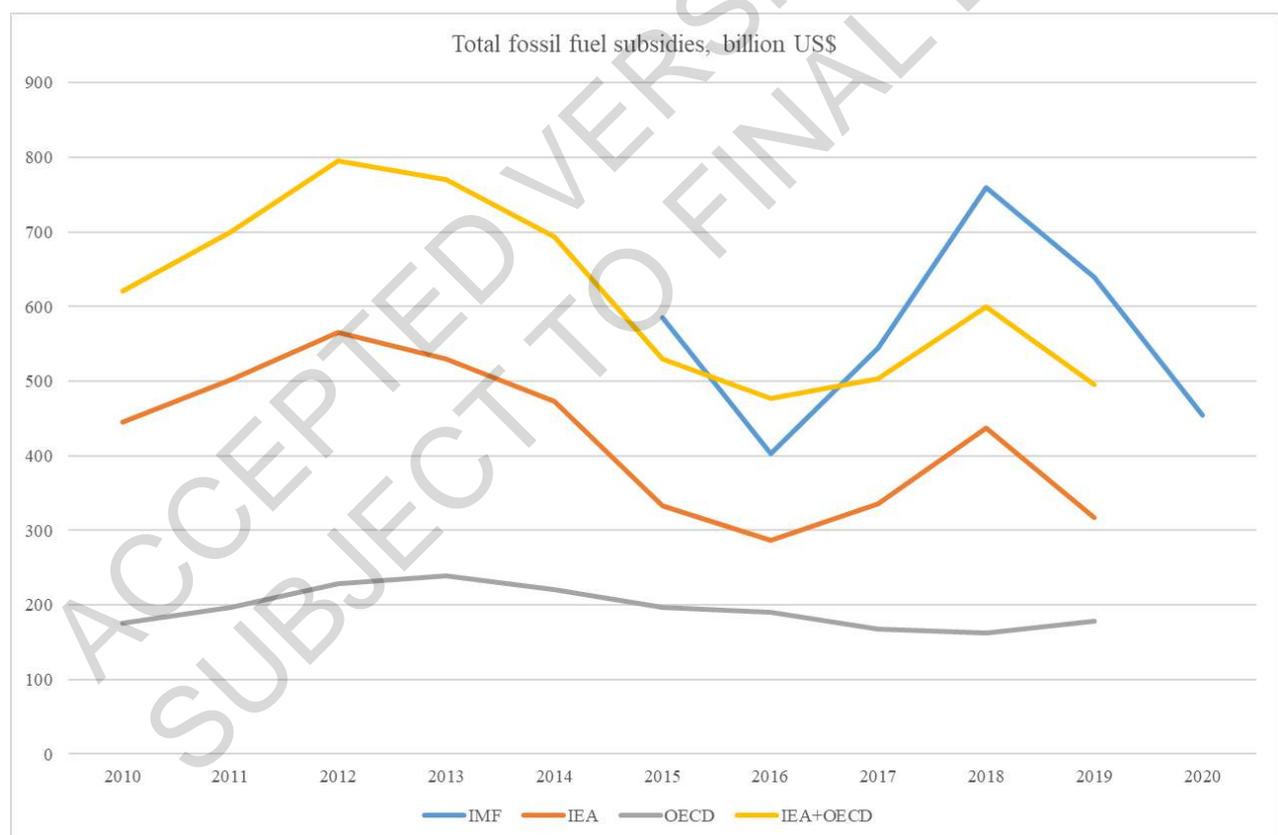

36 Reducing fossil fuel subsidies would lower CO₂ emissions, increase government revenues (Dennis 2016;
37 Gass and Echeverria 2017; Rentschler and Bazilian 2017; Monasterolo and Raberto 2019; Jakob et al. 2015),
38 improve macroeconomic performance (Monasterolo and Raberto 2019), and yield other environmental and
39 sustainable development benefits (Solarin 2020; Rentschler and Bazilian 2017; Jakob et al. 2015) (*robust
40 evidence, medium agreement*). The benefits of gasoline subsidies in developing countries accrue mainly to
41 higher income groups, so subsidy reduction usually will reduce inequality (Coady et al. 2015; Dennis 2016;
42 Monasterolo and Raberto 2019; Labeaga et al. 2021). Some subsidies, like tiered electricity rates, benefit
43 low income groups. Reductions of broad subsidies lead to price increases for fuels, electricity, transport, food
44 and other goods and services that adversely affect the most economically vulnerable (Coady et al. 2015;
45 Zeng and Chen 2016; Rentschler and Bazilian 2017). Distributing some of the revenue saved can mitigate
46 the adverse economic impacts on low income groups (Dennis 2016; Zeng and Chen 2016; Labeaga et al.
47 2021; Schaffitzel et al. 2020).

1 The emissions reduction that could be achieved from fossil fuel subsidy removal depends on the specific
 2 context such as magnitude and nature of subsidies, energy prices and demand elasticities, and how the fiscal
 3 savings from reduced subsidies are used. Modelling studies of global fossil fuel subsidy removal result in
 4 projected emission reductions of between 1 and 10 per cent by 2030 (Delpiazzi et al. 2015; IEA 2015; Jewell
 5 et al. 2018; IISD 2019) and between 6.4 and 8.2 per cent by 2050 (Schwanitz et al. 2014; Burniaux and
 6 Chateau 2014).

7 An extensive literature documents the difficulties of phasing out fossil fuel subsidies (Schmidt et al. 2017;
 8 Skovgaard and van Asselt 2018; Kyle 2018; Perry 2020; Gass and Echeverria 2017; Gençsü et al. 2020).
 9 Fossil fuel industries lobby to maintain producer subsidies and consumers protest if they are adversely
 10 affected by subsidy reductions (Fouquet 2016; Coxhead and Grainger 2018). Yemen (2005 and 2014),
 11 Cameroon (2008), Bolivia (2010), Nigeria (2012), Ecuador (2019) all abandoned subsidy reform attempts
 12 following public protests (Mahdavi et al. 2020; Rentschler and Bazilian 2017). Indonesia is an example
 13 where fossil fuel subsidy removal was successful, helped by social assistance programs and a communication
 14 effort about the benefits of reform (Chelminski 2018; Burke and Kurniawati 2018). To-date instances of
 15 fossil fuel subsidy reform or removal have been driven largely by national fiscal and economic considerations
 16 (Skovgaard and van Asselt 2019).

17

 22 subsidies), IMF ((Parry et al. 2021); explicit subsidies for all countries).

23

1 **13.6.4 Regulatory instruments**

2 Regulatory instruments are applied by governments to cause the adoption of desired processes, technologies,
3 products (including energy products) or outcomes (including emission levels). Failure to comply incurs
4 financial penalties and/or legal sanctions. Regulatory instruments range from performance standards, which
5 prescribe compliance outcomes – and in some cases allow flexibility to achieve compliance, including the
6 trading of credits – to more prescriptive technology-specific standards, also known as command-and-control
7 regulation. Regulatory instruments play an important role to achieve specific mitigation outcomes in sectoral
8 applications (*robust evidence, high agreement*). Mitigation by regulation often enjoys greater political
9 support but tends to be more economically costly than mitigation by pricing instruments (*robust evidence,*
10 *medium agreement*).

11 **13.6.4.1 Performance standards, including tradable credits**

12 Performance standards grant regulated entities freedom to choose the technologies and methods to reach a
13 general objective, such as a minimum market share of zero-emission vehicles or of renewable electricity, or
14 a maximum emissions intensity of electricity generated. Tradable performance standards allow regulated
15 entities to trade compliance achievement credits; under-performers can buy surplus credits from over-
16 performers thereby reducing the aggregate cost of compliance (Fischer 2008).

17 Tradable performance standards have been applied to numerous sectors including electricity generation,
18 personal vehicles, building energy efficiency, appliances, and large industry. An important application is
19 Renewable Portfolio Standards (RPS) for electricity supply, which require that a minimum percentage of
20 electricity is generated from specified renewable sources sometimes including nuclear and fossil fuels with
21 CCS when referred to as a clean electricity standard (Young and Bistline 2018)(see also Chapter 6). This
22 creates a price incentive to invest in renewable generation capacity. Such incentives can equivalently be
23 created through feed-in tariffs, a form of subsidy (Section 13.6.3) and some jurisdictions have had both
24 instruments (Matsumoto et al. 2017). RPS can differ in features and stringency are in operation in many
25 countries and sub-national jurisdictions, including a majority of US States (Carley et al. 2018).

26 Vehicle emissions standards are a common form of performance standard with flexibility (Chapter 9). A
27 corporate fuel efficiency standard specifies an average energy use and/or GHG emissions per kilometre
28 travelled for vehicles sold by a manufacturer. Another version of this policy, the zero-emission vehicle (ZEV)
29 standard, requires vehicle sellers to achieve minimum requirements for sales of zero-emission vehicles
30 (Bhardwaj et al. 2020). Both instruments allow manufacturers to use tradable credits to achieve compliance.

31 Low carbon fuel standards (LCFS), which set an average life-cycle carbon intensity for energy that declines
32 over time, are another example. LCFS are in place in many different jurisdictions (Chapter 9) and have been
33 applied to petroleum products, natural gas, hydrogen and electricity (Yeh et al. 2016). An LCFS allows
34 regulated entities to trade credits creating the potential for high carbon intensity fuel suppliers to cross-
35 subsidize low carbon intensity transport energy providers including low-carbon biofuels, hydrogen and
36 electricity (Axsen et al. 2020).

37 Trading and other flexibility mechanisms improve the economic efficiency of standards by harmonizing the
38 marginal abatement costs among companies or installations subject to the standard. Nevertheless tradable
39 performance standards are less economically efficient in achieving emissions reductions than carbon pricing,
40 sometimes by a significant amount (Giraudet and Quirion 2008; Chen et al. 2014; Holland et al. 2015; Fox
41 et al. 2017; Zhang et al. 2018).

42 **13.6.4.2 Technology standards**

43 Technology standards take a more prescriptive approach by requiring a specific technology, process or
44 product. They typically take one of three forms: requirements for specific pollution abatement technologies;
45 requirements for specific production methods; or requirements for specific goods such as energy efficient
46 appliances. They can also take the form of phase-out mandates, as applied for example to planned bans of

1 internal combustion engines for road transport (Bhagavathy and McCulloch 2020), coal use (e.g. Germany's
2 decisions to phase out coal (Oei et al. 2020)), and some industry processes and products (e.g. HFCs and use
3 of SF6 in some products (see Box 13.10 on Non-CO₂ gases). Technology standards are also referred to as
4 command-and-control standards, prescriptive standards, or design standards.

5 Technology standards are a common climate policy particularly at the sector level (Chapters 6-11).
6 Technology standards tend to score lower in terms of economic efficiency than carbon pricing and
7 performance standards (Besanko 1987). But they may be the best instrument for situations where decisions
8 are not very responsive to price signals such as consumer choices related to energy efficiency and recycling
9 and decisions relating to urban land use and infrastructure choices.

10 By mandating specific compliance pathways, technology standards risk locking-in a high-cost pathway when
11 lower cost options are available or may emerge through market incentives and innovation (Raff and Walter
12 2020). Furthermore, standards may require high-cost GHG reductions in one sector while missing low-cost
13 options in another sector. Technology standards can also stifle innovation by blocking alternative
14 technologies from entering the market (Sachs 2012). Benefits of technology standards include their potential
15 to achieve emission reductions in a relatively short timeframe and that their effectiveness can be estimated
16 with some confidence (Montgomery et al. 2019).

17 **13.6.4.3 Performance of regulatory instruments**

18 Regulatory policy instruments tend to be more economically costly than pricing instruments, as explained
19 above. However, regulatory policies may be preferred for other reasons.

20 In some cases, regulatory policy can elicit greater political support than pricing policy (Tobler et al. 2012;
21 Lam 2015; Drews and van den Bergh 2016). For example, U.S. citizens have expressed more support for
22 flexible regulation like the RPS than for carbon taxes (Rabe 2018). And a survey in British Columbia a few
23 years after the simultaneous implementation of a carbon tax and two regulations – the LCFS and a clean
24 electricity standard – found much less strong opposition to the regulations, even after being informed that
25 they were costlier to consumers (Rhodes et al. 2017). The degree of public support for regulations depends,
26 however, on the type of regulation, as outright technology prohibitions can be unpopular (Attari et al. 2009;
27 Cherry et al. 2012).

28 In comparison to economic instruments, regulatory policies tend to cause greater cost of living increases in
29 percentage terms for lower income consumers – called policy regressivity (Levinson 2019; Davis and Knittel
30 2019). And unlike carbon taxes, regulations do not generate revenues that can be used to compensate lower
31 income groups.

32 A renewable energy procurement obligation in South Africa successfully required local hiring with perceived
33 positive results (Walwyn and Brent 2015; Pahle et al. 2016), a clean energy regulation in Korea was
34 perceived to provide greater employment opportunities (Lee 2017), and a UK obligation on energy
35 companies to provide energy retrofits to low-income households improved energy affordability according to
36 participants (Elsharkawy and Rutherford 2018).

37 From an energy system transformation perspective, technology standards, including phase-out mandates,
38 have particular promise to achieve profound change in specific sectors and technologies (Tvinnereim and
39 Mehling 2018). As such policies change the technologies available in the market, then economic instruments
40 can also have a greater effect (Pahle et al. 2018).

42 **START BOX 13.10 HERE**

43 **Box 13.10 Policies to limit emissions of Non-CO₂ Gases**

1 Non-CO₂ gases weighted by their 100 year GWPs represent approximately 25% of global GHG emissions,
2 of which methane (CH₄) accounts for 18%, nitrous oxide (N₂O) – 4%, and fluorinated gases (HFCs, PFCs,
3 SF₆ and NF₃) – 2% (Minx et al. 2021). Only a small share of these emissions are subject to mitigation
4 policies.

5 **Methane.** Anthropogenic sources include agriculture, mainly livestock and rice paddies, fossil fuel
6 extraction and processing, fuel combustion, some industrial processes, landfills, and wastewater treatment
7 (US EPA 2019). Atmospheric measurements indicate that methane emissions from fossil fuel production are
8 larger than shown in emissions inventories (Schwietzke et al. 2016). Only a small fraction of global CH₄
9 emissions is regulated. Mitigation policies focus on landfills, coal mines, and oil and gas operations.

10 Regulations and incentives to capture and utilize methane from coal seams came into effect in China in 2010
11 (Tan 2018; Tao et al. 2019). Inventory data suggest that emissions peaked and began a slow decline after
12 2010 (Gao et al. 2020) though satellite data indicate that China's methane emissions, largely attributable to
13 coal mining, continued to rise in line with pre-2010 trends (Miller et al. 2019). Methane emissions from
14 sources including agriculture, waste and industry are included in some offset credit schemes, including the
15 CDM and at national level in Australia's Emissions Reductions Fund (Australian Climate Change Authority
16 2017) and the Chinese Certified Emission Reduction (CCER) scheme (Lo and Cong 2017).

17 **Nitrous Oxide.** N₂O emissions are produced by agricultural soil management, livestock waste management,
18 fossil fuel combustion, and adipic acid and nitric acid production (US EPA 2019). Most N₂O emissions are
19 not regulated and global emissions have been increasing. N₂O emissions by adipic and nitric acid plants in
20 the EU are covered by the ETS (Winiwarter et al. 2018). N₂O emissions are included in some offset schemes.
21 China, the United States, Singapore, Egypt, and Russia produce 86% of industrial N₂O emissions offering
22 the potential for targeted mitigation action (US EPA 2019).

23 **HFCs.** Most HFCs are used as substitutes for ozone depleting substances. The Kigali Amendment (KA) to
24 the Montreal Protocol will reduce HFC use by 85% by 2047 (UN Environment 2018). To help meet their
25 KA commitments developed country parties have been implementing regulations to limit imports, production
26 and exports of HFCs and to limit specific uses of HFCs.

27 The EU, for example, issues tradable quota for imports, production and exports of HFCs. Prices of HFCs
28 have increased as expected (Kleinschmidt 2020) which has led to smuggling of HFCs into the EU (European
29 Commission 2019b). HFC use has been slightly (1 to 6%) below the limit each year from 2015 through 2018
30 (EEA 2019). China and India released national cooling action plans in 2019, laying out detailed, cross-
31 sectoral plans to provide sustainable, climate friendly, safe and affordable cooling (Dean et al. 2020).

32 **PFCs, SF₆ and NF₃.** With the exception of SF₆, these gases are emitted by industrial activities located in the
33 European Economic Area (EEA) and a limited number (fewer than 30) of other countries. Regulations in
34 Europe, Japan and the US focus on leak reduction as well as collection and reuse of SF₆ from electrical
35 equipment. Other uses of SF₆ are banned in Europe (European Union 2014).

36 PFCs are generated during the aluminium smelting process if the alumina level in the electrolytic bath falls
37 below critical levels (US EPA 2019). In Europe these emissions are covered by the EU ETS. The industry is
38 eliminating the emissions through improved process control and a shift to different production processes.

39 The semiconductor industry uses HFCs, PFCs, SF₆ and NF₃ for etching and deposition chamber cleaning
40 (US EPA 2019) and has a voluntary target of reducing GHG emissions 30% from 2010 by 2020 (World
41 Semiconductor Council 2017). Europe regulates production, import, export, destruction and feedstock use
42 of PFCs and SF₆, but not NF₃ (EEA 2019). In addition, fluorinated gases are taxed in Denmark, Norway,
43 Slovenia and Spain.

44 <<END BOX 13.10 HERE>>

45

1 In some jurisdictions, the analysis of regulatory instruments is subject to an assessment on the basis of a
2 shadow cost of carbon, which can influence the choice and design of regulations that affect GHG emissions
3 (Box 13.11).

5 **START BOX 13.11 HERE**

6 **Box 13.11 Shadow cost of carbon in regulatory analysis**

7 In some jurisdictions, public administrations are required to apply a shadow cost of carbon to regulatory
8 analysis

9 Traditionally, for example in widespread application in the United States, the shadow cost of carbon is
10 calibrated to an estimate of the social cost of carbon as an approximation of expected future cumulative
11 economic damage from a unit of greenhouse gas emissions (Metcalf and Stock 2017). Social cost of carbon
12 is usually estimated using integrated assessment models and is subject to fundamental uncertainties (Pezzey
13 2019). An alternative approach, used for example in regulatory analysis in the United Kingdom since 2009,
14 is to define a carbon price that is thought to be consistent with a particular targeted emissions outcome. This
15 approach also requires a number of assumptions, including about future marginal costs of mitigation (Aldy
16 et al. 2021).

17 **END BOX 13.11 HERE**

19 **13.6.5 Other policy instruments**

20 A range of other mitigation policy instruments are in use, often playing a complementary role to pricing and
21 standards.

22 **13.6.5.1 Transition support policies**

23 Effective climate change mitigation can cause economic and social disruption where there is transformative
24 change, such as changes in energy systems away from fossil fuels (See 13.9). Transitional assistance policies
25 can be aimed to ameliorate effects on consumers, workers, communities, corporations or countries (Green
26 and Gambhir 2020) in order to create broad coalitions of supporters or to limit opposition (Vogt-Schilb and
27 Hallegatte 2017).

28 **13.6.5.2 Information programs**

29 Information programs, including energy efficiency labels, energy audits, certification, carbon labelling and
30 information disclosure, are in wide use in particular for energy consumption. They can reduce GHG
31 emissions by promoting voluntary technology choices and behavioural changes by firms and households.

32 Energy efficiency labelling is in widespread use, including for buildings, and for end users products including
33 cars and appliances. Carbon labelling is used for example for food (Camilleri et al. 2019) and tourism
34 (Gössling and Buckley 2016). Information measures also include specific information systems such as smart
35 electricity meters (Zangheri et al. 2019). Chapters 5 and 9 provide detail.

36 Information programs can correct for a range of market failures related to imperfect information and
37 consumer perceptions (Allcott 2016). Alongside mandatory standards (13.6.4), information programmes can
38 nudge firms and consumers to focus on often overlooked operating cost reductions (Carroll et al. 2022). For
39 example, consumers who are shown energy efficiency labels on average buy more energy efficient
40 appliances than those who are not (Stadelmann and Schubert 2018). Information policies can also support
41 the changing of social norms about consumption choices, which have been shown to raise public support for
42 pricing and regulatory policy instruments (Gössling et al. 2020).

1 Energy audits provide tailored information about potential energy savings and benchmarking of best
2 practices through a network of peers. Typical examples include the United States Better Buildings Challenge
3 that has provided energy audits to support US commercial and industrial building owners, energy savings
4 have been estimated at 18% to 30% (Asensio and Delmas 2017); and Germany’s energy audit scheme for
5 SMEs achieving reductions in energy consumption of 5 to 70 percent (Kluczek and Olszewski 2017).

6 Consumption-oriented policy instruments seek to reduce GHG emissions by changing consumer behaviour
7 directly, via retailers or via the supply chain. Aspects that hold promise are technology lists, supply chain
8 procurement by leading retailers or business associations, a carbon-intensive materials charge and selected
9 infrastructure improvements (Grubb et al. 2020).

10 The information provided to consumers in labelling programs is often not detailed enough to yield best
11 possible results (Davis and Metcalf 2016). Providing information about running costs tends to be more
12 effective than providing data on energy use (Damigos et al. 2020). Sound implementation of labelling
13 programs requires appropriate calculation methodology and tools, training and public awareness (Liang
14 Wong and Krüger 2017). In systems where manufacturers self-report performance of their products, there
15 tends to be misreporting and skewed energy efficiency labelling (Goeschl 2019).

16 A new form of information programs are financial accounting standards as frameworks to encourage or
17 require companies to disclose how the transition risks from shifting to a low carbon economy and physical
18 climate change impacts may affect their business or asset values (Chapter 15). The most prominent such
19 standard was issued in 2017 by the Financial Stability Board’s Task Force on Climate-related Financial
20 Disclosures. It has found rapid uptake among regulators and investors (O’Dwyer and Unerman 2020).

21 Traditionally, corporate reporting has treated climate risks in a highly varied and often minimal way (Foerster
22 et al. 2017). Disclosure of climate related risks creates incentives for companies to improve their carbon and
23 climate change exposure, and ultimately regulatory standards for climate risk (Eccles and Krzus 2018).
24 Disclosure can also reinforce calls for divestment in fossil fuel assets predominantly promoted by civil
25 society organisations (Ayling and Gunningham 2017), raising moral principles and arguments about the
26 financial risks inherent in fossil fuel investments (Green 2018; Blondeel et al. 2019).

27 **13.6.5.3 Public procurement and investment**

28 National, subnational and local governments determine many aspects of infrastructure planning, fund
29 investment in areas such as energy, transport and the built environment, and purchase goods and services,
30 including for government administration and military provisioning.

31 Public procurement rules usually mandate cost effectiveness but only in some cases allow or mandate climate
32 change consideration in public purchasing, for example in EU public purchasing guidelines (Martinez
33 Romera and Caranta 2017). Green procurement for buildings has been undertaken in Malaysia (Bohari et al.
34 2017). A paper cites Taiwan’s green public procurement law, which has contributed to reduced emissions
35 intensity (Tsai 2017). In practice, awareness and knowledge of ‘green’ public procurement techniques and
36 procedures is decisive for climate-friendly procurement (Testa et al. 2016). Experiences in low-carbon
37 infrastructure procurement point to procedures being tailored to concerns about competition, transaction
38 costs and innovation (Kadefors et al. 2020).

39 Infrastructure investment decisions lock in high or low emissions trajectories over long periods. Low-
40 emissions infrastructure can enable or increase productivity of private low-carbon investments (Jaumotte et
41 al. 2021) and is typically only a little more expensive over its lifetime, but faces additional barriers including
42 higher upfront costs, lack of pricing of externalities, or lack of information or aversion to novel products
43 (Granoff et al. 2016). In low-income developing countries, where infrastructure has historically lagged
44 developed countries, some of these hurdles can be exacerbated by overall more difficult conditions for public
45 investment (Gurara et al. 2018).

1 Governments can also promote low-emissions investments through public-private partnerships and
2 government owned ‘green banks’ that provide loans on commercial or concessional basis for
3 environmentally friendly private sector investments (David and Venkatachalam 2019; Ziolo et al. 2019).
4 Public funding or financial guarantees such as contracts-for-difference can alleviate financial risk in the early
5 stages of technology deployment, creating pathways to commercial viability (Bataille 2020).

6 Government provision can also play an important role in economic stimulus programs, including as
7 implemented in response to the pandemic of 2020-21. Such programs can support low-emissions
8 infrastructure and equipment, and industrial or business development (Elkerbout et al. 2020; Hainsch et al.
9 2020; Barbier 2020; Hepburn et al. 2020).

10

11 **START BOX 13.12 HERE**

12

Box 13.12 Technology and R&D policy

13 Private businesses tend to under-invest in R&D because of market failures (Geroski 1995), hence there is a
14 case for governments to support research and technology development. A range of different policy
15 instruments are used, including government funding, preferential tax treatment, intellectual property rules,
16 and policies to support the deployment and diffusion of new technologies. Chapter 16 treats innovation policy
17 in-depth.

18 **END BOX 13.12 HERE**

19

20 **13.6.5.4 Voluntary agreements**

21 Voluntary Agreements result from negotiations between governments and industrial sectors that commit to
22 achieve agreed goals (Mundaca and Markandya 2016). When used as part of a broader policy framework,
23 they can enhance the cost effectiveness of individual firms in attaining emission reductions while pricing or
24 regulations drive participation in the agreement (Dawson and Segerson 2008).

25 Public voluntary programs, where a government regulator develops programs to which industries and firms
26 may choose to participate on a voluntary basis, have been implemented in numerous countries. For example,
27 the United States Environmental Protection Agency introduced numerous voluntary programmes with
28 industry to offer technical support in promoting energy efficiency and emissions reductions, among other
29 initiatives (United States Environmental Protection Agency 2017). A European example is the EU Ecolabel
30 Award program (European Commission 2020b). Agreements for industrial energy efficiency in Europe
31 (Cornelis 2019) and Japan (Wakabayashi and Arimura 2016) have been particularly effective in addressing
32 information barriers and for smaller companies. The International Civil Aviation Organization’s CORSIA
33 scheme (Prussi et al. 2021) is an example of an international industry-based public voluntary program.

34 Voluntary agreements are often implemented in conjunction with economic or regulatory instruments, and
35 sometimes are used to gain insights ahead of implementation of regulatory standards, as in the case of energy
36 efficiency PVPs in South Korea (Seok et al. 2021). In some cases, industries use voluntary agreements as
37 partial fulfilment of a regulation (Rezessy and Bertoldi 2011; Langpap 2015). For example, the Netherlands
38 have permitted participating industries to be exempt from certain energy taxes and emissions regulations
39 (Veum 2018).

40

13.6.6 International interactions of national mitigation policies

One country's mitigation policy can impact other countries in various ways including changes in their GHG emissions (leakage), creation of markets for emission reduction credits, technology development and diffusion (spillovers), and reduction in the value of their fossil fuel resources.

13.6.6.1 Leakage effects

Compliance with a mitigation policy can affect the emissions of foreign sources via several channels over different time scales (Zhang and Zhang 2017) (also see Box 13.13). The effects may interact and yield a net increase or decrease in emissions. The leakage channel that is of most concern to policymakers is adverse international competitiveness impacts from domestic climate policies.

10

START BOX 13.13 HERE

12

Box 13.13 Possible sources of leakage

Competitiveness: Mitigation policy raises the costs and product prices of regulated sources which causes production to shift to unregulated sources, increasing their emissions.

Fossil fuel channel: Regulated sources reduce their fossil fuel use, which lowers fossil fuel prices and increases consumption and associated emissions by unregulated sources.

Land use channel: Mitigation policies that change land use lead to land use and emissions changes in other jurisdictions (Bastos Lima et al. 2019).

Terms of trade effect: Price increases for the products of regulated sources shift consumption to other goods, which raises emissions due to the higher output of those goods.

Technology channel: Mitigation policy induces low carbon innovation, which reduces emissions by sources that adopt the innovations that may include unregulated sources (Gerlagh and Kuik 2007).

Abatement resource effect: Regulated sources increase use of clean inputs, which reduces inputs available to unregulated sources and so limits their output and emissions (Baylis et al. 2014).

Scale channel: Changes to the output of regulated and unregulated sources affect their emissions intensities so emissions changes are not proportional to output changes (Antweiler et al. 2001).

Intertemporal channel: Capital stocks of all sources are fixed initially but change over time affecting the costs, prices, output and emissions of regulated and unregulated products.

END BOX 13.13 HERE

30

In principle, implementation of a mitigation policy in one country creates an incentive to shift production of tradable goods whose costs are increased by the policy to other countries with less costly emissions limitation policies (see Section 12.6.3 in Chapter 12). Such 'leakage' could to some extent negate emissions reductions in the first country, depending on the relative emissions intensity of production in both countries.

Ex ante modelling studies typically estimate significant leakage for unilateral policies to reduce emissions due to production of emissions intensive products such as steel, aluminium, and cement (Carbone and Rivers 2017). However, the results are highly dependent on assumptions and typically do not reflect policy designs specifically aimed at minimizing or preventing leakage (Fowlie and Reguant 2018).

Numerous *ex post* analyses, mainly for the EU ETS, find no evidence of any or significant adverse competitiveness impacts and conclude that there was consequently no or insignificant leakage (Branger et al. 2016; Koch and Basse Mama 2019; Venmans et al. 2020; FSR Climate 2019; Kuusi et al. 2020; aus dem

1 Moore et al. 2019; Verde 2020; Borghesi et al. 2020; Haites et al. 2018) (*medium evidence, medium*
2 *agreement*). This is attributed to large allocations of free allowances to emissions-intensive, trade-exposed
3 sources, relatively low allowance prices, the ability of firms in some sectors to pass costs on to consumers,
4 energy's relatively low share of production costs, and small but statistically significant effects on innovation
5 (Joltreau and Sommerfeld 2019). Few carbon taxes apply to emissions-intensive, trade-exposed sources
6 (Timilsina 2018), so competitiveness impacts usually are not a particular concern.

7 Policies intended to address leakage include a border carbon adjustment (Ward et al. 2019; Ismer et al. 2020).
8 A border carbon adjustment (BCA) imposes costs – a tax or allowance purchase obligation – on imports of
9 carbon-intensive goods equivalent to those borne by domestic products possibly mirrored by rebates for
10 exports (Böhringer et al. 2012; Fischer and Fox 2012; Zhang 2012; Böhringer et al. 2017c) (see also Chapter
11 14). A BCA faces the practical challenge of determining the carbon content of imports (Böhringer et al.
12 2017a) and the design needs to be consistent with WTO rules and other international agreements (Cosbey et
13 al. 2019; Mehling et al. 2019). Model estimates indicate that a BCA reduces but does not eliminate leakage
14 (Branger and Quirion 2014). No BCA has yet been implemented for international trade although such a
15 measure is currently under consideration by some governments.

16 **13.6.6.2 Market for emission reduction credits**

17 A mitigation policy may allow the use of credits issued for emission reductions in other countries for
18 compliance purposes (see also 13.6.3.4 on offset credits and Chapter 14 on international credit mechanisms).
19 Creation of international markets for emission reduction credits tends to benefit other countries through
20 financial flows in return for emissions credit sales (*medium evidence, high agreement*).

21 The EU, New Zealand and Switzerland allowed participants in their emissions trading systems to use credits
22 issued under the Kyoto Protocol mechanisms, including the Clean Development Mechanism (CDM), for
23 compliance. From 2008 through 2014 participants used 3.76 million imported credits for compliance of
24 which 80% were CDM credits (Haites 2016).⁴ Use of imported credits has fallen to very low levels since
25 2014 (World Bank 2014; Shishlov et al. 2016).⁵

26 The Clean Development Mechanism (CDM) is the world's largest offset program (Chapter 14). From 2001
27 to 2019 over 7,500 projects with projected emission reductions in excess of 8,000 MtCO₂-eq were
28 implemented in 114 developing countries using some 140 different emissions reduction methodologies
29 (UNFCCC 2012; UNEP DTU Partnership 2020). Credits reflecting over 2,000 MtCO₂-eq of emission
30 reductions by 3,260 projects have been issued. To address additionality and other concerns the CDM
31 Executive Board frequently updated its approved project methodologies.

32 **13.6.6.3 Technology spillovers**

33 Mitigation policies stimulate low-carbon R&D by entities subject to those policies and by other domestic
34 and foreign entities (FSR Climate 2019). Policies to support technology development and diffusion tend to
35 have positive spillover effects between countries (see section 16.3) (*medium evidence, high agreement*).

36 Innovation activity in response to a mitigation policy varies by policy type (Jaffe et al. 2002) and stringency
37 (Johnstone et al. 2012). In addition, many governments have policies to stimulate R&D, further increasing
38 low-carbon R&D activity by domestic researchers. Emitters in other countries may adopt some of the new
39 low-carbon technologies thus reducing emissions elsewhere. Technology development and diffusion is
40 reviewed in Chapter 16.

FOOTNOTE ⁴ 2010 through 2014 for the New Zealand ETS.

FOOTNOTE ⁵ All three ETSs were modified after 2012 including provisions that affected compliance use of imported credits.

1 **13.6.6.4 Value of fossil fuel resources**

2 Fossil fuel resources are a significant source of exports, employment and government revenues for many
3 countries. The value of these resources depends on demand for the fuel and competing supplies in the relevant
4 international markets. Discoveries and new production technologies reduce the value of established
5 resources. Mitigation policies that reduce the use of fossil fuels also reduce the value of these resources. A
6 single policy in one country is unlikely to have a noticeable effect on the international price, but similar
7 policies in multiple countries could adversely affect the value of the resources. For fossil fuel exporting
8 countries, mitigation policies consistent with the Paris Agreement goals could result in greater costs from
9 changes in fossil fuel prices due to lower international demand than domestic policy costs (Liu et al. 2020)
10 (*medium evidence, high agreement*).

11 The impact on the value of established resources will be mitigated, to some extent, by the reduced incentive
12 to explore for and develop new fossil fuel supplies. Nevertheless, efforts to lower global emissions will mean
13 substantially less demand for fossil fuels, with the majority of current coal reserves and large shares of known
14 gas and oil reserves needing to remain unused, with great diversity in impacts between different countries
15 (McGlade and Ekins 2015) (See also Chapters 3, 6, 15).

16 Estimates of the potential future loss in value differ greatly. There is uncertainty about remaining future fossil
17 fuel use under different mitigation scenarios, as well as future fossil fuel prices depending on extraction
18 costs, market structures and policies. Estimates of total cumulative fossil fuel revenue lost range between US
19 5-67 trillion dollars (Bauer et al. 2015) with an estimate of the net present value of lost profit of around US
20 10 trillion dollars (Bauer et al. 2016). Policies that constrain supply of fossil fuels in the context of mitigation
21 objectives could limit financial losses to fossil fuel producers (See also Chapter 14).

22

23 **13.7 Integrated policy packages for mitigation and multiple objectives**

24 Since AR5, the literature on climate policies and policy-making has expanded in two significant directions.
25 First, there is growing recognition that mitigation policy occurs in the context of multiple climate and
26 development objectives (Chapter 4). Different aspects of these linkages are discussed across the WGIII
27 report, including concepts and framings (Section 1.6.2 in Chapter 1), shifting sustainable development
28 pathways (Section 4.3 in Chapter 4 and Cross-chapter Box 5 in Chapter 4), cross-sectoral interactions
29 (Sections 12.6.1 and 12.6.2 in Chapter 12), evidence of co-impacts (Section 17.3 in Chapter 17), links with
30 adaptation (Section 4.4.2 in Chapter 4) and accelerating the transition (Section 13.9 in chapter 13 and
31 Sections 17.1.1, 17.4.5 and 17.4.6 in Chapter 17). While the concept of development pathways is salient in
32 all countries, it may particularly resonate with policymakers in developing countries focused on providing
33 basic needs and addressing poverty and inequality, including energy poverty (Ahmad 2009; Fuso Nerini et
34 al. 2019; Bel and Teixidó 2020; Caetano et al. 2020; Röser et al. 2020). Consequently, some countries may
35 frame policies predominantly in terms of accelerating mitigation, while in others a multiple objectives
36 approach linked to development pathways may dominate, depending on their specific socio-economic
37 contexts and priorities, governance capacities (McMeekin et al. 2019) and perceptions of historical
38 responsibility (Winkler and Rajamani 2014; Friman and Hjerpe 2015; Pan et al. 2017; Winkler et al. 2015).

39 Second, since AR5 there is growing attention to enabling transitions over time. Literature on socio-technical
40 transitions, rooted in innovation studies, highlights the need for different policy focus at different stages of
41 a transition (Geels et al. 2017b,a; Köhler et al. 2019) (also see Section 1.7.3 in Chapter 1). Other literature
42 examines how broad patterns of development drive both social and mitigation outcomes through shifts in
43 policies and a re-alignment of enabling conditions (Chapter 4). Explicit efforts to shift development
44 pathways, for example by shifting patterns of energy demand and urbanisation, therefore offer broader
45 mitigation opportunities (Cross-Chapter Box 5 in Chapter 4). Common to both approaches is an emphasis
46 beyond the short term, and enabling longer-term structural shifts in economies and societies.

1 Taking these trends into account, Figure 13.6 outlines the climate policy landscape, and how it maps to
2 different parts of this Working Group III report. One axis of variation captures alternative framings of desired
3 outcomes in national policy-making – mitigation versus multiple objectives, while the second captures the
4 shift in policymaking from an initial focus on shifting incentives through largely individual policy
5 instruments, to explicit consideration of how policies and economy-wide measures, including those that shift
6 incentives, can combine to enable transitions. As a result, Figure 13.6 represents interconnected policy ideas,
7 but backed by distinct strands of literature. Notably, each of these categories is salient to climate policy-
8 making, although the balance may differ depending on country context.

This section particularly focuses on climate policymaking for transition – both socio-technical transitions and shifts in development pathways, while direct climate policies and co-benefits are addressed in other parts of the report, as indicated in Figure 13.6. This section focuses in particular on lessons for designing policy packages for transitions, and is complemented by discussion in Section 13.8 on integration between

1 adaptation and mitigation, and Section 13.9 on economy-wide measures and the broader enabling conditions
2 necessary to accelerate mitigation.

4 **13.7.1 Policy packages for low carbon sustainable transitions**

5 Since AR5 an emergent multi-disciplinary literature on policy packages, or policy mixes, has emerged that
6 examine how policies may be combined for sustainable low-carbon transitions (Rogge and Reichardt 2016;
7 Kern et al. 2019). This literature covers various sectors including: energy (Rogge et al. 2017); transport
8 (Givoni et al. 2013); industry (Scordato et al. 2018); agri-food (Kalfagianni and Kuik 2017); and forestry
9 (Scullion et al. 2016).

10 A central theme in the literature is that transitions require policy interventions to address system level
11 changes, thereby going beyond addressing market failures in two ways. First, structural system changes are
12 needed for low-carbon transitions, including building low-carbon infrastructure (or example aligning
13 electricity grids and storage with the requirements of new low-carbon technology), and adjusting existing
14 institutions to low-carbon solutions (for example by reforming electricity market design) (Bak et al. 2017;
15 Patt and Lilliestam 2018). Second, explicit transformational system changes are necessary, including efforts
16 at directing transformations, such as clear direction setting through the elaboration of shared visions, and
17 coordination across diverse actors across different policy fields, such as climate and industrial policy, and
18 across governance levels (Uyarra et al. 2016; Nemet et al. 2017).

19 There are some specific suggestions for policy packages: Van den Bergh et al. (2021) suggest that innovation
20 support and information provision combined with a carbon tax or market, or adoption subsidy leads to both
21 effective and efficient outcomes. Others question the viability of universally applicable policy packages, and
22 suggest packages need to be tailored to local objectives (del Río 2014) Consequently, much of the literature
23 focuses on broad principles for design of policy packages and mixes, as discussed below.

24 Comprehensiveness, balance and consistency are important criteria for policy packages or mixes (Carter et
25 al. 2018; Santos-Iacueva and González 2018; Rogge and Reichardt 2016; Scobie 2016) (*robust evidence,*
26 *high agreement*). Comprehensiveness assesses the extensiveness of policy packages, including the breadth
27 of system and market failures it addresses (Rogge and Reichardt 2016). For example, instrument mixes that
28 include only moderate carbon pricing, but are complemented by policies supporting new low-carbon
29 technologies and a moratorium on coal-fired power plants may not only be politically more feasible than
30 stringent carbon pricing alone, but may also limit efficiency losses and lower distributional impacts (Bertram
31 et al. 2015b). Balance captures whether policy instruments are deployed in complementary ways given their
32 different purposes, combining for example technology-push approaches such as public R&D with demand-
33 pull approaches such as an energy tax. A combination of technology-push and demand-pull approaches has
34 been shown to support innovation in energy efficient technologies in OECD countries (Costantini et al.
35 2017). Consistency addresses the alignment of policy instruments among each other and with the policy
36 strategy, which may have multiple and not always consistent objectives (Rogge 2019). Consistency of policy
37 mixes has been identified as an important driver of low-carbon transformation, particularly for renewable
38 energy (Lieu et al. 2018; Rogge and Schleich 2018). Box 13.14 summarises the economics literature on how
39 policies interact, to inform design of packages.

41 **START BOX 13.14 HERE**

42 **Box 13.14 Policy interactions of carbon pricing and other instruments**

43 The economics literature provides insights on policy interactions among the multiple overlapping policies
44 that directly or indirectly affect GHG emissions, including when different levels of government are involved.
45 Multiple mitigation policies can be theoretically justified if there are multiple objectives or market failures

1 or to achieve distributional objectives and increase policy effectiveness (Stiglitz 2019). Examples include
2 the coexistence of the EU ETS with vehicle emission standards and energy efficiency standards (Rey et al.
3 2013), and the fact that 85% of the emissions covered by California’s ETS are also subject to other policies
4 (Bang et al. 2017; Mazmanian et al. 2020). Policy interactions are also widespread among energy efficiency
5 policies (Wiese et al. 2018).

6 Interactive effects can influence the costs of policy outcomes. With multiple overlapping and possibly non-
7 optimal policies, the effect on total cost is not clear. A modelling study of US mitigation policy finds the
8 costs of using heterogeneous subnational policies to achieve decarbonisation targets is 10 % higher than
9 national uniform policies (Peng et al. 2021). When multiple policy goals are sought, such as mitigation and
10 R&D, a portfolio of optimal policies achieves the goals at significantly lower cost (Fischer and Newell 2008).
11 In some cases, overlapping mitigation policies can raise the cost of mitigation (Böhringer et al. 2016) while
12 lowering the cost of achieving other goals, such as energy efficiency improvements and expansion of
13 renewable energy (Rosenow et al. 2016; Lecuyer and Quirion 2019). It is possible that one or more of the
14 policies is made redundant (Aune and Golombek 2021).

15 While overlapping policies may raise the cost of mitigation, they increase the likelihood of achieving an
16 emission reduction goal. Policy overlap will lead to different optimal carbon prices across jurisdictions
17 (Bataille et al. 2018b). The existence of overlapping policies will usually increase administrative and
18 compliance costs. However, ex-post analysis shows that transaction costs of mitigation policies are low and
19 are not a decisive factor in policy choice (Joas and Flachsland 2016).

20 The effectiveness, as well as economic and distributional effects, of a given mitigation policy will depend
21 on the interactions among all the policies that affect the targeted emissions. Because a market instrument
22 interacts with every other policy that affects the targeted emissions, interactions tend to be more complex for
23 market instruments than for regulations that mandate specific emission reduction actions by targeted sources
24 independent of other policies.

25 An ETS scheme implemented with existing mitigation policies may be subject to the ‘waterbed effect’ -
26 emission reductions undertaken by some emitters may be offset by higher emissions by other ETS
27 participants due to overlapping mitigation policies (Schatzki and Stavins 2012). This reduces the impact of
28 the ETS and lowers carbon trading prices (Perino 2018). However *ex post* assessments find net emissions
29 reductions. ETS design features such as a price floor and ‘market stability reserve’ can limit the waterbed
30 effect (Edenhofer et al. 2017; Kollenberg and Taschini 2019; Narassimhan et al. 2018; FSR Climate 2019).

31 A carbon tax, unlike the allowance price, does not change in response to the effect of overlapping policies
32 but those policies may reduce emissions by sources subject to the tax and so lower the emission reductions
33 achieved by the tax (Goulder and Stavins 2011).

34 Policy interactions often occur with the introduction of new mitigation policy instruments. For example, in
35 China several sub-national ETSs exist alongside policies to reduce emission intensity, increase energy
36 efficiency and expand renewable energy supplies (Zhang 2015). These quantity-based ETSs interact with
37 many other policies (Duan et al. 2017), for example price-based provincial carbon intensity targets (Qian
38 et al. 2017). They also interact with the level of market regulation; for example, full effectiveness of emissions
39 pricing would require electricity market reform in China (Teng et al. 2017).

40 **END BOX 13.14 HERE**

41
42 Policy packages aimed at low carbon transitions are more effective when they include elements to enhance
43 the phase out of carbon-intensive technologies and practices – often called exnovation -- in addition to
44 supporting low carbon niches (Kivimaa and Kern 2016; David 2017). Such policies include stringent carbon
45 pricing; changes in regime rules such as design of electricity markets; reduced support for dominant regime
46 technologies such as removing tax deductions for private motor transport based on internal combustion

1 engines; and changes in the balance of representation of incumbents versus new entrants in deliberation and
2 advisory bodies. For example, CGE modelling for China’s fossil fuel subsidy reform found that integrating
3 both creation and destabilization policies is able to reduce rebound effects and make the policy mix more
4 effective (Li et al. 2017). Sweden’s pulp and paper industry shows that destabilisation policies including
5 deregulation of the electricity market and a carbon tax were an important complement to support policies
6 (Scordato et al. 2018), and other studies show complementary results for Finland’s building sector (Kivimaa
7 et al. 2017b) and Norway’s transport and energy sector (Ćetković and Skjærseth 2019).

8 Policy packages for low-carbon transitions are more successful if they take into account the potential for
9 political contestation and resistance from incumbents who benefit from high-carbon systems (Roberts et al.
10 2018; Kern and Rogge 2018; Rosenbloom 2018; Geels 2014) (*medium evidence, high agreement*). To do so,
11 policies can be sequenced so as to address political obstacles, for example, by initially starting with policies
12 to facilitate the entry of new firms engaged in low-carbon technologies (Pahle et al. 2018). Such policies can
13 generate positive feedbacks by creating constituencies for continuation of those policies, but need to be
14 designed to do so from the outset (Edmondson et al. 2019, 2020). For example, supporting renewable
15 energies through feed-in tariffs can buttress coalitions for more ambitious climate policy, such as through
16 carbon pricing (Meckling et al. 2015). However, negative policy feedback may also arise from ineffective
17 policy instruments that lose public support, or create concentrated losses that arouse oppositional coalitions
18 (Edmondson et al. 2019). Feedback loops can operate through changes in resources available to actors;
19 changes in expectations; and changes in government capacities, (Edmondson et al. 2019).

20 Another promising strategy is to design short term policies which might help to provide later entry points for
21 more ambitious climate policy (Kriegler et al. 2018) and supportive institutions. The sequencing of policies
22 can build coalitions for climate policy, starting with green industrial policy (e.g. supporting renewable
23 energies through feed-in tariffs) and introducing or making carbon pricing more stringent when supportive
24 coalitions of stringent climate policy have been formed (Meckling et al. 2015). Similarly, investing in
25 supportive institutions, with competencies compatible with low-carbon futures, are a necessary supportive
26 element of transitions (Domorenok et al. 2021; Rosenbloom et al. 2019; Pahle et al. 2018).

28 **13.7.2 Policy integration for multiple objectives and shifting development pathways**

29 This sub-section assesses policy integration and packages required to enable shifts in development pathways,
30 with a particular focus on sectoral scale transitions. However, because shifting development pathways
31 requires broad transformative change, it complements discussion on broader shifts in policy-making such as
32 fiscal, educational, and infrastructure policies (Cross-Chapter Box 5 in Chapter 4) and to the alignment of a
33 wide range of enabling conditions required for system transitions (Section 13.9).

34 In many countries, and particularly when climate policy occurs in the context of sustainable development,
35 policymakers seek to address climate mitigation in the context of multiple economic and social policy
36 objectives (Halsnæs et al. 2014; Campagnolo and Davide 2019; Cohen et al. 2019) (*medium evidence, robust
37 agreement*). Studies suggest that co-benefits of climate policies are substantial, especially in relation to air
38 quality, and can yield better mitigation and overall welfare, yet these are commonly overlooked in policy-
39 making (Nemet et al. 2010; Ürge-Vorsatz et al. 2014; von Stechow et al. 2015; Mayrhofer and Gupta 2016;
40 Roy et al. 2018; Karlsson et al. 2020; Bhardwaj et al. 2019) (*robust evidence, robust agreement*). Other
41 studies have shown the existence of strong complementarities between the SDGs and realisation of NDC
42 pledges by countries (McCollum et al. 2018). An explicit attention to development pathways can enhance
43 the scope for mitigation, by paying explicit attention to development choices that lock-in or lock-out
44 opportunities for mitigation, such as around land use and infrastructure choices (Cross-Chapter Box 5 in
45 Chapter 4). While the pay-offs are considerable to an approach to mitigation that takes into account linkages
46 to multiple objectives and the opportunity to shift development pathways, there are also associated challenges
47 with implementing this approach to policymaking.

1 First, spanning policy arenas and addressing multiple objectives places considerable requirements of
2 coordination on the policy-making process (Howlett and del Rio 2015; Obersteiner et al. 2016). Climate
3 policy integration suggests several steps should precede actual policy-formulation, beginning with a clear
4 articulation of the policy frame or problem statement (Adelle and Russel 2013; Candel and Biesbroek 2016).
5 For example, a greenhouse gas limitation framework versus a co-benefits framing would likely yield
6 different policy approaches. It is then useful to identify the range of actors and institutions involved in climate
7 governance – the policy subsystem, the goals articulated, the level at which goals are articulated and the links
8 with other related policy goals such as energy security or energy access (Candel and Biesbroek 2016). The
9 adoption of specific packages of policy instruments should ideally follow these prior steps that define the
10 scope of the problem, actors and goals.

11 In practice, integration has to occur in the context of an already existing policy structure, which suggests the
12 need for finding windows of opportunity to bring about integration, which can be created by international
13 events, alignments with domestic institutional procedures, and openings created by policy entrepreneurs
14 (Garcia Hernandez and Bolwig 2020). Integration also has to occur in the context of existing organisational
15 routines and cultures, which can pose a barrier to integration (Uittenbroek 2016). Experience from the EU
16 suggests that disagreements at the level of policy instruments are amenable to resolution by deliberation,
17 while normative disagreements at the level of objectives require a hierarchical decision structure (Skovgaard
18 2018). As this discussion suggests, the challenge of integration operates in two dimensions: horizontal --
19 between sectoral authorities such as ministries or policy domains such as forestry -- or vertical -- either
20 between constitutional levels of power or within the internal mandates and interactions of a sector (Howlett
21 and del Rio 2015; Di Gregorio et al. 2017). There are also important temporal dimensions to policy goals, as
22 policy and benchmarks have to address not just immediate success but also indications of future
23 transformation (Dupont and Oberthür 2012; Dupont 2015).

24 Second policy-making for shifting development pathways has to account for inherent uncertainties in future
25 development paths (Moallemi and Malekpour 2018; Castrejon-Campos et al. 2020). These uncertainties may
26 be greater in developing countries that are growing rapidly and where structural features of the economy
27 including infrastructure and urbanisation patterns are fluid. For example, reviews of modelling studies of
28 Chinese (Grubb et al. 2015) and Indian emissions futures (Spencer and Dubash 2021) find that differences
29 in projections can substantially be accounted for by alternative assumptions about future economic structural
30 shifts. Consequently, an important design consideration is that policy packages should be robust, that is,
31 perform satisfactorily for all key objectives under a broad range of plausible futures (Castrejon-Campos et
32 al. 2020; Kwakkel et al. 2016; Maier et al. 2016). Such an approach to decision making can be contrasted
33 with one that tries to design an optimal policy package for the “best guess” future scenario (Maier et al.
34 2016). Moreover, policy packages can usefully be adapted dynamically to changing circumstances as part of
35 the policy process (Haasnoot et al. 2013; Maier et al. 2016; Hamarat et al. 2014) including by using
36 exploratory modelling techniques that allow comparison of trade-offs across alternative future scenarios
37 (Hamarat et al. 2014). Another approach is to link quantitative models with a participatory process that
38 enables decision-makers to test the implications of alternative interventions (Moallemi and Malekpour 2018).
39 Rosenbloom et al. (2019) suggest that because policy mixes should adapt to changing circumstances, instead
40 of stability of a particular mix, transitions require embedding policies within a long-term orientation toward
41 a low-carbon economy, including a transition agenda, social legitimacy for this agenda, and an appropriate
42 ecosystem of institutions.

43 Third, achieving changes in development pathways requires engaging with place-specific context. It requires
44 attention to existing policies, political interests that may gain or lose from a transition, and locally specific
45 governance enablers and disablers. As a result, while there may be approaches that carry over from one
46 context to another, implementation requires careful tailoring of transition approaches to specific policy and
47 governance contexts. Cross-Chapter Box 9 in this chapter summarises case studies of sectoral transitions

1 from other chapters in this report (Chapters 5-12) to illustrate this complexity. Broader macro-economic
2 transformative shifts are discussed in more detail in Section 13.9.

3 Common to all the sectoral cases in Cross-Chapter Box 9 is a future-oriented vision of sectoral transition
4 often focused on multiple objectives, such as designing tram-based public transport systems in Bulawayo,
5 Zimbabwe to simultaneously stimulate urban centers, create jobs and enable low carbon transportation.
6 Sectoral transitions are enabled by policy mixes that bring together different combinations of instruments –
7 including regulations, financial incentives, convening, education and outreach, voluntary agreements,
8 procurement and creation of new institutions – to work together in a complementary manner. The
9 effectiveness of a policy mix depends on conditions beyond design considerations and also rests on the larger
10 governance context within which sector transitions occur, which can include enabling and disabling
11 elements. Enabling factors illustrated in Cross-Chapter Box 9 include strong high level political support, for
12 example to address deforestation in Brazil despite powerful logging and farmer interests, or policy design to
13 win over existing private interests, for example, by harnessing distribution networks of kerosene providers
14 to new LPG technology in Indonesia. Disabling conditions include local institutional contexts, such as the
15 lack of tree and land tenure in Ghana, which, along with the monopoly of the state marketing board, posed
16 obstacles to Ghana’s low carbon cocoa transition. These examples emphasize the importance of attention to
17 local context if policy integration and the design of policy mixes are to effectively lead to transitions guided
18 by multiple climate and development objectives.

29 Real world sectoral transitions reinforce critical lessons on policy integration: a high-level strategic goal
30 (Column A), the need for a clear sector outcome framing (column B), a carefully coordinated mix of policy
31 instruments and governance actions (column C), and the importance of context-specific governance factors
32 (column D). Illustrative examples, drawn from sectors, help elucidate the complexity of policymaking in
33 driving sectoral transitions.

13.8 Integrating adaptation, mitigation and sustainable development

There is growing consensus that integration of adaptation and mitigation will advance progress towards sustainable development, and that ambitious mitigation efforts will reduce the need for adaptation in the long term (IPCC 2014a) (*robust evidence, high agreement*). There is no level of mitigation, however, that will completely erase the need for adaptation to climate change (Mauritsen and Pincus 2017) (*robust evidence, high agreement*). It is therefore urgent to design and implement a multi-objective policy framework for mitigation, adaptation, and sustainable development that considers issues of equity and long-term developmental pathways across regions (Jordan et al. 2018a; Mills-Novoa and Liverman 2019; Wang and Chen 2019) (*robust evidence, high agreement*). This section explores the logic behind the integration of adaptation and mitigation in practice (Section 13.8.1), the approaches to this integration including climate-resilient pathways, ecosystem-based solutions, and a nexus approach (Section 13.8.2); examples of the adaptation and mitigation relationships and linkages (Section 13.8.3); and enabling and disabling factors for governance of mitigation and adaptation.

13.8.1 Synergies between adaptation and mitigation

Integrated climate-development actions require a context-specific understanding of synergies and trade-offs with other policy priorities (see Figure 13.6) with the aim of implementing mitigation/adaptation policies that reduce GHG emissions while simultaneously strengthening resilience and reducing vulnerability (Klein et al. 2005; IPCC 2007; Mills-Novoa and Liverman 2019; Solecki et al. 2019; Zhao et al. 2018) (*robust evidence, high agreement*). Efficient, equitable and inclusive policies which also acknowledge and contribute directly to other pressing priorities such as reducing poverty, improving health, providing access to clean water, and fostering sustainable consumption and production practices are helpful for mitigation/adaptation goals (Landauer et al. 2019; Grafakos et al. 2020) (*robust evidence, high agreement*).

Adaptation and mitigation are deeply linked in practice – at the local level, for instance, asset managers address integrated low-carbon resilience to climate change impacts and urban planners do the same (Ürge-Vorsatz et al. 2018; Grafakos et al. 2020) (see Table 13.3 for details). Similarly, ecosystem-based (or nature-based) solutions, may generate co-benefits by simultaneously sinking carbon, cooling urban areas through shading, purifying water, improving biodiversity, and offering recreational opportunities that improve public health (Raymond et al. 2017). Accurately identifying and qualitatively or quantitatively assessing these co-benefits (Leiter and Pringle 2018; Leiter et al. 2019; Stadelmann et al. 2014)– is central to an integrated adaptation and mitigation policy evaluation.

Some studies press the need to consider the complex ways that power and interests influence how collective decisions are made, and who benefits from and pays for these decisions, of climate policy and to be aware of unintended consequences, especially for vulnerable people living under poor conditions (Mayrhofer and Gupta 2016; De Oliveira Silva et al. 2018). The specific adaptation and mitigation linkages will differ by country and region, as illustrated by Box 13.15.

START BOX 13.15 HERE

Box 13.15 Adaptation and mitigation synergies in Africa

1 Synergies between mitigation and adaptation actions and sustainable development that can enhance the
2 quality and pace of development in Africa exist at both sectoral and national levels. Available data on NDCs
3 show the top mitigation priorities in African countries include energy, forestry, transport and agriculture and
4 waste, and adaptation priorities focus on agriculture, water, energy and forestry. The energy sector dominates
5 in mitigation actions and the agricultural sector is the main focus of adaptation measures, with the latter
6 sector being a slightly larger source of greenhouse gases than the former (Mbeva et al. 2015; African
7 Development Bank 2019; Nyiwul 2019).

8 Renewable energy development can support synergies between mitigation and adaptation by stimulating
9 local and national economies through microenterprise development; providing off-grid affordable and
10 accessible solutions; and contributing to poverty reduction through increased locally available resource use
11 and employment and increased technical skills (Dal Maso et al. 2020; Nyiwul 2019). The Paris Agreement's
12 technology transfer and funding mechanisms could reduce renewable energy costs and providing scale
13 economics to local economies.

14 Barriers to achieving these synergies include the absence of suitable macro- and micro- level policy
15 environments for adaptation and mitigation actions; coherent climate change policy frameworks and
16 governance structures to support adaptation; institutional and capacity deficiencies in climate and policy
17 research such as on data integration and technical analysis; and the high financial needs associated with the
18 cost of mitigation and adaptation (African Development Bank 2019; Nyiwul 2019). Strengthening of national
19 institutions and policies can support maximising synergies and co-benefits between adaptation and
20 mitigation to reduce silos and redundant overlaps, increase knowledge exchange at the country and regional
21 levels, and support engagement with bilateral and multilateral partners and mobilising finance through the
22 mechanisms available (African Development Bank 2019).

23 **END BOX 13.15 HERE**

25 **13.8.2 Frameworks that enable the integration of adaptation and mitigation**

26 The 5th Assessment report of the IPCC emphasised the importance of climate-resilient pathways --
27 development trajectories that combine adaptation and mitigation through specific actions to achieve the
28 sustainable development goals (Prasad et al. 2009; Lewison et al. 2015; Fankhauser and McDermott 2016;
29 Romero-Lankao et al. 2016; Solecki et al. 2019) -- from the household to the state level, since risks and
30 opportunities vary by location and the specific local development context (IPCC 2014b; Denton et al. 2015)
31 (*robust evidence, high agreement*).

32 Synergies between adaptation and mitigation are included in many of the NDCs submitted to the UNFCCC,
33 as part of overall low-emissions climate-resilient development strategies (UNFCCC Secretariat 2016). A
34 majority of developing countries have agreed to develop National Adaptation Plans (NAPs) in which many
35 initiatives contribute simultaneously to the SDGs (Schipper et al. 2020) as well to mitigation efforts (Hönle
36 et al. 2019; Atteridge et al. 2020). For example, developing countries recognize that adaptation actions in
37 sectors such as agriculture, forestry and land use management can reduce GHGs. Nevertheless, other more
38 complex trade-offs also exist between bioenergy production or reforestation and the land needed for
39 agricultural adaptation and food security (African Development Bank 2019; Hönle et al. 2019; Nyiwul 2019,
40 see Chapter 7). For some of the Small Islands Development States (SIDS), forestry and coastal management,
41 including mangrove planting, saltmarsh and seagrass are sectors that intertwine both mitigation and
42 adaptation (Atteridge et al. 2020; Duarte et al. 2013). Integrated efforts also occur at the city level, such as
43 the Climate Change Action Plan of Wellington City, which includes enhancing forest sinks to increase carbon
44 sequestration while at the same time protecting biodiversity and reducing groundwater runoff as rainfall
45 increases (Grafakos et al. 2019).

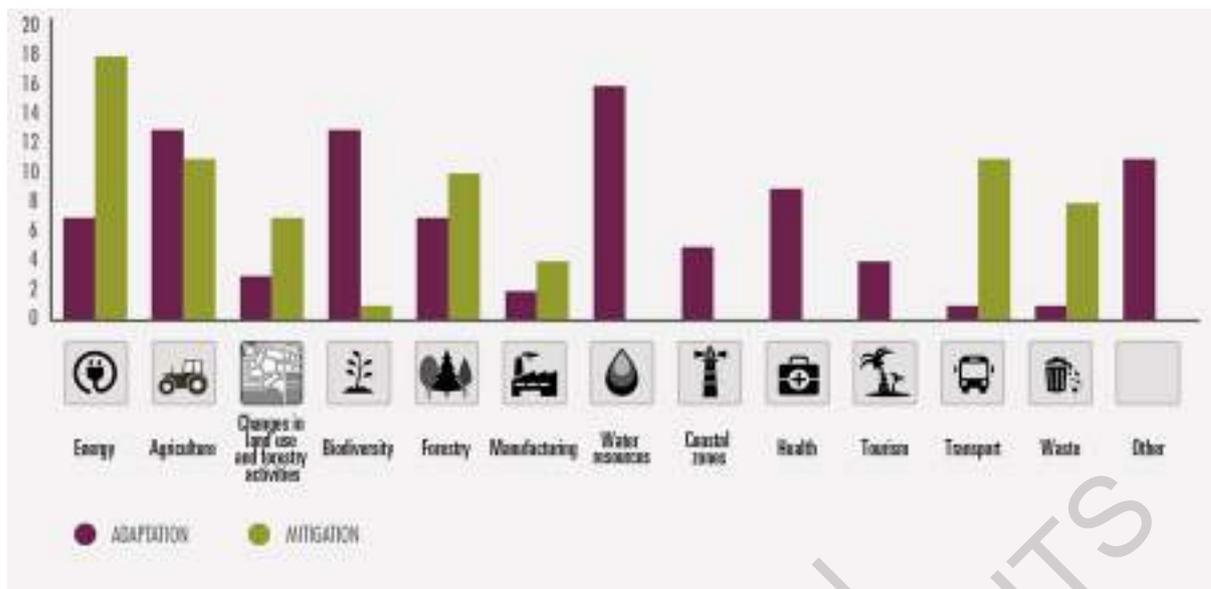

1 To fully maximise their potential co-benefits and trade-offs of integrating adaptation and mitigation, these
2 should be explicitly sought, rather than accidentally discovered (Spencer et al. 2017; Berry et al. 2015), and
3 policies designed to account for both (Caetano et al. 2020) (*robust evidence, high agreement*). For example,
4 the REDD+ initiative focus on mitigation by carbon sequestration was set up to provide co-benefits such as:
5 nature protection, political inclusion, monetary income, economic opportunities. However, some unintended
6 trade-offs may have occurred such as physical displacement, loss of livelihoods, increased human–wildlife
7 conflicts, property claims, food security concerns, and an unequal distribution of benefits to local population
8 groups (Bushley 2014; Duguma et al. 2014a; Gebara et al. 2014; Anderson et al. 2016; Di Gregorio et al.
9 2016, 2017; Kongsager and Corbera 2015). Ultimately, ecosystem (or nature-based) strategies, such as the
10 use of wetlands to create accessible recreational areas that improve public health while improving
11 biodiversity, sinking carbon and protecting neighbourhoods from extreme flooding events, may lead to more
12 efficient and cost-effective policies (Locatelli et al. 2011; Klein et al. 2005; Mills-Novoa and Liverman 2019;
13 Kongsager et al. 2016).

15 **START BOX 13.16 HERE**

16 **Box 13.16 Latin America region adaptation linking mitigation: REDD+ lessons**

17 Thirty-three countries in the Latin American region have submitted their NDCs, and 70% of their initiatives
18 have included mitigation and adaptation options focusing on sustainable development (Bárcena et al. 2018;
19 Kissinger et al. 2019). However, most of these policies are disconnected across sectors (Loaiza et al. 2017;
20 Locatelli et al. 2017). National governments have identified their relevant sectors as: energy, agriculture,
21 forestry, land-use change, biodiversity, and water resources (see Figure 1 below). The region houses 57% of
22 the primary forest of the planet. REDD+ aims to reduce GHG while provide ecosystems services to
23 vulnerable communities (Bárcena et al. 2018). Lessons from successful REDD+ programs include the
24 benefits of a multilevel structure from international to national down to strong community organization, as
25 well as secure resources funding, with most of the projects relying on external sources of funding (Kissinger
26 et al. 2019; Loaiza et al. 2017) (*medium evidence, high agreement*). However, there is limited evidence of
27 effective adaptation co-benefits, which may be related to the lack of provision of forest standards; a
28 disproportionate focus on mitigation and lack of attention to the well-being of the population in rural and
29 agricultural areas (Kongsager and Corbera 2015).

30 Conflicts have emerged over political views, government priorities of resources (oil, bioenergy,
31 hydropower), and weak governance among national and local authorities, indigenous groups and other
32 stakeholders such as NGOs which play a critical role in the technological and financial support for the
33 REDD+ initiative (Reed 2011; Kashwan 2015; Gebara et al. 2014; Locatelli et al. 2011, 2017). A more
34 holistic approach which recognises these social, environmental and political drivers would appear to have
35 benefits but assessment is needed to allow evidence based actionable policy statements.

Box 13.16, Figure 1 Latin America and the Caribbean: High priority sectors for mitigation and adaptation. Number of countries that name the following sector in their national climate change plans and/or communications. The purple and green bars represent adaptation and mitigation respectively.

Source: Reproduced from Bárcena et al. 2018

END BOX 13.16 HERE

The ‘nexus’ approach is another widely used framework that describes the linkages between water, energy, food, health and other socio-economic factors in some integrated assessment approaches (Rasul and Sharma 2016). The Food-Energy-Water (FEW) nexus, for example, considers how water is required for energy production and supply (and thus tied to mitigation), how energy is needed to treat and transport water, and how both are critical to adaptable and resilient food production systems (Mohtar and Daher 2014; Biggs et al. 2015). Climate change impacts all these dimensions in the form of multi-hazard risk (Froese and Schilling 2019). Although integrative, the FEW nexus faces many challenges including: limited knowledge integration; coordination between different institutions and levels of government; politics and power; cultural values; and ways of managing climate risk (Leck and Roberts 2015; Romero-Lankao et al. 2017; Mercure et al. 2019). More empirical assessment is needed to identify potential overlaps between sectoral portfolios, as this could help to delineate resources allocation for synergies and to avoid trade-offs.

13.8.3 Relationships between mitigation and adaptation measures

There are multiple ways that mitigation and adaptation may be integrated. Table 13.3 sets out those relationships broken down into four areas: adaptation that contributes to mitigation; mitigation that contributes to adaptation; holistic, sustainability first strategies; and trade-offs. The table shows that more holistic and sustainability-oriented policies can open up the possibility for accelerated transitions across multiple priority domains (*robust evidence, high agreement*).

Table 13.3 Relationships between adaptation and mitigation measures

Policy/action	Interrelation explained	Reference
<i>Adaptation that contributes to mitigation</i>		
<p>Coastal adaptation and blue carbon; developing strategies for conservation and restoration of blue carbon ecosystems generating resilient communities and landscapes.</p> <ul style="list-style-type: none"> • Contributes to carbon storage and sequestration. 	<p>Conservation of habitats and ecosystems, protect communities from extreme events, increase food security, and provide ecosystem services. At the same time, restoration of mangroves, tidal marshes, and seagrasses have high rates of carbon sequestration, act as long-term carbon sinks, and are contained within clear national jurisdictions. Example: Conservation programs on Brazilian mangroves, Spanish seagrass meadows, the Great Barriers Reef in Australia, and Coastal Management Strategy in New Zealand</p>	<p>(Andresen et al. 2012; Herr and Landis 2016; Duarte 2017; Doll and Oliveira 2017; Howard et al. 2017; Gattuso et al. 2018; Cooley et al. 2019; Karani and Failler 2020; Lovelock and Reef 2020)</p>
<p>Nature-based Solutions (NbS); Nature-based solutions are interventions that use the natural functions of healthy ecosystems to protect the environment but also provide numerous economic and social benefits.</p> <ul style="list-style-type: none"> • Contributes to carbon storage and sequestration using individual and clustered trees. 	<p>NbS complement and shares common elements with a wide variety of other approaches to building the resilience of social-ecological systems. Policies at national and subnational level include community-based adaptation, ecosystem-based disaster risk reduction, climate-smart agriculture, and green infrastructure, and often place emphasis on using participatory and inclusive processes and community/stakeholder engagement. Examples: Mexico and the United Kingdom provide support for NbS in their national biodiversity strategies and action plans some related to water management. UK launched the Green Recovery Challenge Fund to create jobs with a focus on tree planting and the rehabilitation of peatlands.</p>	<p>(Doswald and Osti 2011; Secretariat of the Convention on Biological Diversity 2019; Ihobe - Environmental Management Agency 2017; Zwierzchowska et al. 2019; Seddon et al. 2020; Choi et al. 2021; OECD 2021b)</p>
<p>Ecosystem-based Adaptation (EbA); use biodiversity and ecosystem services to help people to adapt to the adverse effects of climate change, aiming to maintain and increase the resilience and reduce the vulnerability of ecosystems and people</p> <ul style="list-style-type: none"> • Contributes to carbon storage and sequestration 	<p>EbA involves the conservation, sustainable management and restoration of ecosystems, such as forests, grasslands, wetlands, mangroves or coral reefs to reduce the harmful impacts of climate hazards including shifting patterns or levels of rainfall, changes in maximum and minimum temperatures, stronger storms, and increasingly variable climatic conditions. Examples: Some NDCs include EbA and NbS harmonizing national policies (e.g.: National Adaptation Plan) with other national climate and development policy processes, such as: water resources management plan, disaster risk reduction strategies, land planning codes.</p>	<p>(IPBES 2019; Doswald et al. 2014; Secretariat of the Convention on Biological Diversity 2009; McAllister 2007; Colls et al. 2009; Rubio 2017; Raymond et al. 2017; Duarte 2017; Gattuso et al. 2018)</p>
<p>Urban Greening; urban forestry, planting in road reserves and tree planting along main streets.</p> <ul style="list-style-type: none"> • Contributes to carbon storage and sequestration • Energy use reduction 	<p>Urban afforestation and reforestation produce cooling effect and water retention while helping to reducing carbon dioxide from the atmosphere. Green walls and rooftops increase energy efficiency of buildings and decrease water runoff and provide insulation for the buildings. Examples: Wellington City Council and other entities must comply with the New Zealand Emission Trading System regulatory framework that provides guidance and requirements of climate change planning and implementation for both M&A.</p>	<p>(Santamouris 2014; Sharifi and Yamagata 2016; Grafakos et al. 2018; Pasimeni et al. 2019; Anderson et al. 2016)</p>

<p>Climate adaptation plans at city level; Subnational policies that would lead to carbon reduction to support climate mitigation. Contribution to mitigation:</p> <ul style="list-style-type: none"> • Carbon storage and sequestration • Energy use reduction • Renewable energy 	<p>Cities with Climate Actions Plans include urban spatial planning and capacity-building initiatives. Some cities with adaptation and mitigation combined climate change action plans are: Bangkok, Chicago, Montevideo, Wellington, Durban, Paris, Mexico City, and Melaka. And cities with A&M actions are: Los Angeles, Vancouver, Barcelona, London, Accra, Santiago de Chile, Bogota, Curitiba, and other.</p> <p>Co-benefits generated by climate actions at cities: heat stress reduction; water scarcity, stormwater and flood management; air quality improvement, human health and well being, aesthetic/ amenity, recreation / tourism, environmental justice, real estate value, food production, green jobs opportunities.</p>	<p>(Garcetti 2019; Horne 2020; Barcelona City Council 2018; Greater London Authority 2018; Accra Metropolitan Assembly 2020; Choi et al. 2021; Grafakos et al. 2019; Nakano et al. 2017; Peng and Bai 2018; Zen et al. 2019; Bai et al. 2018)</p>
<i>Mitigation that contributes to adaptation</i>		
<p>Green Infrastructure; Policies to support the design and implementation of a hybrid network of natural, semi-natural, and engineered features within, around, and beyond urban areas at all scales, to provide multiple ecosystem services and benefits.</p> <ul style="list-style-type: none"> • Carbon storage and sequestration • Reduced energy consumption 	<p>Adaptation benefits: flood management, heat stress reduction individually, or jointly, coastal protection, water scarcity management, groundwater resources, ecosystem resilience improvement, air quality, water supply, flood control, water quality improvement, groundwater recharge. Social co-benefits: aesthetic, recreation, environmental education, improved human health/wellbeing, social cohesion, and poverty reduction. Policy examples: National building code guidelines, flood safety standards, local land-use plans, local building codes, integrated water management for flood control,</p>	<p>(Atchison 2019; Conger and Chang 2019; Schoonees et al. 2019; De la Sota et al. 2019; Choi et al. 2021; Zwierzchowska et al. 2019)</p>
<p>REDD+ Strategies; An incentive for developing countries to increase carbon sinks, to protect their forest resources and coastal wetlands. Mostly are national strategies led by the state with contribution of international donors.</p> <ul style="list-style-type: none"> • Contributes to carbon storage and sequestration • Renewable energy 	<p>REDD+ strategies aim to generate social benefits such as poverty reduction, and ecological services such as water supply, water quality enhancement, conserves soil and water by reducing erosion. For example; indigenous communities of Socio Bosque in Ecuador have sustained livelihoods and maintaining ties to land, place, space, and <i>cosmovision</i> While in Cameroon, upfront contextual inequities with respect to technical capabilities, power, gender, level of education, and wealth have been barriers to individuals' likelihood of participating in and benefiting from the projects.</p>	<p>(McBurney 2021; Tegegne et al. 2021; Anderson et al. 2016; Busch et al. 2011; Bushley 2014; Dickson and Kapos 2012; Froese and Schilling 2019; Gebara et al. 2014; Pham et al. 2014; Jodoin 2017)</p>
<p>Household energy-efficiency and renewable energy measures; Energy policies may improve socioeconomic development.</p> <ul style="list-style-type: none"> • Energy use reduction 	<p>Energy Efficiency (EE) emerges as a feasible and sustainable solution in Latin America, to minimise energy consumption, increase competitiveness levels and reduce carbon footprint. Achieving high levels of EE in the building sector requires new policies and strengthening their legal framework. Microenterprise development contributes to poverty reductions as renewable energy stimulate local and national economies</p>	<p>(Chan et al. 2017; Silvero et al. 2019; Zabaloy et al. 2019; Alves et al. 2020; Nyiwul 2019; Dal Maso et al. 2020)</p>
<i>Sustainability first: Holistic approaches</i>		
<p>Integrated community sustainability plans.</p>	<p>Climate change mitigation and adaptation are embedded in a plan to improve affordability, biodiversity, public health, and other aspects of communities.</p>	<p>(Burch et al. 2014; Shaw et al. 2014; Stuart et al. 2016; Dale et al. 2020)</p>

<p>Inclusive future visioning using social-ecological systems or socio-technical systems thinking.</p>	<p>Participatory processes that highlight the cultural and social dimensions of climate change responses and synergies/trade-offs between priorities rather than an exclusive focus on technical aspects of solutions.</p>	<p>(Gillard et al. 2016; Krzywoszynska et al. 2016)</p>
<p>Climate Resilience Cities; integrating New Urban Agenda (NUA), SDGs, climate actions for A&M, and Disaster Risk Reduction (DRR) for local and subnational governments, and DRR within a multi-hazard approach based on Sendai Framework.</p>	<p>Resilient cities are including SDGs, targets, A&M options and DRR to build a resilient plan for urban planning, health, life quality and jobs creation.</p> <p>Climate mitigation and sustainable energy actions adopted at the local level are interconnected. For instance, cities with Sustainable Energy and Climate Action Plan, which required the establishment of a baseline emission inventory and the adoption of policy measures, are already showing a tangible achievement regarding sustainable goals.</p>	<p>(Barcelona City Council 2018; Garcetti 2019; Accra Metropolitan Assembly 2020; Blok 2016; Giampieri et al. 2019; Gomez Echeverri 2018; Long and Rice 2019; Pasimeni et al. 2019; Romero-Lankao et al. 2016)</p>
<p><i>Trade-offs</i></p>		
<p>Land use strategies; for mitigation or adaptation considered in isolation, may cause a conflict in land planning.</p> <ul style="list-style-type: none"> • Carbon storage and sequestration • Energy use reduction • Renewable energy 	<p>Increasing density of land use, land use mix and transit connectivity could increase climate stress and reduce green open spaces. It may increase the urban heat island impacting human health, and expose population to coastal inundation. Some of the policies and strategies to minimise this are: land use planning, zoning, land-use permits, mobilizing private finance in the protection of watersheds, integrated coastal zone management, flood safety standards, and other. More assessment is needed prior to new land use to reduce or prevent actions which negatively alter ecosystem services and environmental justice</p>	<p>(O'Donnell 2019; Bush and Doyon 2019; Grafakos et al. 2019; Landauer et al. 2015; Vigiúé and Hallegatte 2012; Floater et al. 2016; Xu et al. 2019; Landauer et al. 2019)</p>
<p>Low-carbon, net zero and climate change resilient building codes that fail to account for affordability.</p> <ul style="list-style-type: none"> • Energy reduction • Renewable energy 	<p>Low carbon or net zero emissions have multi-objective strategies, integrated policies, regulations, and actions at the national and sub-national levels. Trade-offs may be related to policy mechanisms that must be implemented comprehensively, not individually. However, different administrative levels and institutions may create a barrier to inter-sectoral coordination. For example: “Greening” programmes may produce positive mitigation and adaptation outcomes but may also accelerate displacement and gentrification at city level.</p>	<p>(Chaker et al. 2021; del Río and Cerdá 2017; Choi et al. 2021; Papadis and Tsatsaronis 2020; Wolch et al. 2014; Garcia-Lamarca et al. 2021; Haase et al. 2017; Sharifi 2020; Vigiúé and Hallegatte 2012; del Río 2014)</p>

1 **13.8.3.1 Governing the linkages between mitigation and adaptation at the local, regional, and global** 2 **scales**

3 International policy frameworks, such as the 2015 Paris Agreement, the Sendai Framework for Disaster Risk
4 Reduction, and the New Urban Agenda for sustainable urban systems, provide an integrated approach for
5 both adaptation and mitigation, while promoting sustainable development and climate resilience across
6 scales (from global, regional, to local government actions (Nachmany and Setzer 2018; Duguma et al. 2014b;
7 Heidrich et al. 2016; Di Gregorio et al. 2017; Locatelli et al. 2017; Mills-Novoa and Liverman 2019) (*robust*
8 *evidence, high agreement*). Even so, the specific ways that these linkages are governed vary widely
9 depending on institutional and jurisdictional scale, competing policy priorities, and available capacity
10 (Landauer et al. 2019).

11 Supranational levels of action such as the EU climate change policy have influenced the development and
12 implementation of Climate Change Action Plans (CCAPs) at the subnational level (Reckien et al. 2018;
13 Villarroel Walker et al. 2017; Heidrich et al. 2016). While adaptation is gaining prominence and is
14 increasingly included in the NDCs of EU nations, the implementation of adaptation and mitigation by EU
15 states are at different stages (Fleig et al. 2017). Fleig et al. (2017) found that all EU states, with the exception
16 of Hungary, have adopted a framework of laws tackling mitigation and adaptation to climate change.
17 However, an assessment of climate legislation in Europe pointed out that there has been little coordination
18 between mitigation and adaptation, and that implementation varies according to different national conditions
19 (Nachmany et al. 2015). More recently, however, integrated adaptation/mitigation plans have been prepared
20 in Europe under the Covenant of Mayors, in which synergies and trade-offs can be better revealed and
21 assessed (Bertoldi et al. 2020).

22 Local governments and cities are increasingly emerging as important climate change actors (Gordon and
23 Acuto 2015) (see also Section 13.5). While cities and local governments are developing Climate Change
24 Action Plans (CCAPs), plans that explicitly integrate the design and implementation of adaptation and
25 mitigation are a minor percentage, with few cities establishing inter-relationships between them (Nordic
26 Council of Ministers 2017; Grafakos et al. 2018). Compared to national climate governance, local
27 governments are more likely to develop and advance climate policies, generating socio-economic or
28 environmental co-benefits, and improve communities' quality of life (Gill et al. 2007; Bowen et al. 2014;
29 Deng et al. 2017; Hennessey et al. 2017; Mayrhofer and Gupta 2016; Duguma et al. 2014b). There may be a
30 disconnect, however, between the responsibility that a particular jurisdiction has over mitigation and
31 adaptation (city officials, for instance) and the scale of resources or capacities that they have available to
32 bring to bear on the problem (regional to national provision of energy and transport) (Di Gregorio et al. 2019;
33 Dale et al. 2020).

34

35 **13.8.4 Integrated governance including equity and sustainable development**

36 Climate policy integration carries implications for the pursuit of the SDGs, given that it is nearly impossible
37 to achieve the desired socio-economic gains if fundamental environmental issues, such as climate change,
38 are not addressed (Gomez-Echeverri 2018). Research on climate resilient development pathways (Roy et al.
39 2018), for instance, argues for long term policy planning that combines the governance of national climate
40 and SD goals, builds institutional capacity across all sectors, jurisdictions, and actors, and enhances
41 participation and transparency (*robust evidence, high agreement*) (also see Chapter 4 and 17).

42 In the Global South, climate change policies are often established in the context of sustainable development
43 and of other pressing local priorities (e.g., air pollution, health, and food security). National climate policy
44 in these countries tends to give prominence to adaptation based on country vulnerability, climatic risk,
45 gender-based differences in exposure to that risk, and the importance of local/traditional and indigenous
46 knowledge (Beg et al. 2002; Duguma et al. 2014b). Despite the evidence that integrated mitigation and
47 adaptation policies can be effective and efficient (Klein et al. 2005) and can potentially reduce trade-offs,

1 there is still limited evidence of how such integrated policies would specifically contribute to progress on
2 the SDGs (Antwi-Agyei et al. 2018; De Coninck et al, 2018; Di Gregorio et al. 2017; Campagnolo and
3 Davide 2019; Kongsager et al 2016) (*robust evidence, high agreement*).

4 Where mainstreaming of environmental concerns has been attempted through national plans, they have had
5 success in some cases when backed by strong political commitments that support a vertical coordination
6 structure rather than horizontal structures led by the focus ministry (Nunan et al. 2012). Such political
7 commitments are therefore crucial to success but insufficient in and of themselves (Runhaar et al. 2018;
8 Wamsler et al. 2020). Integration of the budget process is particularly important, as are aligned timeframes
9 across different objectives (Saito 2013). Recognition of the functional interactions across policy sectors is
10 improved by a translation of long-term policy objectives into a plan that aligns with integration goals (Corry
11 2012; Oels 2012; Dupont 2019).

12 There are important links between inequality, justice and climate change (Ikeme 2003; Bailey 2017). Many
13 of these operate through the benefits, costs and risks of climate action (distributive justice), while others
14 focus on differential participation and recognition of subnational actors and marginalized groups (procedural
15 justice) (Bulkeley and Castán Broto 2013; Bulkeley et al. 2013; Hughes 2013; Romero-Lankao and Gnatz
16 2019; Reckien et al. 2018).

17 Justice principles are rarely incorporated in climate change framing and action (Sovacool and Dworkin 2015;
18 Genus and Theobald 2016; Heikkinen et al. 2019; Romero-Lankao and Gnatz 2019). Yet, equity is salient to
19 mitigation debates, because climate change mitigation policies can have also negative impacts (Brugnach et
20 al. 2017; Ramos-Castillo et al. 2017; Klinsky 2018), exacerbated by poverty, inequality and corruption
21 (Markkanen and Anger-Kraavi 2019; Reckien et al. 2018). The siting of facilities and infrastructure that
22 advance decarbonisation (such as public transit infrastructure, renewable energy facilities etc.) may have
23 implications for environmental justice. Integrated attention to justice in climate, environment and energy, as
24 well as involvement of host communities in siting assessments and decision-making processes, can help to
25 avoid such conflict (McCord et al. 2020; Hughes and Hoffmann 2020). As a result, successful policy
26 integration goes beyond optimizing public management routines, and must resolve key trade-offs between
27 actors and objectives (Meadowcroft 2009; Nordbeck and Steurer 2016).

28 The potential for transformative climate change policy that delivers both adaptation and mitigation is also
29 shaped by a number of enabling and disabling factors tied to governance processes (Burch et al. 2014)(also
30 see Section 13.9) (*robust evidence, high agreement*).

31

32 **START BOX 13.17 HERE**

33 **Box 13.17 Enabling and disabling factors for integrated governance of mitigation and adaptation**

34 *Ensuring participatory governance and social inclusion:* Interlinkages in the food-energy-water nexus
35 highlight the importance of inclusive processes (Cook and Chu 2018; Shaw et al. 2014; Nakano et al. 2017;
36 Romero-Lankao and Gnatz 2019). The cultivation of urban grassroots innovations and social innovation may
37 accelerate progress (Wolfram and Frantzeskaki 2016), as may the development of carefully-designed climate
38 and energy dialogues that enable learning among multiple stakeholders (Cashore et al. 2019).

39 *Considering synergies and trade-offs with broader sustainable development priorities:* The explicit
40 consideration of synergies and trade-offs will enable more integrated policy making (von Stechow et al.
41 2015; Dang et al. 2003). Policy frameworks to do so are just emerging, such as analysis of trade-offs between
42 energy and water policies and agriculture (Huggel et al. 2015; Antwi-Agyei et al. 2018).

43 *Employing a diverse set of tools to reach targets:* Building codes, land use plans, public education initiatives,
44 and nature-based solutions such as green ways may impact adaptation and mitigation simultaneously (Burch
45 et al. 2014). Ecological restoration provides another suite of tools, for instance the Brazilian target of

1 restoring and reforesting 0.12 million km² of forests by 2030, which can enhance biodiversity and ecosystem
2 services while also sinking carbon (Bustamante et al. 2019). Mandatory retrofits to improve indoor air quality
3 can also increase energy efficiency and resilience to climate change impacts (Friel et al. 2011; Houghton
4 2011).

5 *Monitoring and evaluating key indicators, beyond only greenhouse gas emissions, such as biodiversity, water*
6 *quality, and affordability:* An integrated approach requires robust process for collecting data on these
7 indicators. Challenges are related to the limited evidence-base on synergies, co-benefits, and trade-offs across
8 sectors and jurisdictions (Di Gregorio et al. 2016; Kongsager et al, 2016; Locatelli et al. 2017; Zen et al.
9 2019). Moreover, adaptation policies mostly lack measurable targets or expected outcomes increasing the
10 challenge of designing an integrated framework (OECD 2017).

11 *Iterative and adaptive management:* Adaptive management helps to address the underlying uncertainty
12 (Kundzewicz et al. 2018) that characterizes implementation of integrated approaches to adaptation and
13 mitigation. Policy integration needs to be considered iteratively along the process of development,
14 implementation, and evaluation of climate policies.

15 *Strategic partnerships that coordinate efforts:* Strategic partnerships among diverse actors, therefore, bring
16 diverse technical skills and capacities to the endeavour (Burch et al. 2016; Islam and Khan 2017). However,
17 realising strategic approaches for joint adaptation and mitigation require adequate financial, technical and
18 human resources.

19 *Participatory and collaborative planning approaches can help overcome injustices and address power*
20 *differentials:* Participatory and collaborative planning approaches can provide multiple spaces of deliberation
21 where marginalised voices can be heard (Blue and Medlock 2014; UN Habitat 2016; Castán Broto and
22 Westman 2017; Waisman et al. 2019). These tools organise climate and sustainability action by addressing
23 its democratic deficit and facilitating the recognition of multiple perspectives in environmental planning
24 alongside material limits of development (Agyeman 2013).

25 **END BOX 13.17 HERE**

26

27 **13.9 Accelerating mitigation through cross sectoral and economy wide system** 28 **change**

29 **13.9.1 Introduction**

30 Section 13.9 assesses literature related to economy wide and cross - sector systemic change as an approach
31 to accelerate climate mitigation.

32 It focuses specifically on policy and institutions, as two of the six enabling conditions for economy wide
33 system change and thus provides a third dimension of the role of policy and institutions to climate mitigation.
34 Enabling conditions in general are discussed in Chapter 4 of the SR1.5 (IPCC 2018), as well as Chapter 4 of
35 this report. This section follows on from Section 13.6 (single policy instruments) and 13.7 (policy packages).
36 Section 13.9 literature follows closely on from Section 13.7 literature on policy packages, which discusses
37 change within one system, although there remains an overlap.

38 Section 13.9.2 provides a brief introduction to policy and institutions as 2 of the 6 dimensions of enabling
39 conditions, and the importance of enabling conditions to systemic change and climate mitigation. Section
40 13.9.3 briefly introduces actions for transformative justice, which seek to restructure the underlying system
41 framework that produces mitigation inequalities. Section 13.9.4 provides a brief overview of Net Zero
42 policies and targets (often no more than aspirational), which imply economy wide measures and system
43 change. Section 13.9.5 assesses the literature arguing for a system restructuring approach to climate
44 mitigation, based on systemic restructuring. Section 13.9.6 assesses the literature on stimulus packages and

1 green new deals which aim for systemic change, sometimes with value for climate mitigation. And finally,
2 Section 13.9.7 assesses emerging literatures which argues that there are existing challenges to accelerating
3 climate mitigation that may be overcome by systemic change and targeted actions.

5 **13.9.2 Enabling acceleration**

6 IPCC AR6 WG3, particularly Chapter 4, following on from the IPCC WG3 SR1.5 (IPCC 2018), has
7 highlighted the importance of enabling conditions for delivering successful climate mitigation actions. The
8 AR6 Glossary term for enabling conditions is: ‘enabling conditions include *finance, technological*
9 *innovation*, strengthening policy instruments, *institutional capacity, multi-level governance*, and changes
10 in *human behaviour* and lifestyles (See Glossary) (*medium evidence, high agreement*). The IPCC SR1.5
11 report adds to these 6 dimensions saying enabling conditions also includes ‘inclusive processes, attention to
12 power asymmetries and unequal opportunities for development and reconsideration of values’ (IPCC 2018)
13 (*medium evidence, high agreement*). Not only is the presence of enabling conditions necessary for delivering
14 the successful implementation of single policy instruments and policy packages, but also for delivering
15 systemic change (de Coninck et al. 2018; IPCC 2018; Waisman et al. 2019) (*medium evidence, high*
16 *agreement*). The feasibility of 1.5°C compatible pathways is contingent upon enabling conditions for
17 systemic change (de Coninck et al. 2018; Waisman et al. 2019) (*medium evidence, high agreement*).

18 At the same time, again following on from SR1.5 report, Section 1.8.1 explains that there are six feasibility
19 dimensions of successful delivery of climate goals. These feasibility dimensions include geophysical;
20 environmental & ecological; technological; economic; behaviour and lifestyles and institutional dimensions.
21 The presence or absence of enabling conditions would affect the feasibility of mitigation as well as adaptation
22 pathways and can reduce trade-offs whilst amplifying synergies between options (Waisman et al. 2019).
23 Policies and institutions, which are two of the six enabling conditions, are therefore central to accelerated
24 mitigation and systemic change. Identifying, and ensuring, the presence of all the enabling conditions for
25 any given goal, including systemic transformation and acceleration of climate mitigation, is an important
26 first step (Roberts et al. 2018; Le Treut et al. 2021; Singh and Chudasama 2021) (*medium evidence, medium*
27 *agreement*).

29 **13.9.3 Transformative justice action and climate mitigation**

30 Chapter 4 is the lead chapter of this Report for justice and climate mitigation issues, and includes an overview
31 of institutions which have been set up to ensure a Just climate transition (see Section 4.5 in Chapter 4).
32 Chapter 13 has sought to integrate justice issues in Section 13.2 in reference to procedural justice and the
33 impact of inequalities on sub-national institutions, 13.6 in regard to distribution, and 13.8 in relation to
34 integrating mitigation and adaptation policies.

35 This sub-section introduces the concept of transformative justice as part of measures intending to accelerate
36 mitigation. Fair and effective climate policymaking requires institutional practices to: consider the
